Maxwell's Duikers are widespread and seem to support hunting pressure better than other duikers, due to a broad tolerance of habitat disturbance and diet (Newing 2001). Nevertheless, they are among the most hunted ungulates in much of their range, and around 30% of the hunted ungulates in secondary forest zones in Côte d'Ivoire are Maxwell's Duikers, which means an average of nearly 3% of the hunted mammal populations in this region (Nett 2002). Some 30% of the delivered biomass in the bushmeat restaurants in the region of Taï N. P. is made up of Maxwell's Duikers (Caspary *et al.* 2001). Intense poaching in Comoé N. P. in Côte d'Ivoire led to numbers of Maxwell's Duikers declining by more than 90% within 20 years, resulting in a low density estimate of 0.04/km² (Fischer & Linsenmair 2001a). Brugière *et al.* (2005) also recorded significant decreases in this species between 1997 and 2002 (whereas other ungulate species increased or remained stable), and attributed this to changes in hunting patterns in the area. Whereas hunters used to come from the whole of the Haut Niger region and hunted in large groups for several weeks in the Mafou forest prior to its gazettelement as a core area of the Park in 1997, solitary or small groups of hunters now originated

mainly from nearby villages and enter the forest for short periods (less than a day), hunted opportunistically (almost exclusively by night), and hence focused on the most abundant species.

Maxwell's Duikers are still common in several protected areas in their range, particularly Ziama and Diécké Forest Reserves, National Park of Upper Niger and Mt Nimba Strict N. R. (Guinea), Gola N. P. and Tiwai Island Game Sanctuary (Sierra Leone), Sapo N. P. (Liberia), Taï, Azagny, Mont Sangbe and Marahoue National Parks (Côte d'Ivoire) and Kakum, Bia and Mole National Parks (Ghana).

Measurements

Philantomba maxwelli

TL (♂ ♂): 860 (820–940) mm, n = 184

TL (♀ ♀): 890 (830–950) mm, n = 91

T (♂ ♂): 140 (120–160) mm, n = 184

T (♀ ♀): 150 (120–160) mm, n = 91

HF c.u. (♂ ♂): 200 (180–240) mm, n = 184

HF c.u. (♀ ♀): 210 (180–230) mm, n = 91

E (♂ ♂): 62 (58–69) mm, n = 184

E (♀ ♀): 60 (58–69) mm, n = 91

Sh. ht (♂ ♂): 350 (320–420) mm, n = 184

Sh. ht (♀ ♀): 360 (330–420) mm, n = 91

WT (♂ ♂): 7.5 (6.5–11.2) kg, n = 184

WT (♀ ♀): 8.0 (6.5–12.0) kg, n = 91

Ghana (Wilson 2001)

Includes only non-pregnant ♀ ♀. Average body weight for 131 pregnant ♀ ♀ was 9.1 kg (range 7.5–12.6)

Maximum recorded horn length is 6.6 cm for a pair of horns from Sierra Leone (Rowland Ward)

Philantomba monticola **BLUE DUIKER**

Fr. Céphalophe bleu; Ger. Blauducker

Philantomba monticola (Thunberg, 1789). Resa uti Europa Africa, Asia ..., 2: 66. South Africa, 'Lange Kloof'; since identified as borders of Western and Eastern Cape, Uniondale and Humansdorp Dist., Langkloof, 33° 48' S, 23° to 24° 30' E; see Grubb (1999: 21).

Blue Duiker *Philantomba monticola* adult female.

Taxonomy Ansell (1972) recognized 16 subspecies, noting that the range limits and validity of many require further investigation. Grubb & Groves (2001), in their review of the classification of the duikers, recognized 12 subspecies, divided in two major groups, a grey-legged and a red-legged group (see Geographic Variation). Synonyms: *aequatorialis*, *aequinoctialis*, *anchietae*, *bakeri*, *bicolor*, *caerulea*, *caffer*, *congius*, *defreisi*, *fuscicolor*, *hecki*, *ludlami*, *lugens*, *melanorheus*, *musculoides*, *minuta*, *nyasae*, *pembae*, *perpusilla*, *pygmaea*, *ruddi*, *schultzei*, *schusteri*, *simpsoni*, *sundevalli*. Chromosome number is $2n = 60$, the same as *P. maxwelli* (Hard 1969, Robinson *et al.* 1996b).

Description The smallest duiker in Africa, which varies greatly in colour and has differentiated into a large number of regional and insular forms. Blue Duikers have large eyes, somewhat swollen nostrils, small ears, lined with off-white hair, and a very wide, flexible mouth. The forehead profile is relatively flat. The pelage varies greatly in tonality and colour ranging from near black in some subspecies to slate-grey, bluish-grey and various shades of brown. The length and density of hair-cover varies between populations. The lower legs are generally lighter in tone than the back and the black

hooves are narrow and pointed. There are no inguinal glands, and the pedal gland (which secretes a whitish liquid) has a simple orifice, unlike that of Maxwell's Duiker *P. maxwelli* which has a subcircular sac at the end of a narrow canal between the hooves (Pocock 1910). The preorbital gland exudes secretions through a series of pores that are arranged along an oblique arc across the swollen gland (the pores in most other duikers have an almost straight alignment). The secretion, while fresh, has a pale bluish-grey colour, and the chemical compounds are discussed in detail by Burger & Pretorius (1987). The tail, which is vigorously whisked up and down (not side to side), has very conspicuous white hair lining on its underside and a nearly black dorsal surface.

Compared with Maxwell's Duiker, the skull is notably smaller, shorter (typically <139 mm) and narrower, but with orbits somewhat tubular; the rostrum is sharply constricted so that the palate and snout are narrower, and the nasals narrow strongly towards the tips. The horns, which are very short (usually 4–5 cm), are well ridged around their bases and tend to be partially concealed under a crest of elongated hair. Females in some populations have horns, but they may be absent in others (Grubb & Groves 2001).

Geographic Variation The enormous range of variation within this species was bisected into two super-divisions by Grubb & Groves (2001), who used leg colour as a distinguishing feature. The first grouping, from northern parts of the species' range, was characterized by greyish legs (*aequatorialis*, *congicus*, *lugens*, *melanorheus*, *musculoides* and *sundevalli*). The more southern grouping was identified by its reddish legs (*anchietae*, *bicolor*, *defriesi*, *hecki*, *simpsoni* and *monticola*). Another geographically based arrangement (Kingdon 1997) was broadly consistent with the above, but recognized seven main populations plus three montane and three insular isolates. Here, we selectively combine the two treatments, which also approximate to the 'Northern/Southern Forest Faunas' model suggested in Kingdon (1971). Characteristics of subspecies follow Grubb & Groves (2001).

Southern group:

- P. m. monticola*: Western Cape and Eastern Cape Provinces of South Africa. Lighter than *bicolor*, light grey or fawn; legs reddish-tan; haunches slightly reddened with very little transition from rump.
- P. m. bicolor* (includes *fuscicolor*): Zambezi south to KwaZulu-Natal, South Africa. Intermediate in tone between *hecki* and *lugens*; flanks normally dark rufous-orange.
- P. m. hecki*: Malawi, Zambia (east of the Luangwa Valley), N Mozambique. Back light fawn-grey; flanks light red, and rump medium to dark brown; there is a fairly distinct transition line to the reddish-fawn of haunches; legs reddish-tan; underside white. Intergrades with *lugens*.
- P. m. anchietae*: N Angola. Back pale grey-brown; flanks grey with hint of red; legs pale red-fawn; haunches red grading into grey of flanks anteriorly; there is a well-marked transition on the haunches to the rump; tail black; underside broadly grey-white, extending half-way down the legs. The largest subspecies overall.
- P. m. defriesi*: Zambia, west of the Muchinga escarpment. Paler than *hecki*, with a distinct dark grey zone on the mid-dorsal region; flanks pale red-fawn, and haunch and legs noticeably reddish; rump and tail dark; white below, extending down inner surface of upper half of the legs. Intergrades with *aequatorialis*.
- P. m. simpsoni*: between lower Congo R. and Kasai R. Flanks red-brown, fading to a broadly white belly; haunches redder than flanks; legs brownish, pale on inner surfaces; there is a well-marked face-stripe. Females occasionally lack horns. Intergrades with *anchietae* and *defriesi*.

Northern group:

- P. m. congicus*: from east bank of the Cross R. to the Congo R. across the Oubangui into DR Congo as far east as Lisala; south through Cameroon, Gabon and Congo to the Mayombe district of DR Congo, north of the Congo R. mouth. The dorsum is bright, grey-brown to black in colour, the flanks pale greyish, and the haunches browner; a clear dark-brown stripe marks the transition from the blackish-brown rump to the haunches; underside white; cheeks red-tinged.
- P. m. aequatorialis*: from the contact zone with *congicus* east and south-east across DR Congo into Uganda, at least to Bunyoro and probably to the Nile R.; north-east to Imatong Mts in Sudan and south, in DR Congo, as far as Namoyo. Range in the west bounded by the Congo R. Drabber and browner than *congicus*; underside of rump usually light grey; transition on haunches less sharp than in *congicus*, but still noticeable. Females usually hornless.

P. m. musculoides: E Uganda to Kenya, as far as the Rift Valley. Also on Mt Elgon. Darker than *aequatorialis* on dorsum, but flanks lighter; the haunch stripe is less well marked. Females are apparently always hornless.

Montane isolates:

- P. m. lugens*: Southern Highlands of Tanzania, to the border of Malawi (but the Nyika plateau population is difficult to assign with any certainty to either *lugens* or *hecki*). Very dark, grey-brown, with little contrast between flanks and dorsum; rump black, with no perceptible transition to the dark haunches; legs dark, except for light streak down front; underside greyish; hair generally reversed on mid-line of neck.
- P. m. schusteri*: Eastern Arc Mts of Tanzania. Uniformly coloured, with fawn-tinted medium-grey body colour extending to head and down legs, but slightly paler on throat and cheeks; rump has small, but graduated, near-black patch immediately adjacent to tail; hair is sleek and of medium length and density on both body and neck; upper part of inner hindlegs and belly white; upper lips pale, lower lips dark; pencil-thin pale brow-stripe above orbit.

Insular forms:

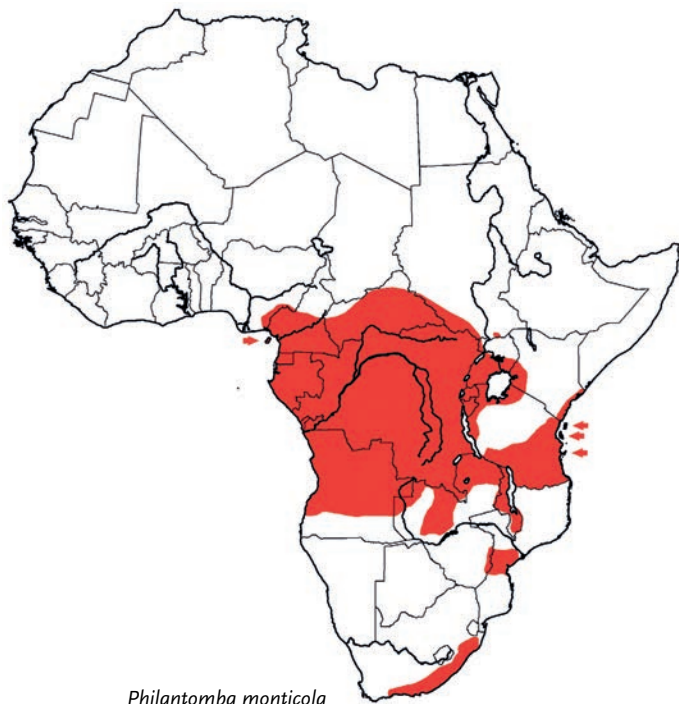

- P. m. sundevalli* (includes *pembae*): islands of Pemba, Mafia and Zanzibar (Unguja); also coastal East Africa (specimens from Shimba Hills and Sokoke). Light brownish colour, with little differentiation between dorsum and flanks; white below.
- P. m. melanorheus*: Bioko, Equatorial Guinea. Related to the form *congicus*, but with black dorsum, pinkish-grey flanks. Fur long and thick. Very small size.

Similar Species

Philantomba maxwelli. Allopatric, occurring only west of the Cross R. Significantly larger (skull length usually >139 mm), and with longer tail, as much as 160 mm in length, whereas in Blue Duiker few specimens have tails longer than 100 mm. Also differs in colour, lacking the strongly marked break on the haunches between the dark croup and the light colour of the flanks and lower haunches; the cheeks are lighter and superciliary streaks more prominent (Grubb & Groves 2001).

Distribution Currently, many populations occur nearly contiguously across all of central Africa, but the two major clusters of subspecies, as described above, represent a significant and potentially long-standing geographic separation. Past climatic fluctuations are likely to have fragmented both northern and southern types, but two principal barriers appear to have maintained the primary north-south divide. These barriers are the Congo R. in the west and the semi-arid corridor that, in East Africa, separates well-established, south-eastern, and mainly coastal, biota from a more recently expansive, predominantly western and equatorial biota (Kingdon 1971, 1982, 1990).

Until recently, the Blue Duiker ranged throughout much of central, eastern and southern Africa. Localized populations occurred wherever suitable forest and thicket existed and this is still one of the few species of duiker that continues to survive over most of its historically known range (East 1999). In the west, the species occurs eastwards from the Cross R.; Happold (1987) mapped the Niger R. as the western

limit, but the Blue Duiker seems to be absent or extinct in the intervening area, although Maxwell's Duiker occurs (see Wilson 2001 for discussion of western limits). This species then ranges east through the forest and ecotone belts of S and C Cameroon, Gabon, Equatorial Guinea (including the island of Bioko), Congo, Cabinda (Angola), most of DR Congo, across S Central African Republic and locally north, with populations in gallery forests and dry relict forest patches in the north of the country. Recorded at 8° 17' N on the Koumbala R., in Manovo-Gounda-St Floris N. P. (Malbrant & Maclatchy 1949), through extreme SW Sudan (Azande lowlands) and SE Sudan (Imatong and Dongotona Mts). Its range in East Africa comprises a number of disjunct populations in forest patches of S and W Uganda, W Kenya and E and S Tanzania and possibly in W Rwanda and Burundi, as well. The species is absent from the dry country east of L. Tanganyika, but occurs again in the coastal forests and scrub of Mozambique, Kenya and in Tanzanian forests. Andanje *et al.* (2011a) have confirmed the presence of the species in low numbers north of the Tana R. in the Boni-Dodori forests in N Kenya, a range extension of some 200 km.

The Blue Duiker occurs on the islands of Pemba, Zanzibar and Mafia (Moreau & Pakenham 1941, Pakenham 1984, Kock & Stanley 2009) and there have been somewhat implausible suggestions that one or more of these isolates could have been the result of human introduction. It is also found in forested areas of the Tanzanian Southern Highlands (including Ufipa) and the Eastern Arc Mts (Usambara, Uluguru and Udzungwa). The species' southern range includes localized populations in N and C Angola, where the current distribution is not well known (but is mapped south to at least 15° S by Crawford-Cabral & Veríssimo 2005), through remnant forests and thickets in Zambia, Malawi, E Zimbabwe and parts of C Mozambique on both sides of the Zambezi (East 1999, Wilson 2001). In South Africa, this species is primarily confined to the evergreen forest and thicket along the coast and adjacent hinterlands from N KwaZulu–Natal to the eastern Western Cape Province; there are no records of the Blue Duiker occurring west of George (Wilson 2001). Some

authors (e.g. Bowland 1990) make mention of Blue Duiker in the Magaliesberg Mts in Limpopo Province, but Rautenbach (1982) never recorded them anywhere in the former Transvaal. There are, as yet, no confirmed records from Swaziland (Monadjem 1998) and none from southern Mozambique (Smithers & Lobão Tello 1976), suggesting a break in distribution from N KwaZulu–Natal to E Zimbabwe/C Mozambique.

Habitat Thrives in a wide range of forested and wooded habitats, including mature and secondary forests, gallery forests, dry forest patches, coastal scrub farmland and regenerating forest from sea level up to 3000 m. Bowland (1990) found the species in *Podocarpus* mist forests on the KwaZulu–Natal coast. In eastern Africa and eastern DR Congo, the species has a preference for areas with dense undergrowth, but animals that were living at exceptionally high densities in Gabon were thought to prefer areas with relatively little undergrowth (Dubost 1980). Blue Duikers can persist in small patches of modified or degraded forest and thicket, even on the edge of urban centres. Availability of free-standing water is not an essential habitat requirement (Dubost 1980, Mockrin 2010).

Abundance Usually the most abundant duiker in communities where it occurs, and co-exists with up to seven other small ungulate species (including up to five other duikers) in some central African forests. Dubost (1980) recorded densities of 70/km² in a small area (74 ha) at Ipassa, Makokou, in NW Gabon, though it is unlikely that such high densities can be extrapolated over larger areas. In the Ituri Forest, DR Congo, non-hunted populations surveyed on 5 km² study areas range from 21/km² in mixed evergreen forest, to 10/km² in large stands of mono-dominant *Gilbertiodendron dewevrei* forest, representing about half the total small ungulate population in a community of eight species and 17–18% of small ungulate biomass (Hart 2000). Most population surveys report densities from 5 to 35/km² across the species' range, with the exception of some very small populations in isolated habitats in southern Africa (Payne 1992, Bowland & Perrin 1994, Hart 2001, Newing 2001, Wilson 2001, Lannoy *et al.* 2003). East (1999) estimated total population size at more than 7 million animals.

Adaptations The ecological and demographic success of Blue Duikers is made possible by several factors, not least among which is their extraordinary fecundity, which, in turn, seems to depend upon their ability to maintain a high nutritional plane across a wide range of habitats. Blue Duikers' consistently good metabolic and reproductive condition is assisted by a rumen anatomy (e.g. densely papillated rumen and fungiform papillae) that is typical for antelopes with concentrated nutrient diets (Faurie & Perrin 1995), but the animals are also sustained by an exceptionally broad diet. In addition to small fruits, seeds, gum, fungi and fallen flowers, they eat standing and fallen foliage, including, remarkably, dry fallen foliage especially when fruits are in short supply (Kingdon 1982, Hart 1985, Newing 2001, Wilson 2001).

Possible explanations for such dietary adaptability are more complex than would appear at first sight. For example, their small body size allows them to occupy smaller patches of habitat and exploit dispersed food sources, but the combination of small size and a more leafy diet is counter-intuitive, even contradictory, in the

Lateral and palatal views of skull of Blue Duiker *Philantomba monticola*.

sense that most ruminant bovids become *better* able to cope with difficult foliage diets the *larger* they are: yet this *small* duiker is *better* able to sustain itself on dead leaves than many of the larger duikers.

Philantomba is a basal group that derives from the earliest beginnings of the duiker radiation (Jansen van Vuuren & Robinson 2001). Therefore, the Blue Duiker's ability to shift to a leafy diet may be as much a reflection of its phylogenetic history as a proximate or late specific adaptation. Duikers are thought to derive from small, already folivorous ancestors with the larger species having made ever-more decisive secondary shifts into frugivory and omnivory (Kingdon 1982). In the course of evolution the folivorous habits of early, small duikers would have pre-adapted them to buffer temporary shortages of the more nutritious elements in their diet. This residual flexibility, deriving from their folivorous ancestry, might have combined with their small size to give them advantages over less flexible competitors.

It is possible, therefore, that the ecological success of the Blue Duiker is of very long standing. Furthermore, a long evolutionary history, relative to other duikers, could have special implications for understanding progressive adaptation by some Blue Duiker populations to the localized conditions of their region or phytogeographic zone. This offers scientists unique opportunities to study refinements of physiological adaptation along several parameters or gradients (such as altitude, latitude, relative humidity or vegetation type) as well as the role of genetic drift or selection in isolates.

Here is an economically important forest mammal that spans an enormous geographic range, has adapted to strong seasonal changes on the forest floor while regional populations have further refined their adaptation to quite localized conditions. While this duiker remains reasonably numerous across most of its far-flung range the opportunity should be seized to try to understand the foundations for its extraordinarily wide range and sustained ecological success. Wilson (2001) has pleaded for an intensification of research on digestive physiology and reproduction in duikers (and on this species in particular), before it is too late.

The most eye-catching feature of this species' behaviour is the continuous flagging, up and down, of the tail, the fringe of which is composed of slightly crinkled white hairs that reflect light exceptionally well. In appropriate lighting conditions this flashing resembles a discrete heliographic signalling device. Quite remarkably for a species that characteristically spends much time alone, this flashing (which in the

Blue Duiker *Philantomba monticola*.

dim lighting of the forest understorey may be the only visible feature of an otherwise sombrely coloured animal) would appear to be oriented towards other animals in its dispersed community, including individuals that share a territory.

Of special interest is the development of horns in the ♀♀ of some populations and their absence in others. Extrapolating from the Klipspringer *Oreotragus oreotragus*, it is possible that recently, or at some time in the past, there was a correlation between high population densities and the development of female horns. Given the very substantial differences in density that have already been recorded, this subject offers opportunities for interesting and fundamental research.

Foraging and Food Blue Duikers feed selectively from the forest floor on a wide diversity of ripe and unripe fallen fruits and seeds. They also eat freshly fallen foliage, flowers, pieces of bark, fungi, resin (in particular exudates from *Albizia* spp.) and some animal matter (Wilson 2001). Of 18 stomachs examined by Wilson (2001) in Chirinda Forest, Zimbabwe, the average stomach contained 75% fruits, 15% browse, 5% flowers and 5% fungi. In Gabon, foliage averaged 20% of rumen contents collected throughout the year, while over 67% of contents consisted of small fruits and seeds measuring 0.5–2 cm, the balance being made up of flowers, animal matter and fungi (Dubost 1984). Gautier-Hion *et al.* (1980) recorded that stomach contents contained 79% fruit, 20% leaves and very small quantities of animal matter, flowers and gum. On the other hand, in KwaZulu-Natal, Bowland (1990), also from an analysis of stomach contents ($n = 12$), found that about 70% was made up of dicotyledonous leaves and 23% seeds and fruits, probably because fruit was an unreliable resource whereas freshly fallen leaves were available year-round and abundant. Similarly, Hanekom & Wilson (1991) reported that dicotyledonous leaves constituted 57% of stomach contents from Tsitsikamma N. P., South Africa. None the less, Bowland (1990) recorded a strong correlation between fruit and freshly fallen leaves in the diet, suggesting a much greater preference for the former. Animal matter is not uncommonly recorded in stomachs (Grimm 1970, Gautier-Hion *et al.* 1980, Dubost 1984, Wilson 2001), and Dubost (1984) witnessed Blue Duiker hunting ants by licking them off the ground; ingestion of

Diptera was less common, although duikers were seen snapping at them in flight.

In Chirinda Forest, the fruits of the various *Ficus* species were the most favoured fruits, with duikers eating large numbers of fruits (one stomach contained over 65 *F. chirindensis* fruits); other fruits eaten included *Croton sylvaticus*, *Dovyalis macrocalyx*, *Rauvolfia caffra* and *Diospyros abyssinica* (Wilson 2001). In Uganda, the seeds and fruit of the genera *Maesopsis*, *Ricinodendron*, *Cordia*, *Musanga* and *Pycnanthus* and the leaves of the genera *Mammea* and *Mildbraediodendron* have been recorded as preferred foods (Kingdon 1982). Most of these genera occur in the Ituri Forest and have been recorded in duiker diets (Hart 1985). Other important foods recorded in the Ituri Forest include fruits and seeds from a variety of species in the families Caesalpiniaceae, Sapotaceae, Sapindaceae, Sterculiaceae, Rubiaceae, Ulmaceae and Euphorbiaceae. The seeds of *Pancovia harmsiana*, *Landolphia* spp. and *Cola* spp. are frequent in the diet. Blue Duikers prefer a number of fruits only at an unripe stage, notably *Klainedoxa gabonensis*, *Irvingia grandifolia* and *Blighia welwitschii*, all large trees that regularly abort large portions of developing fruit crops at an early stage. When ripe, these fruits are too large for Blue Duikers to handle, though they are eaten (and in the case of *K. gabonensis* and *I. grandifolia*, the seeds dispersed) by the larger duiker species (Hart 1985). The species also joins many other primary consumers by concentrating on seeds of *Julbernardia seretii*, *Cynometra alexandri* and *Gilbertiodendron dewevrei* during periods of mast fruiting, and body fat levels rise during these periods (J. A. Hart pers. obs.). Blue Duikers, like the larger duikers, though to a lesser extent, forage on several species of fruits with large armoured seeds (*Ricinodendron heudelotii*, *Chrysophyllum pruniformes*, *Celtis adolfi-friderici*, *Canarium schweinfurthii*) that they regurgitate during rumination and disperse (Hart 1985, Feer 1995).

In feeding trials with captive animals, Blue Duikers were consistently selective and had reduced capacity to digest structural carbohydrates compared with several of the larger duiker species (Hart 1985, Faurie & Perrin 1993, Newing 2001, Plowman 2002). Preferences of forest fruits and seeds determined by paired food choices in trials were not correlated with any single nutritional or chemical constituent (Molloy & Hart 2002). Blue Duikers preferred fruits over foliage, but when confronted with less preferred fruit choices, they increased foliage intake to a greater extent than larger species (White-bellied Duiker *Cephalophus leucogaster* and Bay Duiker *C. dorsalis*). Fruits and seeds with high levels of tannins and indigestible fibre were preferred if they also contained readily digested simple carbohydrates and protein. Blue Duikers produce large quantities of saliva, suggesting a capacity to bind and limit the effect of some digestion inhibitors and toxins. High dietary diversity may prevent rumen fermentation from being overwhelmed by any specific plant toxin in the foods.

Blue Duikers forage slowly and methodically over small areas, picking over the forest floor for individual food items; they browse standing vegetation only infrequently. In common with other duikers, they locate and follow groups of colobus monkeys and guenons, as they pass over their home-range. The duikers feed from fruits, leaves and other plant parts that fall beneath the primates. Activity peaks in the early morning and late afternoon with relative inactivity in the middle of the day and at night (Bowland & Perrin 1995, Wilson 2001). Blue Duikers are variably active at night, possibly on a seasonal basis (Bowman & Plowman 2006).

Social and Reproductive Behaviour Pairs or small groups live permanently on small home-ranges (Dubost 1983, Bowland & Perrin 1995). Territories may be grouped in loose aggregations and animals appear to form a dispersed social unit possibly composed of related individuals. Dubost (1980) found that territories on a 74 ha study area in Gabon with a very high density of Blue Duikers were exclusive and averaged 2.5–4 ha. He noted that discontinuities in the terrain, such as large fallen trunks, small streams (wet or dry) and the pathways of larger animals served to demarcate boundaries. At the heart of each territory was a regularly inhabited zone or core area from which brief excursions were made, mainly to feed on temporary food sources.

Core home-ranges of radio-collared Blue Duikers in the Ituri Forest ranged from 2.6 to 11.9 ha and were similar in size for both ♂♂ (mean = 6.2 ha, n = 10) and ♀♀ (mean = 6.0 ha, n = 9), which is not dissimilar from a hunted population in Congo (Mockrin 2010). Males and ♀♀ in adjacent home-ranges spent over one-third of their time together. Subadults of both sexes dispersed away from the maternal home-range. Dispersal distances were <1 km, and mostly less than 500 m for 21 animals monitored in mixed forest (Hart 2000), whereas 2 of 17 collared animals dispersed >1 km in a monitored population in mono-dominant *Gilbertiodendron dewevrei* forest (Mockrin 2010). Neighbouring radio-collared individuals sometimes aggregated into temporary groups of four to five animals, in particular when pursued by hunters.

Of 11 ♂♂ and 12 ♀♀ monitored by Dubost (1980), only one, a subadult ♀, changed her mate, indicating that couples generally tend to be stable and maintain permanent pair-bonds. He found that young ♀♀ left the parental home-range at age 1–1.5 years old whereas ♂♂ tended to stay on until they were nearly two years old and fully mature, at which point they appeared to depart voluntarily. In spite of apparent tolerance within families, Dubost found that resident ♂♂ were intolerant of other fully adult ♂♂ on their territories and captured adults of either sex were extremely aggressive to any adults placed in the same pen. Dubost found that the ♂ of a mated pair greatly reduced the time spent with his mate immediately after parturition and he even observed one or two unknown subadult ♂♂ keeping company with postpartum ♀♀.

Blue Duikers of both sexes mark tree trunks, branches and other objects in their territories with their preorbital glands. Dung may be somewhat aggregated in a home-range, but they do not create dung middens. Adult ♂♂ and ♀♀ and young of both sexes greet, groom and mark each other by touching their facial glands upon contact (Dubost 1980, Bowland 1990, Wilson 2001). Blue Duikers make a highly distinctive 'sneeze-whistle', which is commonly uttered when the animal has been disturbed and is running away. Populations of hunted duikers whistle more than those that are less hunted, the latter often moving away without signalling (Croes *et al.* 2007). The whistle is mimicked by hunters, and actually serves to attract animals, suggesting that this species-specific loud call is a generalized auditory advertisement (Kingdon 1982). A less distinctive and relatively quiet snort signifies a lower level of excitement. Individuals apparently seeking contact with another animal utter a soft groan, especially ♂♂ in pursuit of ♀♀ (Dubost 1983). Animals also stamp their forefeet, which may release secretions from pedal glands between the hooves, and ♂♂ grate their horns on plant stems.

Courtship is initiated by the ♂ who follows the ♀ closely and practises laufsclag (leg tapping) when the ♀ permits it. Females that

Blue Duiker *Philantomba monticola*.

are not in oestrus tend to evade the ♂ and keep their tail down. If pursuit of an unreceptive ♀ is sustained she may even utter a 'sneeze-whistle' (Dubost 1983). Animals bleat in distress and are said to make cat-like yowls. After birth the young does not follow its mother but keeps hidden until it is about three months old. The temporary absenteeism of ♂♂ after the birth of their mate's lamb has been interpreted as a mechanism to reduce risks of predation on the young (Kingdon 1982).

Reproduction and Population Structure The gestation period has been variously estimated at 4–7 months, with estimates based in part on figures for the similar congeneric Maxwell's Duiker. Aeschlimann (1963) gives a gestation period of four months or about 120 days. Mentis (1972) reports a figure of 167 days, a figure similar to the 188 days recorded by Kadjo (2000). Dittrich (1972) reports 205 days, the same figure cited by von Böhner *et al.* (1984) and Wilson (2001). The latter author notes that he determined gestation based on 19 known instances where copulation was observed and the day of birth recorded. An analysis of foetal growth rates of Blue Duiker in the Ituri Forest supports a gestation period of 120–150 days, with a lower likelihood of a gestation period over 200 days (J. A. Hart pers. obs.). Shorter gestation periods would also be consistent with the relatively high fecundity observed in a number of populations. Animal keepers at Epulu Okapi Station who maintained a colony of Blue Duikers over a number years also report (unpublished) that gestation is about four months. New observations, possibly supported by hormone studies, will be required to clarify gestation period for this species.

Von Böhner *et al.* (1984) reported that, in captivity, ♂♂ are sexually mature at nine months, and ♀♀ at 6–17 months; Hofmann *et al.* (1998) recorded first oestrus in ♀♀ of a heavily hunted wild population at six months. Wilson (2001) notes that female Blue Duikers usually become sexually mature before 13 months, and that the earliest a ♀ became sexually mature was eight months. He notes that ♂♂ become sexually mature much later than ♀♀, from 11–14 months.

Births occur throughout the year (Brand 1963, von Ketelhodt 1973, 1977a, Dubost & Feer 1992, Wilson 2001) with lowered birth rates around the dry season. A single young is born. Full-term foetuses in the Ituri had mean weight of 726 g (range 590–950, $n = 13$) or 13.2% of mean maternal body weight. There is a postpartum oestrus of 3–5 days following birth (OIA 1991). Wilson

(2001) reports an inter-birth interval of 202–248 days ($n = 32$ captive births), while von Ketelhodt (1977a) reports a mean inter-birth interval of 266 days in captive animals. In a multi-year project inspecting animals killed by local hunters in the Ituri Forest, 78.6% of 196 adult ♀♀ presumed to be multiparous were pregnant and 28% were both pregnant and lactating, the highest percentage of the six species of duikers occurring at the site (other species ranged from 0 to 25% for adult ♀♀ both pregnant and lactating). Composition of Blue Duiker milk is reported on by Taylor *et al.* (1990) and von Ketelhodt (1976b). Young are reported to be weaned in five months. Captive animals have lived for 16 years (Weigl 2005).

Using mark-and-release in an area of undisturbed rainforest (near Makokou, NE Gabon), Dubost (1980) determined that 62% of the population were reproductively mature animals (of even sex ratio) with 38% immature, i.e. less than one year old. Over one-third of young died in their first year of life, whereas adult annual mortality rates ranged from 7.3 to 10.4% (and see Hart 2000).

In the Ituri Forest, sex ratios in a heavily hunted population were even but were skewed toward ♂♂ (1.28 : 1 and 1.22 : 1) in two unhunted populations. Pre-reproductive individuals represented 33% of an unhunted population in mixed forest, but less than 18% of an unhunted population in mono-dominant *Gilbertiodendron dewevrei* forest. In the latter forest type, duikers also had lower mortality and higher rates of emigration (Hart 2000). In unhunted populations, female Blue Duikers reach maturity at about the same time that their third molar (M3) erupts. Females in hunted populations mature earlier, with 20–45% of subadults with the second molar only erupted with full udder development or pregnancy. Less than 5% of ♀♀ with the second molar erupted were sexually mature in the unhunted populations (Hart 2000).

Predators, Parasites and Diseases Common predators include the African Rock Python *Python sebae*, the Crowned Eagle *Stephanoaetus coronatus* and the Leopard *Panthera pardus* (Wilson 2001). Wilson (2001) reported Crowned Eagles being a major predator in NE Zambia, and several other studies of the diet of Crowned Eagles have recorded Blue Duikers as being important prey items (Jarvis *et al.* 1980, Boshoff *et al.* 1994; and see Vernon 2001); predation by these raptors is also reported in Uganda and Tanzania (J. Kingdon pers. obs.). Blue Duikers represented less than 5% of eagle prey in one survey in the Kibale Forest, in an area with a very high primate biomass, and where primates were the dominant eagle prey (Mitani *et al.* 2001). Leopards and African Golden Cats *Profelis aurata* are primary predators in the Ituri Forest and Blue Duikers were the single most abundant prey species in felid diets. However, they were not killed disproportionately in relation to their abundance, and were not the most selected prey (Hart, J. A. *et al.* 1996). Annual predation rates of 2.3 kills per km² and 1.1 kills per km² were recorded over a four-year study of radio-collared animals monitored in mixed and mono-dominant forest, respectively (Hart 2000). Annual per capita predation rates of Blue Duikers were 14–34% those of the larger duikers, which are selected prey of Leopards. In Tsitsikamma N. P., Hanekom & Wilson (1991) reported Blue Duiker remains found in 27% of Leopard scats and 7% of Caracal *Caracal caracal* scats.

In a health evaluation of 95 individuals of five species of duikers (including 37 Blue Duikers) in the Ituri Forest, all the animals examined were healthy and in physically good condition. Faecal parasite ova

were detected in about one-third of animals examined, comparable with frequencies in most other duiker species. Serologic titres for bluetongue, epizootic haemorrhagic disease, infectious bovine rhinotracheitis and leptospirosis were recorded, indicating widespread exposure to these diseases (Karesh *et al.* 1995).

Round (1968) provided a checklist of helminth parasites recorded from Blue Duiker at the time, including *Haemonchus lawrencei*, *Oesophagostomum eurycephalon*, *Setaria caelum*, *S. dipetalamotoides*, *S. labiotapapillosa*, *Acuaria dartevelli*, *Moniezia expansa* and *Stilesia hepatica*. Jooste (1984) reported additional parasites from three animals taken in E Zimbabwe, including *Cooperia chabardi*, *Trichostrongylus axei*, which Boomker *et al.* (1986) also recorded from a Blue Duiker from Tsitsikamma N. P. Boomker *et al.* (1991b) reported on helminth parasites of three Blue Duikers from KwaZulu–Natal, including: *Taenia hydatigena*, *Gonglynesia* sp. and several *Trichostrongylus* spp. The only record of an arthropod parasite in Blue Duiker is that of a *Rhipicephalus* sp. recorded by Karesh *et al.* (1995).

Conservation IUCN Category: Least Concern. CITES: Appendix II.

Arguably the most important wild ungulate economically and ecologically in Africa, the Blue Duiker is one of the most frequent species reported in bushmeat surveys across the continent (Wilson 2001) and withstands hunting pressure better than most of the larger duikers (Hart 2000, Waltert *et al.* 2006, Van Vliet *et al.* 2007). Unlike many of the other forest duikers, Blue Duikers tolerate and even thrive in a range of human-modified habitats, even in the vicinity of settlement, and often persist well in small habitat patches. However, some South African populations may be vulnerable to isolation and local extinction due to habitat fragmentation (Lawes *et al.* 2000), while the long-term decline since the mid-1970s of at least one Blue Duiker population in the coastal Cape forests is attributed to decreasing habitat quality associated with raising ambient temperatures brought on by climate change (Seydack *et al.* 1998). In East Africa, Blue Duiker are now relatively rare in the Eastern Arc Mts, being apparently absent from Nguru, Ukaguru, Rubeho and Pare. In the Udzungwa Mts, it has a very localized occurrence, but it is generally absent from lowland forests, such as Matundu. In some places this may be due to poaching, but competition with very abundant Sunis might be another factor in localities where trapping pressure is still light (F. Rovero pers. comm.). None the less, Blue Duikers occur in large and stable numbers in many protected areas across the bulk of the species' range (East 1999).

Blue Duikers adapt well to captivity (Bowman & Plowman 2006) and have been considered as potential candidates for domestication and for use as a ruminant model in research (OIA 1991). However, singleton births and high aggression levels between adult ♂♂ limit their potential for husbandry.

Like other duikers, the Blue Duiker is largely dependent on the rain of plant parts falling from the canopy. This derives, in large part, from the activities of arboreal mammals such as primates and fruit-bats, and of birds. How the elimination, or depletion, of arboreal animals might affect duikers is unknown. The difficulties of inferring effects of hunting on duikers are compounded because heavy hunting hits both arboreal and terrestrial fauna and the details of interactions between arboreal and terrestrial communities are seldom taken into account.

GENUS *Sylvicapra*

Common Duiker

Sylvicapra Ogilby, 1837. Proc. Zool. Soc. Lond. 1836: 138 [1837].

These are the 'bush duikers', which appear to have reversed many of the deep-forest adaptations of the Cephalophini as a whole, such as the wedge-shaped form and the swept-back horns. They are slenderly built, with long legs (particularly the distal segments) and have a longer neck than other duikers. With *Philantomba*, this genus shares the elongated ischium, the evenly haired (untufted) tail, the somewhat curved horns, the somewhat tubular orbits, and the oblique occipital plane and paraoccipital processes. On the other hand, the hairs of the pelage are agouti-banded, and the hairs on the forehead are restricted to a coronal tuft, as in *Cephalophus*. The horns, which are largely restricted to ♂♂, have more of an upright direction than in other duikers, and the coronal tuft is dominated by forwardly directed hairs. The dorsal profile of the

skull is straight, rather than convex as in most other duikers, and the nasal opening is enlarged.

According to Jansen van Vuuren & Robinson (2001), this genus is not, as has been previously supposed, the most phylogenetically distinct of the duikers (that position belongs to *Philantomba*). Further, recent molecular evidence reveals that *Cephalophus* is paraphyletic with respect to *Sylvicapra* (Hassanin *et al.* 2012). Normally, a single species is recognized in this genus, but two or more could prove to be valid; for example, Grubb & Groves (2001) suggested that the taxon *coronata*, from far West Africa, may be a distinct species.

Colin Groves

Sylvicapra grimmia COMMON DUIKER (GREY DUIKER, BUSH DUIKER, GRIMM'S DUIKER)

Fr. Céphalophe de Grimm (Céphalophe couronne, Céphalophe du Cap); Ger. Kronenducker.

Sylvicapra grimmia (Linnaeus, 1758). Syst. Nat., 10th edn, 1: 70. 'Habitat in Africa'; based on a specimen seen by Grimm in the fort at Cape Town (Thomas 1911: 153) so now known to be South Africa, Western Cape Prov., Cape Town.

Common Duiker *Sylvicapra grimmia*.

that he thought corresponded well with general biogeographic patterns, while allowing for high-altitude isolates of lowland parent populations as well as supposed hybrid swarms from 'overlap zones'. Meester *et al.* (1986) listed six subspecies for the southern African sub-region. Grubb & Groves (2001) recognized 14 subspecies (including one undescribed form from Mt Kilimanjaro). Wilson (2001), who examined thousands of skulls and skins in many museums and dozens of live animals throughout the species' range, concurred with this treatment, which is followed here. As the distribution of *S. grimmia* is continuous in sub-Saharan Africa and some forms show individual variation, there are obviously substantial intergradations between different subspecies or regional populations and it is currently impossible to accurately delineate boundaries between the subspecies listed under Geographic Variation. Synonyms: Grubb (2005) lists 38 synonyms. Chromosome number: $2n = 60$; the X chromosome is a metacentric (Robinson *et al.* 1996b).

Description The Common Duiker is a medium-sized animal with a body colouration that varies from light grey in Botswana through many ranges of grey, yellow-ochre to almost red on the Nyika Plateau in Malawi to specimens in West Africa that are grey on the hindquarters to rufous coloured on the shoulders. In Malawi, Mozambique, E Zambia and even parts of Zimbabwe a distinct white ring occurs around the eyes (hence the name *orbicularis* for the subspecies occurring in that region). The colour of the ears varies, with some animals having a great deal of white inside the ears and others no white at all. The ears are comparatively long and pointed. A long tuft of hair occurs on the head and in many cases it is very long and pointed and in other animals short and 'square-topped'. Colour of the frontal tuft varies from black to grey and even rufous. A dark-coloured frontal blaze is found in almost every animal, but

Taxonomy Haltenorth (1963) recognized 19 subspecies of *Sylvicapra grimmia* and these, with some changes, were accepted by Ansell (1972). However, Ansell indicated that the validity and distributional limits of many were doubtful. Kingdon (1982, 1997) broke down more than 30 named forms into eight regional groupings

occasionally no dark band occurs at all (especially in animals from East Africa). This frontal blaze varies in colour from light brown to pitch-black and occurs from the rhinarium to the front of the eyes and occasionally even beyond to the frontal crest. Underparts are snow-white in some populations to greyish-brown in others. Many Zimbabwean and Zambian specimens have snow-white bellies. Body hairs are fairly short in most animals, but several specimens examined in Botswana had hair that were, in places, in excess of 6 cm long; in the central Kalahari of Botswana, both long- and short-haired duikers can be found in the same population (Wilson 2001). Some isolated montane populations have long hair, such as those on Mt Kilimanjaro and Mt Elgon, likely an adaptation to the environment. The legs are generally the same colour as the body and the fetlocks brownish-black to pitch-black, the black colour often extending up the front of the legs to the body. The tail underneath is white and reddish-brown to black above, but again this varies with animals even in a small area. Albinos, characterized by white fur and pink eyes, are also recorded (Wilson 2001).

Preorbital glands are present, and consist externally of a row of pores exuding from a bare streak of skin. The length of this streak varies, being much shorter in specimens from Ghana than those from Botswana (Wilson 2001). The secretion consists of a thick black melanin-containing component and a thin, yellowish clear liquid. The secretion is heterogeneous, comprising water, mucus, a thin yellowish oil and large concentrations of heavy waxy material in varying proportions. Burger *et al.* (1990) isolated 33 constituents of this preorbital gland secretion. Pedal glands are also present in all four feet, those on the forefeet being deeper and larger, and contain a creamy-white secretion. Inguinal glands are also present, as much as 65 mm long, and contain large quantities of a white to creamy secretion with a powerful odour (Wilson 2001). The size of the hooves depends a great deal on the environment and soil on which the animal lives. Those on Kalahari sand have very long hooves while those on the Nyika Plateau are short and rounded. Lateral (false) hooves are present in all animals. Females are generally larger than ♂♂.

Males have a pair of stout pointed horns; occasionally ♀♀ have been recorded with horns (Miller 1912, Shortridge 1934, Ansell 1960b, Wilson & Clarke 1962). Shortridge (1934) considered that 10% of all Common Duiker ♀♀ in Namibia have horns. Horned ♀♀ appear to be more frequent in some localities than others (Wilson 2001). Wilson (2001) found that in E Zambia, in a sample of 980 female skulls examined, 0.6% had horns. In Zimbabwe, of 720 female skulls, 3.8% had horns (Sebungwe area) and in Botswana in a sample of only 55 female skulls, 12.7% had horns. In all cases horns appearing in ♀♀ were short, thin and often stunted.

The skull has a straight profile, enlarged nasal opening, and somewhat tubular orbits. The median palatal notch is very broad, and V-shaped (Grubb & Groves 2001). The dentition of the Common Duiker is diphyodont and similar to most other bovids. Riney & Child (1960) established ageing criteria for the Common Duiker based on a series of skulls with known collection dates supplemented by a few captive 'known-age' animals ranging from a neonate to one individual aged 21.5 years. This was revised by Wilson *et al.* (1984) after working with a very large collection of more than 90 known-age skulls (and see Wilson 2001). As with some other ungulates the Common Duiker has a modified lower canine tooth that has become the last incisiform. The first premolar has also been lost in the process

Lateral view of skull of Common Duiker *Sylvicapra grimmia*.

of evolution. At birth the Common Duiker has either partially or fully erupted lower milk canines and incisors with erupting upper and lower premolars; interestingly, P₃ was usually the first premolar to be fully erupted and not P₂ as one would expect. At the age of 26 months both mandibular and maxillary permanent molariform teeth are fully erupted and in wear. There is very little variation in the age of eruption and replacement of all molariform teeth making it a very useful feature for age determination (see Wilson 2001: Table 16). However, there is considerable difficulty in distinguishing deciduous incisiform teeth from permanent ones because of the great variability in eruption. The Common Duiker is one of the few ungulates in which the canines and incisors are replaced last and long after the eruption of the third molar. The final eruption and replacement of the canines and incisors usually takes place at between 30 and 38 months. Dental abnormalities, including, for example, having one or two upper canines present or the lower second premolar absent, are discussed by Riney & Child (1960) and Wilson (2001).

Geographic Variation As already mentioned above, the distribution of the Common Duiker is continuous in sub-Saharan Africa, and therefore it is currently impossible to delineate exactly where one subspecies starts and another takes its place. However, several of the subspecies do have clear distinguishing characteristics and some of these features are discussed below. There is considerable colour and size variation in this species even within very limited areas.

- S. g. grimmia*: in the extreme south of the continent this subspecies is a great deal greyer than any other subspecies (it is known as the Grey Duiker in the Cape). It is not in any way tawny-coloured, and there is no white on the belly, but there are traces of white on the throat and on the upper half of the inner side of the legs. Roberts (1951) described medium development of speckling and an incomplete face-blaze, which does not extend to the frontal tuft on the head.
- S. g. caffra*: occurs north of *S. g. grimmia* and common in KwaZulu-Natal and Limpopo Provinces of South Africa, S Mozambique (Coguno) and E Zimbabwe. It is speckled, fawn-brown to grey-yellow in colour with the mid-dorsal zone being much darker. The face-blaze is nearly black and well marked up to the eyes. Some white occurs on the belly, but the underside is mainly light buff. The tail is nearly all black on the upper surface and white below (Grubb & Groves 2001). Intergrades between *S. g. grimmia* and *S. g. caffra* occur in the 'Caffraria' (Algoa Bay area).
- S. g. steinhardti*: occurs throughout Namibia; south as far as Port Nolloth in the Northern Cape of South Africa; north to Namburi and Cahama in Angola, and east to Kazungula and Chobe district in Botswana. This subspecies is very pale sandy-coloured or even fawn. Very little speckling. In this subspecies the face-blaze fails

to reach even the level of the eyes. The undersides are off-white, chest and throat buff.

- S. g. splendidula*: the subspecies occurring in Angola, from Mupa district north to Kunungu, DR Congo, and across the Congo R. to Odzala (Congo). It also occurs in the south-east of DR Congo to the southern end of L. Tanganyika, north-east to Uvira and in Zambia west to the Luangwa Valley and north as far as Mpika. It is also found in W Zimbabwe (Grubb & Groves 2001). This subspecies is the largest of all the common duikers. It has a light reddish-ochre colour and a short face-stripe. Specimens from Hwange N. P. in Zimbabwe are intergrades between *S. g. steinhardtii* and *S. g. splendidula*. The Latin name (*splendidula*), meaning 'splendid animal', is appropriate, given its bright, contrasting colour, unparalleled in any other form of *Sylvicapra*.

Common Duiker *Sylvicapra grimmia orbicularis* crouching.

- S. g. orbicularis*: occurs north of the Zambezi R. in Mozambique, Malawi and in Zambia east of the Luangwa R. It is also present throughout Tanzania (perhaps absent from the extreme far north-west), along the Kenya coast and inland to Voi and the Juba R. in Somalia. This beautiful subspecies has a distinct white ring around the eyes in specimens from E Zambia and much of Malawi. The general body colour is light fawn with a narrow face-blaze, the tail is black and so are the pasterns. Females are considerably larger than ♂♂. The controversial form *walkerii* is a melanistic example of *S. g. grimmia* (Grubb 1988) and can be assigned to *S. g. orbicularis*.
- S. g. hindei*: Kenya highlands, east of the Great Rift Valley, as far east as Machakos and Sultan Hamud and south as far as Moshi in Tanzania. This subspecies has much speckling along the mid-dorsal region on a generally ochre-coloured body. The face-blaze is bold, broad and dark and extends up to the frontal tuft of hair on the head. The belly is white, throat buff with no white line. This is a small subspecies, but has a broad skull.
- S. g. nyansae*: in Kenya, west of the Rift Valley west to Busoga district in Uganda and to the eastern levee of the Nile in S Sudan north to Reseires in Ethiopia on the Blue Nile. This subspecies is brighter than *S. g. hindei*, but with less mid-dorsal darkening and much whiter underparts. The face-blaze is deep brown rather than blackish.
- S. g. altivallis*: Afroalpine zone of the Aberdares and also probably on Mt Kenya. On Mt Kenya, *S. g. hindei* reaches up to the edge of the forest belt at 1980 m and the two subspecies are isolated from one another by montane forest. It is much greyer than *hindei* with heavier speckling, more marked face-stripe, black pasterns and drabber tone on underparts. It has long, thick fur (Grubb & Groves 2001).
- S. g. lobeliarum*: Afroalpine zone on Mt Elgon. Has a pinkish-grey coat with heavy speckling and a wide face-stripe, which is chocolate-brown. The ears are short and pointed and the pasterns black. In most of its characters this race seems to be the most distinctive of the afroalpine forms.
- S. g. grimmia* subsp. nov.: this is the duiker described by King (1975) from Mt Kilimanjaro. This distinct form has a grey-brown colour, thick black face-blaze, reduced black on tail, and off-white underparts not extending down the inner sides of the limbs. It differs from *altivallis* in having heavier speckling, less black on tail, foreleg stripe usually reaching the knee, 'squared off' ears and a shorter tail (Grubb & Groves 2001).
- S. g. madoqua*: Ethiopian Highlands, both east and west of the Rift Valley, as high as 2990 m in the Sahatu Mts and as low as 610 m at Hawash Station. It is generally grey-buff to brownish-ochre with heavy speckling and the mid-dorsal zone darkened. The face-stripe is complete in the highland form, less so in those from the lowlands. According to Grubb & Groves (2001) this is a very variable race, difficult to define although the various component samples do differ as a whole from the Kenya races and from *campbelliae*.
- S. g. campbelliae*: savanna country from Burundi and Karagwe in the south-east to north of Bahl-el-Ghazal; also occurs in the north-east of DR Congo, southernmost Central African Republic, S Chad, N Cameroon and Nigeria, west to Ghana, Burkina Faso (Fada-N-Gourma) and Sierra Leone. This is a dull ochre to grey-buff duiker, heavily speckled and dark on the mid-dorsal zone. It has a dark face-blaze, which extends to the crest, the tail black above and brown pasterns. The foreleg stripe is well marked. The belly is buff-white to white and no throat patch.
- S. g. pallidior*: distribution of this subspecies is not accurately known, but it does occur in the Sahel Zone from Mani (furthest west locality) as far east as Gallabet on the borders of the Ethiopian Highlands; north as far as Jebel Marra Darfur; south as far as Fort Archambault. *S. g. pallidior* is much paler than the previous race, it is pale buff and weakly speckled but still has a mid-dorsal darkening. The face-blaze extends to the crest.
- S. g. coronata*: this subspecies has only been recorded from a small area on the borders of Guinea, Guinea-Bissau, Senegal and Gambia. It is a beautiful bright orange-yellow colour with no speckling and a mid-dorsal darker shade, which is almost reddish. The face-blaze is red and not extending to the crest. The foreleg stripe is indistinct and not reaching the knee. It has yellowish white underparts and no throat streak. This is the most distinctive of all the subspecies and could possibly be raised to specific rank depending on its relationship with the neighbouring *campbelliae* (Grubb & Groves 2001).

Similar Species

Ourebia ourebi. Occurs on open grassland and could be confused with the Common Duiker in places where both species occur. Much taller, with longer horns, and a much longer neck. Oribi normally

occur in small family groups, whereas the Common Duiker is a solitary animal.

The Common Duiker is the only duiker species found in open savanna woodlands and, therefore, unlikely to be confused with any of the other duikers (although, to a lesser extent, the Red-flanked Duiker *Cephalophus rufilatus* occurs in some open country in West Africa in the Guinea Savanna zone).

Distribution The Common Duiker is one of the most widely distributed antelopes on the African continent, and in spite of dense human populations in many areas its historical distribution has remained largely unchanged, managing to survive where many other species of large mammals have been exterminated. In West Africa, the Common Duiker is widespread and common in savanna woodlands from C and S Senegal, Gambia and Guinea-Bissau east through N Guinea, SW Mali, N Côte d'Ivoire, S and C Burkina Faso, N Ghana, Togo, N and C Benin, N and C Nigeria, SW Niger and N Cameroon. They are naturally absent from the Guinean rainforests, being entirely absent from Liberia; however, there is one old record from NE Sierra Leone (Stanley & Hodgson 1929; and see Grubb *et al.* 1998). From Cameroon, their distribution extends through S Chad, Central African Republic and S Sudan to north-east Africa. Here, while still widespread and common in many areas in W and C Ethiopia, they are now rare and hardly ever seen within their former range in S Somalia and SC Eritrea; they are recorded only from the Forêt du Day in Djibouti, but there have been no confirmed records in several decades (Künzel *et al.* 2000, Heckel & Rayaleh 2008). In East Africa, the Common Duiker occurs throughout Kenya (except semi-arid and arid northern rangelands from which it is naturally absent), Tanzania, Uganda, Rwanda and Burundi, west into N, E and S DR Congo. They then occur southwards widely in all countries, with the exception of the arid coastal deserts of Namibia (East 1999, Wilson 2001). In central Africa, the Common Duiker occurs in the savannas of C and SE Congo, and in neighbouring

E and SE Gabon, where little is known of the species' distribution (East 1999, Wilson 2001).

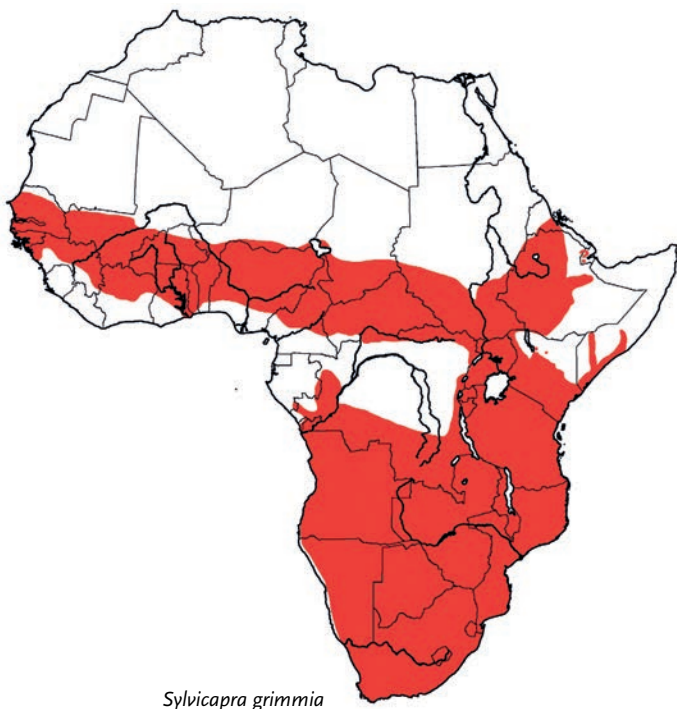

Habitat Although the Common Duiker is typically a savanna woodland species, it is often found in relatively open country and even extends into the alpine zone in some mountainous areas such as on Mt Kenya (to 4900 m; Young & Evans 1993) and Mt Kilimanjaro (to 5600 m; see King 1975, Grimshaw *et al.* 1995), the highland plateau to 3300 m in the mountains of Arssi and Bale in Ethiopia (Yalden *et al.* 1996), and at altitudes above 2200 m in the Drakensberg Mts of South Africa (Vincent 1962, Rowe-Rowe 1994).

Although the species is generally associated with rather open country and woodland it nevertheless still requires at least some small patches of bush in which to hide. This is well demonstrated on the open montane grasslands on the Nyika Plateau in N Malawi and NE Zambia. In this area the species is often seen on the open grasslands but once disturbed it rushes into the edges of the montane forests to hide. Wilson (2001) identified six vegetational types as habitats for the Common Duiker: *Brachystegia*–*Isoberlinia* woodland – one of the preferred habitat types; Mopane *Colophospermum mopane* woodland – while the Common Duiker is not plentiful in this habitat type it nevertheless can still be found in many places where Mopane woodland occurs; Montane Grasslands – the species is common in this habitat and especially on the border of such grasslands where *Uapaca* and stunted *Brachystegia* woodland is found; Kalahari/Acacia veld – the species is common in these dry areas where it can go without drinking water for months at a time; Guinea Savanna – as with the southern African savanna woodlands, the species is plentiful in the northern Guinea savannas; and *Terminalia* woodlands, on Kalahari sand – a much-favoured habitat. In reality, the Common Duiker can be found in almost every habitat type in sub-Saharan Africa, with the exception of dense evergreen rainforests, and in more open areas as long as sufficient cover exists in which it can hide.

Abundance The Common Duiker can be found in very large numbers in many places in Africa. In several places where game elimination as a means of controlling tsetse flies has been carried out, tens of thousands of individuals have been shot and yet today the species is still very common in those places. For example, 83,784 duikers were shot in Zimbabwe between 1924 and 1945 (White 1954), and yet the species is still very common in these areas today. Similar operations were undertaken in the Chipata district of E Zambia (see Wilson & Clarke 1962 and Wilson & Roth 1967 for details), yet they still occur widely in this part of the country.

Wilson (2001) summarizes some recorded densities of Common Duikers from various localities in Africa in different vegetation types using line transects, including: 3.2/km² in the Guinea savanna of Mole N. P. in N Ghana; 2.9/km² in *Brachystegia*–*Isoberlinia* woodland in Lukuzuzi G. R. in E Zambia; 2.0/km² in *Acacia*/*Combretum*/*Grewia* savanna in the south-west lowveld of Zimbabwe; 2.4/km² in the Matopo Hills of Zimbabwe; and 9.0/km² in the *Baikiaea* woodland of Hwange N. P.

East (1999) indicates that aerial surveys generally produce estimates of population densities in the range of 0.01–0.15/km², such as in W N. P. (Burkina Faso) (Belemsobgo & Chardonnet 1996), and Pendjari (Benin) (Chardonnet 1995). However, East (1999) notes that aerial surveys underestimate the numbers of this small, secretive

Sylvicapra grimmia

species by a large but unknown factor. Ground surveys in areas where the species is common often produce density estimates of the order 0.3–1.7/km². As the Common Duiker is a species that is capable of altering its periods of activity depending on disturbances caused by local conditions it becomes extremely difficult to assess the size of populations accurately. Therefore, ground surveys are often inaccurate if undertaken at a time when duikers are not active. The very best times of the day for surveys are very early in the morning soon after sunrise and late in the afternoon just before sunset and early evening. East (1999) estimates the total population for sub-Saharan Africa as 1,660,000, indicating that this is a conservative figure. The present author believes the total population of the Common Duiker is more likely to be in the order of 10 million animals.

Adaptations This duiker is a most adaptable species and capable of occupying a wide range of habitat types. Apart from the Rwenzori Red Duiker *Cephalophus rubidus* on the Rwenzori Mts, the Common Duiker appears to be the only species of African antelope able to adapt to habitats high up on the mountains, often to the snowline. It also occurs in the hot and seasonally dry valleys of the Zambezi and Limpopo valleys and is very common in the waterless and very dry Kalahari Desert in Botswana and Namibia. An experiment carried out on a captive duiker in Zambia indicated that one animal went without water for 40 days (Wilson 1966a). Dietary flexibility, the ability to survive without surface water and fecundity all contribute to this species' success, but the basis of its adaptive flexibility is undoubtedly physiological, an aspect of the Common Duiker's biology that awaits a comparative investigation.

Studies of the preorbital gland secretion of male and female Common Duikers have shown that two compounds, both thiazole derivatives, are present in higher concentrations in ♂♂ than in ♀♀. This is the only consistent difference between the secretions of the sexes, and coupled with the fact that only ♂♂ mark territories, could be seen as evidence that these two compounds play a role as sex recognition cues and in territorial behaviour (Burger *et al.* 1988, 1990). There is a great increase in the size of the preorbital gland of the ♂ while the ♀ is in oestrus and he will mark trees, shrubs and even stones far more vigorously than normal. The secretion, which is squeezed out by rubbing the gland against some hard object, crystallizes and forms a dark stain on the object marked. In E Zambia, and on several occasions in Zimbabwe, the author has observed a ♂ rubbing his preorbital glands on the hindquarters of a ♀ in his enclosure, leaving the secretion on her. Sikes (1958) also observed a ♂ marking a ♀ in Nigeria.

During a detailed study of food and feeding habits in Matobo N. P. (W Zimbabwe), Wilson (2001) watched a duiker feeding under foraging monkeys: every now and then the duiker would look up into the trees to see where the monkeys were, seemingly waiting for them to drop more flowers to the ground. Such behaviour reveals *Sylvicapra* as a typical duiker and can be presumed to have derived from forest-dwelling ancestors.

Foraging and Food The Common Duiker is a browser and frugivore, rarely taking grass, and has been recorded feeding on a very large number of plants. In one study, in E Zambia, the leaves of 44 different plants were identified from the rumens of 191 duikers. In addition, from the same sample 33 different fruits and seeds were recorded as well as 15 species of flowers (Wilson 1966a).

A detailed study of the food and feeding habits of the Common Duiker was carried out in Matobo N. P. (see Wilson 2001). Tame male and female duikers were used for the study in granite hills where the vegetation consisted of *Colophospermum mopane* in addition to *Brachystegia* spp. and *Julbernardia globilifera*, *Parinari curatellifolia*, *Terminalia sericea* and *Peltophorum africanum* were also common. Contrary to what was expected, green leaves of large trees and shrubs were not the most important foods eaten by the duikers studied. Most of the leaves of the larger trees are well out of reach unless the trees occurred in a shrub form or as seedlings. Fallen leaves of some of the large trees were often gleaned from the ground even though they were partly dry, as in the case of *Kirkiana acuminata*, which were eaten in large amounts during the dry season. Instead, leaves, stems, flowers and fruits of many small herbs were eaten in very large quantities, for example, *Commelina welwitschii*, *C. benghalensis*, *Ipomoea omaneyi* and *Sida cordifolia*. In this study 65% of the duikers' total feeding time was spent feeding on these plants. The duikers often climbed among the boulders at the base of rocky outcrops in the study area and both animals fed on herbs growing in the litter between the boulders. The duikers often pulled entire small plants out of the soft soil among the boulders and ate the entire plant, including the roots.

After herbs, fruits and seeds were most important in the diet. The fruits, seeds and flowers of many species of trees and shrubs were eaten, when available, in very large quantities. The fallen dry pods and also green pods of *Acacia robusta* and *A. nilotica* were eaten in fair numbers. The following fruits were eaten whenever they were available and formed a major part of the duikers' diet: *Ximenia caffra*, *Dovaylis caffra*, *Flueggea virosa*, *Flacourtia indica*, *Ziziphus mucronata*, *Grewia flavescens*, *Solanum* sp. and *Pseudolachnostylis maprouneafolia*. Both green and dry pods (in bunches) of *Dichrostachys cinerea* were much sought after as were the ripe bunches of *Lannea discolor*. Various species of *Ficus* fruits were also greatly relished and in some instances eaten in very large quantities. *Flueggea virosa* was an important tree as the tiny white fruits were eaten, when available, in vast amounts. On numerous occasions the ♂ was seen to stand on his hindlegs in order to get to fruits and leaves of shrubs that were just out of reach. This was particularly noticeable when feeding on the ripe fruits of *Ximenia caffra*, *Flacourtia indica*, *Grewia* spp. and *Flueggea virosa*.

The flowers of most species were eaten, some in large numbers, while in other species only a few were eaten. In nearly all cases the flowers had fallen from the larger trees and these were gleaned from the ground. The duikers were like vacuum cleaners as they moved about sucking up the flowers. Flowers eaten included: *Bauhinia petersiana*, *Cassia abbreviata*, *Brachystegia* spp., *Hibiscus* sp., *Loranthus* sp., *Dichrostachys cinerea* and *Acacia* spp. In the case of the small legumes, *Crotalaria podocarpa*, *C. sphaerocarpa*, *C. virgulata* and *Dolichos daltonii* flowers were often plucked from the plants and eaten in bunches together with any green pods and leaves that were present on the plant. In one part of the male duiker's home-range there were four *Cassia abbreviata* trees. Vervet Monkeys *Chlorocebus pygerythrus* were on two occasions seen feeding on the recently flushed yellow flowers and on both occasions the male duiker picked up some of the fallen flowers from the ground and ate them.

In the Matobo Hills study, although the leaves of trees and shrubs were not the most important dietary item, the following were eaten: *Grewia flavescens*, recently flushed *Parinari curatellifolia*, *Dichrostachys cinerea*, *Acacia nilotica*, *A. robusta*, *Combretum hereroense*, *Dombeya*

rotundifolia, *Combretum apiculatum*, *Ximena caffra*, *Pavetta schumanniana*, *Terminalia brachystema*, *Flueggea virosa*, *Lannea edulis*, *Flacourtia indica*, *Ziziphus mucronata*, *Pseudolachnostylis maprouneifolia*, *Pterocarpus angolensis* and newly flushed *Protea angolensis*. *Albizia amara*, *Burkea africana*, *Euclea divinorum*, *Lannea discolor*, *Azara garkeneana*, *Faurea saligna*, *Peltophorum africanum* and *Rhus tunuinervis* were occasionally eaten but only in very small quantities. *Dichrostachys cinerea*, *Flueggea virosa*, *Combretum hereroense*, *Flacourtia indica* and *Combretum apiculatum* were some of the more important trees from which leaves were picked and eaten. The leaves and fruits of the small tree *Securingea virosa* were often eaten in very large quantities. Taking all three years of the study into account, only 25% of the total feeding time was spent feeding on the leaves of large trees.

As soon as the wet season ended in late Mar the trees and other plants started drying out. This normally started with the small herbs and climbers and ended with the leaves of the large trees falling to the ground. By late Jul there were very few large trees with leaves still on them and the country looked extremely dry. It was at that time of the year that fruits were still falling and these became extremely important in the duiker's diet. By Aug temperatures were already increasing and fires had swept through the countryside including the study area. With the increase in temperature after the winter, many trees and shrubs started flushing new leaves. By Sep and Oct, long before the rains fell in the middle of Nov, the vegetation in the entire study area, for each of the three years of the study, was attractively green and provided good supplies of food for browsers. With the commencement of the wet season in late Nov and early Dec, most of the small herbs and climbers flushed, and for the following five months there was an abundance of vegetation again. The onset of the dry season led to the drying out of the vegetation and both the male and female duikers had to cover a larger area in order to find food. A lot of time was spent slowly walking about sniffing at dry plants and looking for food. By Aug both duikers were ranging over an area almost twice the size of the area occupied during the wet period and both duikers appeared to have lost weight.

Soon after the first rains had fallen the duikers fed on a small quantity of freshly sprouted grass yet, even though the grass was luxuriant, it did not represent even 2% of their diet. Interestingly, the rains brought an abundance of harvester termites. On seven occasions (four times with the ♀ and three times with the ♂) the duikers were seen feeding on termites emerging from holes in the ground. On one occasion the ♂ was seen to lick up at least 50 harvester termites *Trinervitermes rhodesiensis* as they emerged. On the other six occasions not more than between 10 and 20 termites were eaten. With the rains, fungi also became evident. Three species were eaten by the duikers, but only one or two plants at a time. After eating the top umbrella part of the fungus the duikers would occasionally also eat the entire stem. Once the ♀ dug a plant out of the ground and tried to dislodge the remaining small parts of the stem that remained in the ground. For over eight minutes she dug with her front hooves into the soft ground, removing the remains of the fungus and picking up and eating all the small pieces.

During the study, it was noticed that resin that exuded from the trunk of *Acacia robusta* and *Acacia karroo* trees were eaten by both the male and female duikers. They pulled soft balls of resin from the trees and these were chewed thoroughly before being swallowed. On one occasion the ♂ removed six balls of resin from one tree and

spent another 10 minutes at the tree licking the bark and removing small pieces of bark. Common Duikers will also feed on cultivated crops, including beans, sweet potatoes, tomatoes and groundnuts. Analysing faeces in Grants Valley, Eastern Cape, South Africa, Kigozi (2003) found that chicory provided more than one-third (35.6%) of the winter diet and a substantial proportion (14.4%) of the spring diet of the Common Duiker.

The species is well known for its tendency to eat meat, and there are records of Common Duikers feeding on Helmeted Guineafowl *Numida mitrata* chicks, ducklings, Red-billed Queleas *Quelea quelea*, a Laughing Dove *Stigmatopelia senegalensis*, mopane caterpillars *Conimbrasia belina*, lizards and insects (Smithers 1971, Wilson 2001). Hofmann (1973) once saw a duiker take a striped mouse *Rhabdomys* sp.

The Common Duiker is independent of water and even when water is available the animal rarely drinks (Skinner & Chimimba 2005).

Social and Reproductive Behaviour Common Duikers are generally solitary animals. However, when a ♀ is in oestrus a ♂ and ♀ will come together. They will often stay together for several days at a time and once mating has taken place they will separate again. Pairs will nevertheless still remain in the same general area and will come together from time to time, especially if a tree producing fallen fruit is in their home-range and in that case they will often be seen together. When two duikers are seen together it is usually an adult ♂ with an adult ♀, but a ♀ with her young is another common pairing. When three duikers are seen together it is usually an adult pair and a young animal that has not yet been weaned.

One of the most important factors influencing distribution, territorial behaviour and the home-range in the Common Duiker is food supply. The home-range is determined by the availability of the preferred foods at different times of the year. Therefore, the daily activity and home-range of the duiker is determined by its need to obtain sufficient food and this basic function is complemented by its drive to reproduce. As Allen-Rowlandson (1986) has pointed out, territorial behaviour that limits a species to any given area is likely to affect its performance. A number of authors have briefly mentioned that the Common Duiker does not often move very far and is restricted to a small area (Dixon 1964, Wilson 1966a, Dunbar & Dunbar 1979). In the Ethiopian Highlands, Dunbar & Dunbar (1979) found that known duikers occupied home-ranges that overlapped only to a limited extent. Allen-Rowlandson (1986) found that some adult ♂♂ shared part of their home-ranges with ♀♀. He found that the mean size of the home-range of Common Duikers in KwaZulu-Natal was about 21 ha, which varied between 21.1 and 27.4 ha. In a study in E Zambia, Wilson (2001) found that one adult ♂ had a home-range of 13.2 ha and another a home-range of 15.7 ha. These two ♂♂ had distinct home-ranges that did not overlap, while adult ♀♀ had home-ranges of about 13 ha, which overlapped with each other and also with those of ♂♂. Adult ♂♂ that are sexually mature will defend their territory and drive out any competing adult ♂♂. However, subadult ♂♂ are tolerated and not driven away.

The Common Duiker has a number of behavioural patterns that characterize courtship, including: the ♂ chasing the ♀ when in oestrus; flehmen; constant flicking of the tongue; low-pitched bleats; laufsclag (leg tapping); false mounting attempts; biting of the female's hindquarters and tail; and increased marking of objects with secretion from preorbital glands and final mounting of ♀. Although

Common Duiker *Sylvicapra grimmia*.

these various forms of behaviour are connected with courtship, they do not necessarily follow each other sequentially and some adult ♂♂ do not exhibit all the behavioural patterns. The chasing of the ♀ in oestrus is often very pronounced and ♂♂ in captivity can become most aggressive and will not tolerate other sexually mature ♂♂ in the same enclosure. Very often a ♂ would chase a ♀ in oestrus to near exhaustion and in captivity the ♀ would often lay down in some secluded spot in order to get away from the ♂. If that happened he invariably persisted in attempting to get her to her feet by pawing her with his front feet, or even biting her. If the ♀ rose to her feet the chase would continue. This chasing behaviour was often observed in the wild early in the morning and again late in the afternoon and at sunset.

In the male Common Duiker, flehmen is not as noticeable as it is in other ruminant species, but after close genital olfaction or after testing freshly voided urine from a ♀ in oestrus, the ♂ would raise his head and a slight lip-curl could be seen. After genital olfaction, reproductive activity in the ♂ is increased considerably and this is also noticed if freshly voided urine is tested. It is therefore clear that olfaction is essential in the stimulation of reproductive activity in the ♂. Frequent urination by the ♀ is a common characteristic while she is in oestrus, which suggests maximum output of urine and, therefore, endocrine contents.

During courtship the ♂ follows the ♀ persistently but only seriously begins to court her when she proves to be in oestrus. The flicking of the male's tongue and low-pitched bleats are closely linked and can be clearly observed in ♂♂ following a ♀ in oestrus. The male's tongue will also occasionally come in direct contact with the female's hindquarters, her tail and even her vulva. Low-pitched bleating is a vocal communication between the adult ♂ and ♀ during courtship. The ♀ on the other hand also bleats from time to time but not nearly as much as the ♂ and usually only when running away.

Another form of mating behaviour consists of the ♂ striking out with a stiff, straight forelimb (a behaviour known as laufs Schlag). He nudges the ♀ either between the hindlegs or on her hindquarters. If the ♀ moves slowly away the ♂ will follow and flehmen and laufs Schlag continue. However, once the ♀ stands the ♂ attempts to mount her, and false mounting attempts by the ♂ are extremely common. In this behaviour the ♂ shows no serious attempt to clasp the ♀ with his forelegs as he would do if she is receptive. When he rises onto his hindlegs they are usually too far behind her to complete copulation. As soon as he mounts, the ♀ takes a couple of steps forward and he drops onto all fours again. Often in these false mounting attempts the ♀ would raise one or both of her hindlegs and kicks the ♂. Either of these activities is sufficient to prevent mating, but does not prevent the ♂ from continuing to pursue the ♀. False mounting is carried on repeatedly and long before actual copulation takes place. In the false mounting position the ♂ will never rise to a fully upright stance on his hindlegs as he would when mounting a wholly receptive partner.

It has been recorded in the wild and also with captive duikers that the ♂ will actually bite the female's hindquarters and tail. The continual biting of the ♀ in the same spot will often leave an area of about 4 cm diameter bare of hair and often raw and bleeding. A ♂ has also been recorded actually biting off the tip of a female's tail, leaving a raw stump (Wilson 2001).

Once the ♀ is receptive and no longer runs from the ♂, he rises onto his hindlegs, positioning them as close to those of the ♀ as possible, and, clasping the ♀ with his forelegs, mates with her. Intromission and ejaculation are performed very rapidly. Following ejaculation there is a short refractory period of about half an hour before mounting takes place again. The ♂ will often mate three or four times before moving off. He then loses interest in her but later in the day more mating bouts will take place continuing for as long as the ♀ is receptive.

Females retire to the cover of dense vegetation to give birth. Parturition seems to take place either early morning or late afternoon, or in the hours of darkness (Wilson 2001). The ♀ cleans the lamb immediately following birth, and usually eats the afterbirth; young are precocious and stand up and attempt to suckle shortly after birth. The lamb is hidden near the birthplace, but the ♀ remains in close association with her young for several days following birth, frequently visiting it (four to six times per day) and strengthening the mother–young bond. Lambs will suckle as much as eight times per day, usually early in the morning, late afternoon and during the night (Wilson 2001).

Reproduction and Population Structure The information that follows is summarized from Wilson (2001), unless otherwise indicated. Females become sexually mature when they are between 8.5 and 10.5

months old; a known-age ♀ born in captivity came into oestrus at eight months, and had her first lamb when 15 months old. Males become sexually mature about 3–4 months later. Ovulation takes place in the right horn of the uterus. Of 231 reproductive tracts dissected, Wilson (2001) recorded 110 cases where ovulation was from the left ovary and 121 from the right ovary. In all cases implantation was in the right uterine horn. The gestation period of 29 captive births, in which mating and subsequent births were witnessed, was between 189 and 216 days with an average of 200 days.

Neonates have a mass of about 1.7 kg, but this can vary considerably depending on the size of the ♀. Newly born Common Duikers in Botswana have a mass almost twice those from Ghana, where adults are half the size of those in Botswana. Young gain as much as 600 g in weight in the first week of life (Wilson *et al.* 1984). Lactation lasts approximately 3–4 months and weaning is gradual, with young starting to nibble on leaves when only two weeks old. Common Duiker milk has a crude protein percentage of about 8.5%, ash 1.2%, moisture 79%, fat content 8.2% and lactose 3.9%.

In view of the fact that the gestation period of the Common Duiker is so long for such a small animal and secondly that the ♀ will often come into oestrus soon after giving birth (see below), there is no clear season of birth. However, Wilson (2001), when studying duikers in E Zambia, recorded young throughout the year, while in a similar study in the south-east lowveld of Zimbabwe where the rainfall is a lot less than E Zambia, young duikers were recorded from Nov to Mar, suggesting a birth peak.

Females often come into oestrus within a week of giving birth and many ♀♀ of breeding age are often pregnant and lactating at the same time. Very little information is available on the inter-birth interval of the Common Duiker and all the data that are available come from animals in captivity. Mentis (1972) mentions 267 days while von Ketelhodt (1977b) gave the average interval as 259 days. However, his records were for only one pair of duikers that produced 11 young over a period of seven years. From data collected by Wilson (2001) over an extended period of time from several localities in southern Africa, the mean interval between births was 237 days with a range of 199 to 271 days ($n = 20$).

Jones (1993) gave a longevity record for *S. g. grimmia* in captivity of 11 years and 10 months, but Wilson (2001) noted that the oldest 'known-age' captive duiker reached an age of 26.5 years, while there were several other captive animals that attained ages of 15, 17, 19 and 21.5 years.

Predators, Parasites and Diseases The Common Duiker has a very large number of predators and there is hardly a mammalian carnivore or bird of prey that does not feed on this species. Two very detailed studies of the predators of the Common Duiker, undertaken in E Zambia and in the Matobo Hills in Zimbabwe, showed that at least 22 species of mammals and birds were recorded feeding on this duiker (Wilson 1966b, 2001). The adults are taken by, among others, Leopards *Panthera pardus*, African Wild Dogs *Lycaon pictus*, jackals *Canis* spp., Cheetahs *Acinonyx jubatus* and hyaenas, while young may be taken by baboons *Papio* spp., many of the larger birds of prey, including Martial Eagles *Polemaetus bellicosus*, Verreaux's Eagles *Aquila verreauxii* and Wahlberg's Eagles *A. wahlbergi*, as well as Giant Eagle-owls *Bubo lacteus* and African Rock Pythons *Python sebae*. While the Secretary Bird *Sagittarius serpentarius* feeds on rodents, snakes and

Common Duiker *Sylvicapra grimmia*.

insects, there is a record of a young duiker being killed by one in Matobo N. P. (V. J. Wilson pers. obs.).

Crotalaria, intoxication due to the legume *Crotalaria*, is the only known cause of extreme overgrowth of horn affecting all four feet in domestic animals and some wild antelopes. In the Common Duiker, crotalaria is the laminitic form of crotalism caused by an acute inflammation in the horn-forming tissue due apparently to some toxic process resulting from the ingestion of one or more species of *Crotalaria*. In the acute form there is great pain that later subsides. This induces abnormality of gait, which, together with the excessive growth, results in an elongated and deformed foot becoming noticeable after a period, often showing a succession of rings. Laminitis has been recorded in a number of Common Duiker in Matabeleland, Zimbabwe. Additional details of this disease can be found in Wilson (2001).

A very large number of both external and internal parasites have been recorded from the Common Duiker, including roundworms (nematodes), flukes (trematodes), tapeworms (cestodes), and arthropod parasites such as flies, lice and ticks. Nematodes include species of the genera *Cooperia*, *Haemonchus*, *Impalpia*, *Longistrongylus*, *Nematodirus*, *Ostertagia*, *Teladorsagia*, *Trichostrongylus*, *Trichuris* and *Setaria*, as well as *Oesophagostomum columbianum*, *Skrjabinodera kuelzii*, *Subulura distans* and the lung-worm *Dukerostrongylus kenya* (Round 1968, Dinnik & Boev 1982, Boomker *et al.* 1983, 1986, 1987, 1989a, Boomker & Reinecke 1989). Trematodes include *Paramphistomum* sp. (Boomker *et al.* 1983), *Cotylophoson cotylophoson* (Round 1968), *Schistosoma bovis* (Sobrer 1975) and *Fasciola hepatica* (Graber *et al.* 1980). Cestodes include *Moniezia expansa*, *Cysticercus* spp., *Echinococcus* spp., *Avitinella centripunctata*, *Stilesia hepatica*, *Taenia* spp. and *Thysaniezia* sp. (Round 1968, Graber *et al.* 1980, Boomker *et al.* 1987, 1989a).

Arthropod parasites are also numerous, including: ixodid ticks, such as *Amblyomma hebraeum*, *Boophilus* spp., *Haemaphysalis* spp., *Ixodes* spp. and *Rhipicephalus* spp.; sucking lice, *Linognathus breviceps* and *L. zumpti*; biting lice, *Damalina*; and the louse fly *Lipoptena paradoxa* (Boomker *et al.* 1983, Horak *et al.* 1989).

Conservation IUCN Category: Least Concern. CITES: Not listed.

The Common Duiker is in the very fortunate position that, at the present time, no special conservation measures are necessary to protect this species. Its wide distribution in sub-Saharan Africa, coupled with its adaptability and the fact that it is capable of eating almost anything, means that it survives in many areas where most other antelopes have been eliminated. It occurs in good numbers in many specially protected areas throughout sub-Saharan Africa.

Measurements

Sylvicapra grimmia

TL (♂♂): 920 (910–932) mm, n = 12
 TL (♀♀): 948 (932–954) mm, n = 14
 T (♂♂): 122 (100–149) mm, n = 12
 T (♀♀): 123 (101–146) mm, n = 14
 HF c.u. (♂♂): 262 (231–286) mm, n = 12
 HF c.u. (♀♀): 269 (234–289) mm, n = 14
 E (♂♂): 93 (90–107) mm, n = 12

Common Duiker *Sylvicapra grimmia*.

GENUS *Cephalophus*

Forest Duikers

Cephalophus C.H. Smith, 1827. In: Griffith et al., Anim. Kingd. 5: 344.

Cephalophus is a genus that currently embraces all duikers except for the two or more species of *Philantomba* and the monospecific *Sylvicapra*. The separation of *Philantomba* based on morphological characters (e.g. Pocock 1910) has had strong support from molecular studies that indicate that these small duikers were the first of the extant species to diverge from the rest of the duikers (Jansen van Vuuren & Robinson 2001). The Common Duiker *Sylvicapra grimmia* occupies a much more ambiguous position, with different molecular trees positioning it wholly outside, marginally outside and wholly within the *Cephalophus* mainstream duikers (Heyden 1968, Robinson *et al.* 1996b, Jansen van Vuuren & Robinson 2001, Hassanin *et al.* 2012).

Molecular studies have confirmed that duikers as a whole, as well as the genus *Cephalophus*, conform with the prediction (Kingdon 1982) that small duikers should be the more conservative while the larger duikers are among the most recently evolved (Robinson *et al.* 1996b, Jansen van Vuuren & Robinson 2001). According to the molecular studies of Jansen van Vuuren & Robinson (2001), the most consistently conservative *Cephalophus* species is the small Aders's Duiker *C. adersi*, with another apparently early branch being the smallish and somewhat specialized Zebra Duiker *C. zebra*. The bulk of the radiation is made up of a large number of medium-sized 'red duikers' with a very densely complex genealogy and a later offshoot of 'giant duikers' and 'fibre duikers'. The complexity of red duiker relationships may well be further complicated by long-term hybridization along the frontiers of expanding and contracting ranges.

The most plausible match between the very tentative trees devised by molecular scientists and the biology and biogeography of living species invites the following sketch of possible evolutionary sequences. The relictual Aders's Duiker, confined to Zanzibar and isolated forest fragments along the east African littoral, is the last 'eastern peripheral' relic of a once widespread, very early red duiker. The Zebra Duiker might be an equivalent 'western peripheral' species that has mitigated its marginal status by becoming more highly specialized. The rest of the 'red duikers' are of substantially larger size and can be divided into the following categories:

1. 'Successful peripheral generalists': relatively conservative species living in forests or galleries that are outliers geographically speaking and ecologically degraded (see map right). The relative poverty of fallen fruit and foliage ensures there are few other duikers with which to compete. This category includes the Natal Red Duiker *C. natalensis* and Harvey's Duiker *C. harveyi*. The Red-flanked Duiker *C. rufilatus* could also come here, but fits better in the next category.
2. 'Successful specialists' (deriving from older lineages): species that have escaped competition by becoming specialized in forest types that are less well endowed with a rich variety of fruits. These forests range from mono-dominant patches such as the *Gilbertiodendron* 'Limba' forests of central Africa to a variety of forest 'margins' such as actual forest edges (notably the broad swathe of forest mosaics and galleries along the northern boundaries of the main forest block), swamp forests at both low and high altitudes and the high, cold reaches of tall mountain massifs. Species in this category include

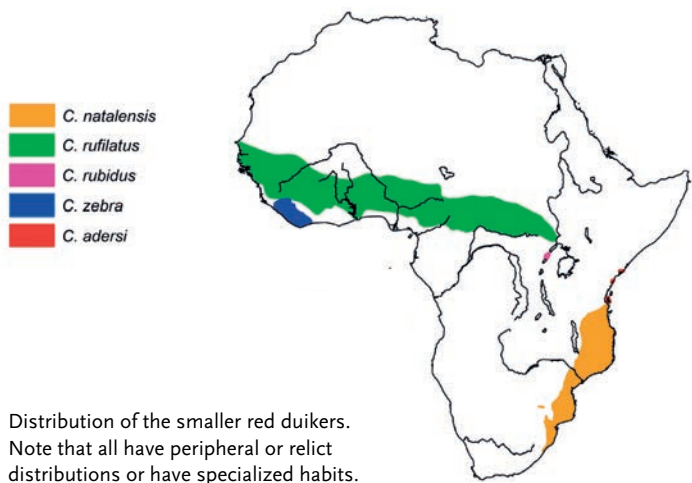

the White-bellied Duiker *C. leucogaster*, Red-flanked Duiker, Black-fronted Duiker *C. nigrifrons* and Rwenzori Red Duiker *C. rubidus*.

3. 'High-forest frugivores': species that only really flourish in highly diverse forests with multi-species fruiting trees and a broad spectrum of primates and birds assisting the wind in dropping high-quality debris from the canopy. Species in this category are highly competitive and suitably rich forests only support one species in this size class (15–25 kg). The situation is complicated by the likelihood that the older members of this class (Ogilby's Duiker *C. ogilbyi* and allies) are being actively displaced by larger and more recently evolved forms (Peters's Duiker *C. callipygus*, Weyns's Duiker *C. weynsi* and the Black Duiker *C. niger*).

Molecular trees are somewhat contradictory in tracing the origins of the remaining *Cephalophus* species. All are large, heavily built animals and they probably derive from an early, large 'high-forest frugivore'. They fall into two groups: the first comprises very large but slender, generalized duikers, including Abbott's Duiker *C. spadix* and the Yellow-backed Duiker *C. silvicultor*, while the second consists of two mainly nocturnal 'fibre duikers' that are primarily nocturnal and seek out widely dispersed, heavy and often fibrous fallen fruit, namely the Bay Duiker *C. dorsalis* and Jentink's Duiker *C. jentinki*. It is possible that nocturnal duikers may be longer-lived than other forms and this might well be an advantage for species that need to get to know a large home-range.

Most duikers are subject to very high levels of predation, particularly by humans. They are easy to snare, net, call up to a lure, dazzle by flash-light and hunt with dogs. The rarer species are already close to extinction and many others are known to be in decline. As one of the most interesting and complex of bovid evolutionary radiations, they deserve much more attention than they have to date. The extinction of once common and widespread providers of high-quality meat will only impoverish further already marginalized forest people. Both research and conservation are urgent.

Jonathan Kingdon

Cephalophus zebra ZEBRA DUIKER (BANDED DUIKER)

Fr. C  palophe z  br   (C  palophe ray  ); Ger. Zebraducker

Cephalophus zebra Gray, 1838. Ann. Mag. Nat. Hist. 1: 27–30. Sierra Leone.Zebra Duiker *Cephalophus zebra*.

Taxonomy Monotypic. Ogilby's (1837) account of *Antelope doria* is actually a reference to the Mhorr Gazelle *Nanger dama mhor* (see Kuhn 1966). Following a request from Ansell (1980), the ICZN ruled that *zebra* is to be given priority over *doria* whenever the two specific names are considered synonyms (see also Grubb 2004 for a discussion). In a multiple analysis of mtDNA, Jansen van Vuuren & Robinson (2001) found the position of this species within the duiker molecular radiation particularly obscure. Parsimony analysis hinted that *C. zebra* and Aders's Duiker *C. adersi* might be sister taxa, but this was not supported by maximum likelihood analysis, which was consistent with both species having basal positions between the 'red duiker' and 'giant duiker' complexes. Other, apparently anomalous linkages with Ogilby's Duiker *C. ogilbyi* (which gives several indications of being an early, conservative relict species) could also imply that *C. zebra* derives from a relatively early stem duiker. Synonyms: *doria*, *doriae*, *zebrata*. In contrast to all other duiker species studied to date, the diploid number is $2n = 58$, with a pair of submetacentric autosomes; the X chromosome is similar to that of other duikers karyotyped, but the Y is one of the smallest acrocentric chromosomes (Bogart *et al.* 1977, Hsu & Benirschke 1977).

Description Small- to medium-sized duiker, with a panel of vertical, vivid black and cream stripes from behind the shoulder to the tail. There is a frontal rufous-coloured tuft, though it is never

very long, and it usually obscures the short horns (with the result that animals may appear hornless, especially ♀♀). Head, shoulders and lower legs russet red with hocks and leg joints nearly black; muzzle slate-grey and nose black. Hair on the neck and shoulders is distinctly shorter than on the body, while the underparts also have rather short hair. The number of dark brown or black vertical stripes varies between 12 and 16, sometimes with light shadow stripes in between, and the width of individual stripes varies greatly (Wilson 2001). Tail tufted, well haired and relatively long, black hairs intermixed above, but white below. Lateral hooves very small. Preorbital glands present. Tarsal glands prominent and tufted just below the heels of the back legs. Inguinal glands entirely different to those of any other duiker, with tiny round holes in the groin (Zeller & Kuhn 1991, Wilson 2001).

Both sexes have small (about 4 cm) but robust, conical, smooth and very sharply pointed horns above a forehead and nasal area where the bone is massively thick and reinforced. The horn cores of the frontalia rise less above the profile line of the frontalia than in other species. The enlarged nasal cavity is particularly conspicuous in the skull. Preorbital depressions are relatively tiny. The second incisor and canine of the lower jaw are further reduced than, for example, in the Bay Duiker *C. dorsalis* or Black Duiker *C. niger* (Kuhn 1966).

Geographic Variation None recorded.

Lateral, palatal and dorsal views of skull of Zebra Duiker *Cephalophus zebra*.

Similar Species Several species, notably Maxwell's Duiker *Philantomba maxwelli*, Bay Duiker, Black Duiker and Brooke's Duiker (*C. ogilbyi brookei*) are sympatric with Zebra Duikers. However, the striped colour pattern of the Zebra Duiker renders this species quite unmistakable.

Distribution Endemic to West Africa, ranging from E Sierra Leone (Moa R.) to Côte d'Ivoire (Niouniourou R.) within the primary forest zone. Most common in east-central Liberia. Its distribution and numbers have declined markedly because of forest destruction and excessive hunting for bushmeat. Its remaining strongholds are Sapo N. P. and other forests of SE Liberia, and Tai N. P. and adjacent forest reserves in Côte d'Ivoire (East 1999).

Historical Distribution In Sierra Leone, the Zebra Duiker probably occurred quite widely in the southern and central moist lowland forests. It appears to be dependent on undisturbed primary forest and has retreated as forest has been cut down and converted to farmland (Teleki *et al.* 1990, East 1999). By the 1980s, it was very rare and localized and known to occur in only a few localities, such as Gola N. P. (Davies 1987), the eastern part of Gaura Chiefdom and, possibly, Western Area F. R. (Grubb *et al.* 1998).

In Liberia, it appears to have been relatively common in some regions. In 1974–75, Jeffrey (1977) recorded that this was the third most frequent duiker species encountered in a survey of bushmeat in east-central Liberia. It was also the third most frequently encountered duiker species in the surveys reported by Kranz & Glumac (1983). It was thinly distributed along the Sehkwén R., but common in the Buto Oil Palm Plantation, and reported by local observers to be abundant along the Sinoe R. (Peal & Kranz 1990).

In Côte d'Ivoire, its distribution never extended further east than the Niouniourou R. (which lies between the Sassandra and Bandama Rivers), such that Zebra Duikers have historically always been restricted to the lowland forests in the south-west. Sightings of Zebra Duikers further to the east, for example in Comoé N. P. (see discussion in Fischer *et al.* 2002), are unsubstantiated.

Cephalophus zebra

Current Distribution Continued presence in Liberia was confirmed in 1997 in Sapo N. P. and from the forests bordering Côte d'Ivoire (East 1999). In Côte d'Ivoire the species is now confined to remaining areas of primary forest within its former range, namely Tai N. P. and the adjoining Haute Dodo–Rapide–Grah–Hana Forest Reserves, and the Cavally–Goin, Scio and Niegé Forest Reserves. Its main stronghold is Tai N. P., where it is seen regularly, and its abundance varies from common in the west to uncommon in the centre and rare in the east (Hoppe-Dominik *et al.* 1998). In Sierra Leone they persist in the Gola N. P. in the south-east (Lindsell *et al.* 2011, F. Dowsett-Lemaire & R. J. Dowsett pers. comm.), but their presence in the west is unclear.

The presence of Zebra Duikers in Guinea was not mentioned by Sournia *et al.* (1990) or Grubb *et al.* (1998), but East (1999) remarked that their presence was confirmed by a report from the Ziamá and Diécké Forest Reserves, presumably a reference to Butzler (1994). Wilson (2001) thought it likely that they should occur. The species was not reported by Barrie & Kant (2006) in a rapid survey of Diécké in 2003.

Habitat Found in undisturbed primary forests and along their margins and in clearings, sometimes extending into secondary growth and swidden cultivation (Newing 2001). It favours intact lowland forest (notably the Sinoe and other river valleys in Liberia), but may also live in low montane and hill forests.

Abundance Assuming average population densities of 2.0/km² where it is known to be common and 0.2/km² elsewhere, East (1999) gives an estimated total population of about 28,000. However, Wilson (2001) regarded this as an overestimate, and doubted that there could be more than 15,000 animals across the range at most. Davies (in Grubb *et al.* 1998) estimated peak population density in little-hunted areas in Sierra Leone at 3–10/km². Hoppe-Dominik *et al.* (2011) calculated a population density of 0.4/km² in Tai N. P.

using night counts and a total population of perhaps 2000 animals. The population trend is generally downwards because of bushmeat hunting and continuing destruction of West Africa's few remaining primary forests. The only exceptions are a few localities where hunting pressures are low and/or there is effective protection against logging and poaching, such as the western section of Tāi N. P. (East 1999, Hoppe-Dominik *et al.* 2011).

Adaptations Known to be a strong stimulus to the eye/brain sensory system, stripes may serve as a focus for social attraction (in which case the resemblance of these duikers to zebras may be more than superficial). An advantage of stripes in this species could be to inhibit goring of the soft abdomen during aggressive encounters. Thus, while other animals shield themselves from the worst effects of aggressive rivalry with thickened skin, bony plates and so forth, these duikers may have a subtler strategy for reducing excessive aggression (Kingdon 1997).

Grubb *et al.* (1998) suggested that Zebra Duikers are both diurnal and nocturnal. Captive animals in Monrovia Zoo, Liberia, were active about 70% of the daytime (Newing 2001); animals in Tāi N. P. were mainly active at night (Hoppe-Dominik *et al.* 2011).

Foraging and Food Diet comprises fruits and foliage. Details are unknown, but the Zebra Duiker does not appear to have specialized teeth or diet. The stomach contents of four duikers shot in Liberia indicated that at least 79% of plants eaten were fruits and seeds, and all four stomachs contained large numbers of the fruits of *Diospyros sanza-minika*; two stomachs contained seeds of *Bussea occidentalis* (Wilson 2001). The animal may use its head to break open the shells of larger fruits. In captivity, occasional consumption of meat (self-caught mice) has been observed (Schweers 1981), and indeed one of the stomachs mentioned by Wilson (2001) contained the remains of an unidentified rodent.

Social and Reproductive Behaviour All of 35 field observations from Tāi N. P. were of lone animals, suggesting a primarily solitary

social system (G. Radl pers. comm.). Friendly relations between captive pairs involve mutual rubbing and licking, suggesting that breeding pairs are the normal social unit (as they are in many duikers). Because both sexes have horns and a thickened skull (which do not appear to correlate with a specialization in ecology or diet), it seems likely that bonded pairs share defence of their home-range against intruding duikers and their offspring against predators. Scarred heads suggest that the collisions that are normal in duiker confrontations are particularly vigorous and uninhibited in these exceptionally stocky and muscular antelopes (Kingdon 1997).

Schweers (1984) conducted a detailed study of breeding behaviour and reproduction on captive Zebra Duikers in Frankfurt Zoo. Males will determine the female's reproductive status by smelling her urine and performing flehmen. While a consorting pair mutually mark each other even outside of the female's oestrous period, the frequency of this marking increases in the ♂ as the ♀ approaches oestrus, with the ♂ applying secretions from his preorbital glands to the head, neck and back of the ♀. As the ♀ approaches oestrus, the ♂ follows the ♀ more closely, and licks her neck, hindlegs and anogenital region. The ♂ usually follows directly behind the ♀, sometimes making grunting sounds, his head stretched forward such that his neck is horizontal and the head is held at the height of the female's tarsal gland. Mounting attempts occur when the ♀ stops moving, and is preceded by the ♂ smelling and licking the female's anogenital region; Schweers (1984) also recorded frequent high lifting of the foreleg past the female's hindlegs (in contrast to between the legs as occurs with laufschiag in gazelles). Copulation is brief, lasting only a few seconds, but is repeated frequently. Birth in captivity is normally in the morning hours, and typically takes place while the mother stands, the neonates mainly appearing front first. The mother then eats the afterbirth. The young are precocious, but remain alone lying up until Day 20 (Schweers 1984).

Expressions of sound are rare and, besides during mating, have only been observed in captivity during initiations of contact between mothers and their offspring, and during fighting (Schweers 1984).

Reproduction and Population Structure Detailed information about reproduction is given by Schweers (1984) and Barnes *et al.* (2002) from observation of captive animals. After a postpartum oestrus, ♀♀ are normally successfully mated as little as 10 days after birth (Schweers 1984). Gestation is between 221 and 229 days (although Pfefferkorn 2001 gives a range of 190–245 days) and the birth interval 241 days (Schweers 1984). A single young is born. The birth weight is around 1270–1550 g for ♂♂ and 1300–1750 g for ♀♀ (Barnes *et al.* 2002). Neonates are born with the dark stripes visible, although they appear closer together, giving the young an overall darker appearance (Schweers 1984). The weight development during the first 60 days ranges from 47 to 74 g/day; at 40–45 days weights are around 4450 g for ♂♂ and 3620–4620 g for ♀♀ (Barnes *et al.* 2002). Young are able to nurse shortly after birth, and for the first few weeks will nurse about four times per day for several minutes (Schweers 1984); solid food is consumed from the fifth week. The young animal is weaned after about 95–111 days (Barnes *et al.* 2002). Horns begin to appear at 1–2 months of age, and at the age of 7–9 months juveniles have the adult colouration and have reached adult height (Schweers 1984). Males reach sexual maturity at about two years of age (Barnes *et al.* 2002). A wild-born animal survived to 13 years in captivity (Weigl 2005).

Zebra Duiker *Cephalophus zebra*.

Predators, Parasites and Diseases The main predator in undisturbed habitat is undoubtedly the Leopard *Panthera pardus*. Hoppe-Dominik (1984) showed that the Zebra Duiker and Black Duiker made up a large part of the spectrum of prey (up to 10%) in Tāi N. P. Immature Zebra Duikers are present in the prey of the Crowned Eagle *Stephanoaetus coronatus* in Tāi N. P., but in low frequency (S. Shultz pers. comm.). Further, the African Golden Cat *Profelis aurata* and the African Rock Python *Python sebae* are likely predators. There is no information available on parasites or diseases.

Conservation IUCN Category: Vulnerable A2cd, C1. CITES: Appendix II.

Formerly widespread over much of Liberia and Sierra Leone, Zebra Duikers are declining fast as their habitat is being destroyed and commercial bushmeat hunting becomes more entrenched and comprehensive in its onslaughts. Wilson (2001) considered them the least adaptable to deforestation of all West African duiker species and therefore the least likely to survive hunting pressure and habitat degradation. Actual consumption of bushmeat was measured by Caspary *et al.* (1999) in a one-year study in the region of Tāi N. P. For the year of 1988 they estimated that 73,000 subsistence hunters killed about 1500–3000 tonnes and a group of professional hunters killed 52–650 tonnes of bushmeat in the region (2700 km²). The share of weight of the Zebra Duiker was about 2.1% of meat at market stands in the east of the park (26 Zebra Duikers out of a total of 2171 animals killed) and 1.8% in the west (36 duikers out of a total of 5101 animals killed there). The share of the Zebra Duikers killed in the forests to the west of the R. Cavally in Liberia and smuggled into Côte d'Ivoire was around 5%. Of a total of 11,215 animals, 440 Zebra Duiker cadavers were counted. Data collected from hunters (representing approx. 3% of the total village population) in three villages in Sinoe County in Liberia over 10 months (2001–2002)

demonstrated that Zebra Duikers represented the fourth most commonly killed animal (R. Hoyt pers. comm.).

Due to undiminished demand for game meat and unsustainable hunting, there is a high risk that species with restricted ranges such as the Zebra Duiker (which is dependent upon primary rainforests) will be extirpated. Existing protected areas therefore need to be extended, networked and their protection considerably improved. Important conservation areas for the protection of this species include the Gola complex of reserves in Sierra Leone, Sapo N. P. and Grebo National Forest (Liberia), and Tāi N. P. and surrounding forest reserves in Côte d'Ivoire (East 1999, Wilson 2001).

Measurements

Cephalophus zebra

HB (♂ ♂): 846 (830–870) mm, n = 4

T (♂ ♂): 125 (122–127) mm, n = 4

HF c.u. (♂ ♂): 221 (215–227) mm, n = 4

E (♂ ♂): 79 (77–80) mm, n = 4

WT (♂ ♂): 13.5, 14.2 kg, n = 2

WT (♀): 14.7 kg, n = 1

Liberia (Kuhn 1966)

Wilson (2001) gives an average of 17 kg for five ♂ ♂ (range 15–21 kg), and 18 kg for four ♀ ♀ (range 15–23 kg). Shoulder height of ♀ ♀ averages 460 mm, compared with 440 mm in ♂ ♂

Maximum recorded horn length is 7.9 cm for a pair of horns from Liberia (Rowland Ward)

Bernd Hoppe-Dominik

Cephalophus adersi ADERS'S DUIKER

Fr. Céphalophe de Aders; Ger. Adersducker

Cephalophus adersi (Thomas, 1918). Ann. Mag. Nat. Hist., ser. 9, 2: 151. Tanzania, 'Zanzibar'.

Aders's Duiker *Cephalophus adersi*.

The vernacular name is after William Mansfield-Aders, a zoologist for the government in Zanzibar in the first few decades of the 1900s.

Taxonomy Monotypic. The species has been considered conspecific with both Natal Red Duiker *C. natalensis* and/or Peters's Duiker *C. callipygus* (e.g. Heyden 1968, Dorst & Dandelot 1970, Haltenorth & Diller 1980), but is currently regarded as a separate species (Kingdon 1982, 1997, Grubb & Groves 2001, Wilson 2001, Grubb 2005). On the basis of a molecular study of duikers, Jansen van Vuuren & Robinson (2001) found that this species occupied a consistently basal position in the duiker radiation, confirming Kingdon's (1982) prediction that this might be a relictual species from an early phase in the evolution of 'red duikers'. Synonyms: none. Chromosome number: not known.

Description A small to medium-sized duiker standing about 40–45 cm at the shoulder when fully grown and weighing 8–12 kg (Kingdon 1982, Williams *et al.* 1995, Wilson 2001). The fur is soft and

ABOVE: Lateral view of skull of Aders's Duiker *Cephalophus adersi*.
BELOW: Occlusal view of the upper-right tooththrow in Aders's Duiker *Cephalophus adersi*.

Aders's Duiker *Cephalophus adersi*.

silky, with a marked cow-lick or whorl of hair on the nape of the neck but little change in texture from the neck to the main body (Kingdon 1982, 1997). The muzzle is pointed, with a flat front to the nose. The overall colour is a reddish-ochre but grey on upper shoulder and back of neck and light fawn on the sides of the face, neck, shoulder and flanks. The bridge of the nose and crown are richly red with a prominent darker tuft at the horns. The underbelly is clear white. Aders's Duiker can be distinguished from other red duikers by the white freckling on the lower limbs and a broad white band on the rump, which merges into the underparts (Kingdon 1982, Wilson 1987, Williams *et al.* 1995). Preorbital glands present; pedal glands long, narrow and well developed. Inguinal glands are absent.

Aders's Duiker have simple spiked horns that grow to a little over 5 cm in length (Kingdon 1982, Williams *et al.* 1995, Wilson 2001). In the skull, the preorbital fossae are deep with a sharply defined upper margin; there is no interfrontal groove and no marked frontal convexity. The nasals broaden distally (Grubb & Groves 2001).

Geographic Variation The species is monotypic, although Kingdon (1982) reported hunters' assertions that animals from NE Zanzibar (Kiwengwa) were darker and heavier than animals from Jozani Forest (south-central), which were paler and lighter in weight (see Wilson 2001).

Similar Species

Cephalophus harveyi. Sympatric in coastal Kenya. Larger, redder and lacks white belly and buttock stripe.

Distribution Endemic to Africa. In Kenya, Aders's Duiker has been described as once widespread in the forests, woodland and thickets north of Mombasa up to the Somali border (Kingdon 1982). However, as a result of rapidly shrinking suitable habitat, the population has succumbed to a severe decline in numbers. Until recently, the species was thought to have become confined to a very small population in the Arabuko-Sokoke Forest north-west of Kilifi (East 1999), which covers approximately 416 km². However, in 2004, an Aders's Duiker was sighted in Dodori National F. R. north of the Tana River Delta on the N Kenya coast (Andanje & Wachter 2004), where earlier recorded by Gwynne & Smith (1974). Since then extensive camera-trapping work has found that Aders's Duiker is the most frequently recorded antelope in the Boni-Dodori forests (Andanje *et al.* 2011a, b). One reason for their distribution and habits being poorly known is that Aders's Duikers

inhabit coastal forests and thickets that often grow on very coarse coral rag, an inhospitable, waterless and, in places, impenetrable, habitat. Given such habitats and a presumably recent connection between the Zanzibar and coastal populations it is possible that the species may survive in other pockets of similar habitat elsewhere along the East African coast, especially in coastal habitats between the Pangani/Rufiji and Galana/Tana rivers (Andanje *et al.* 2011b). Because they show no signs of being exceptionally specialized and because of their likely basal position in the duiker radiation, a primary constraint on their distribution may well be the existence of competition from other red duikers, suggesting that their overall distribution is intrinsically relictual (J. Kingdon pers. comm.).

In Tanzania, Aders's Duikers still occur on Unguja (Zanzibar) I., although the population has declined substantially and now faces an increasingly uncertain future. There is a possibility that Aders's Duikers may have once occurred on Fundo I., off the coast of Pemba I. (see Williams 1998), and it is reported to have been introduced to Funzi I., Pemba (Kingdon 1997), but has since become extinct on both these islands. Archer & Mwinyi (1995) mention unconfirmed, but reliable, reports indicating a thriving population on Tumbatu I. – a small island lying off the north-west of Unguja I. While this was once certainly the case, the Aders's Duiker population on Tumbatu has heavily declined and may now no longer exist. In February 2000, five Aders's Duikers were translocated to Chumbe I. (a private marine reserve) lying off Unguja I. to complement a single previously translocated ♀ (see Mwinyi & Wiesner 2003). A few individuals were also translocated to Mnemba I. off the north-east coast of Unguja and are breeding (K. Siex pers. comm.).

Habitat In Zanzibar, Aders's Duikers inhabit tall, undisturbed thicket known locally as 'msitu mkubwa' (Archer 1994) in the waterless coral-rag on the eastern side of the island. Aders's Duiker is very sensitive to habitat disturbance, but occasionally occurs in secondary thicket (Williams *et al.* 1995). In prime habitat south of Jozani Forest, the emergent tree layer is dominated by *Mystroxydon aethiopicum*, *Diospyros consolatae* and sub-dominantly by *Euclea schimperi*. The shrub layer is dominated mainly by *Polysheria multiflora* and *Canthium hibracteatum* (Swai 1983). In Arabuko-Sokoke Forest, Aders's Duikers are most often sighted in the undisturbed *Cynometra* vegetation, mostly on red soil, with fruiting vegetation (Kanga 1995, 2002). In Dodori National F. R., Aders's Duiker has been recorded

from dense coastal thicket with full canopy cover to ca. 4–5 m and a ground layer of leaf litter and tangled stems on sandy substrate (Andanje & Wacher 2004).

Adaptations Wilson (2001) commented that the preorbital gland of Aders's Duiker was different to any other he had studied, being about one-quarter the size of the preorbital gland of even the smallest duikers. He found the gland to be near-vestigial and only a small part was active from which only small quantities of secretion could be squeezed. The gland of a ♂ had short rufous hair on top of the gland and above the opening, while below the slit there was no hair at all, and the slit of the gland was about 8 mm long and 2 mm wide. Wilson (2001) suggested that Aders's Duikers might not mark their territories to the same extent as other duikers and might, therefore, be losing the use of their preorbital glands. On the other hand, J. Kingdon (pers. comm.) thinks it possible that *C. adersi* conserves an earlier or transitional stage in the evolution of the duiker type of preorbital gland.

Aders's Duikers survive in a very demanding and specifically coastal environment where they must periodically derive their water needs from the plant parts that they eat. To this extent they are coastal specialists and probably have appropriate physiological adaptations. Apart from this they do not exhibit very marked specialization in diet or foraging techniques and their distribution accords with the suggestion that their geographically and ecologically marginal existence may reflect a relictual status (J. Kingdon pers. comm.). These duikers are diurnal/crepuscular and very shy (Archer 1994, Kingdon 1997, Andanje *et al.* 2011a).

Abundance To date three surveys have been carried out on Unguja I. The first in 1982 (Swai 1983) estimated the Aders's Duiker population to be in the region of 5000 individuals. A second, more detailed survey undertaken in 1995 (Williams *et al.* 1995) placed the population between 1200 and 2000. The populations were shown to be located in five main sub-populations with varying degrees of interconnectedness: Kiwengwa Forest in the north, localities in the central Jozani-Chwaka Bay area and Mtende in the south. A third survey carried out in 1999 (Kanga & Mwinyi 1999) placed the population at 614 ± 46 within the same study area as Williams *et al.* (1995). Although the surveys all adopted different methodologies, they show a very substantial decline in the population over a 17-year period. In 1995, Aders's Duikers on Zanzibar were found to occur at an overall density of $4.5 \pm 1.2/\text{km}^2$ in high thicket (comparing favourably with that of $4.3/\text{km}^2$ recorded by Swai [1983]), with higher population densities of up to $11.4 \pm 5.2/\text{km}^2$ in limited areas of particularly undisturbed high thicket habitat (Williams *et al.* 1995). The impact of hunting was not controlled so the species must have once occurred naturally at higher densities than those measured.

Until recently Aders's Duiker in Kenya was thought to have become restricted to the Arabuko-Sokoke Forest where it was once common but is now considered very scarce. A very approximate figure of about 500 individuals was estimated in 1999 based on a small drive-count survey in the Arabuko-Sokoke Forest (Kanga 2002). In Arabuko, Aders's Duikers were found to occur at a density of $2.8/\text{km}^2$ (Kanga 2002, 2003a). Overall, recent surveys have only sighted very low numbers (three in 1999, two in 2002 and two in 2003) (Kanga 2002, 2003b).

Camera-trapping surveys have shown that Aders's Duiker is the most frequently recorded antelope in the camera grids in the Boni-

Cephalophus adersi

Dodori forests and surrounds, being present at 51 of 52 camera sites, returning a standardized photo rate of 75 encounters/100 days across three grids dispersed over 1200 km². In contrast, at Arabuko-Sokoke, a comparable sampling effort returned 0.09 encounters/100 days (Andanje *et al.* 2011a).

Foraging and Food Aders's Duikers are browsers selecting for dicotyledonous leaves, seeds and fruit (Swai 1983). They show a particular dependence on the flowers and berries that grow prolifically from common trees, such as *Diospyros consolataei*, *Cassine aethiopica* and *Euclea schimperi*, and bushes such as *Canthium* spp. and *Polyspheria* (Kingdon 1997); Wilson (2001) recorded the fruits of *D. consolataei*, *Ficus sur* and *Tetracella littoralis*. In addition to these foods they will eat sprouts, buds and other fresh growth found at ground level (Kingdon 1997). Individuals may sometimes follow troops of Gentle Monkeys *Cercopithecus mitis* and Zanzibar Red Colobus *Procolobus kirkii* feeding on discarded fruits and dislodged edibles from the canopy above (Swai 1983, S. Imani pers. comm.).

Feeding occurs from dawn to around 11:00h, followed by a period of rest and rumination, before becoming active again from about 15:00h when they continue to forage until nightfall (Kingdon 1997). The species has been reported as being independent of water (Kingdon 1982).

Aders's Duikers are sympatric with Harvey's Duikers *C. harveyi*, Blue Duikers *Philantomba monticola* and Sunis *Nesotragus moschatus* on the mainland, and with Blue duikers and Sunis on Zanzibar. Little is known regarding their feeding and ecological separation, but camera trapping data suggests that Aders's Duikers hold their own in relative numbers at key sites such as Boni-Dodori (75 encounters/100 days compared with 55 Suni encounters and two for Harvey's Duiker), with broadly similar diurnal activities patterns in all three (T. Wacher pers. comm.). It can be predicted that diurnal feeding allows these duikers to benefit from monkey and bird activity in the canopy (Kingdon 1982).

Aders's Duiker *Cephalophus adersi*.

Social and Reproductive Behaviour Aders's Duikers have been reported to live in pairs and to defend territories (Kingdon 1997). However, Aders's Duikers have also been recorded singly (Williams *et al.* 1995); out of 3021 separate camera-trap records at Boni-Dodori, only 8.5% comprised two animals (mostly adult pairs, but also mother and young) with less than 1% involving trios (T. Wachter pers. comm.).

Reproduction and Population Structure Aders's Duikers reportedly breed throughout the year (Rodgers & Swai 1988). During a six-month survey on Zanzibar, Archer & Mwinyi (1995) recorded 40 Aders's Duikers shot by local hunters, 24 of which were pregnant. Pregnant ♀♀ were recorded in all months, with three of eight and three of four pregnant ♀♀ having large fetuses in Aug and Sep, respectively.

Predators, Parasites and Diseases Natural predators, apart from people, have been eliminated on Zanzibar, most notably the Zanzibar Leopard (sometimes afforded the trinomial *Panthera pardus adersi*), but on the mainland Leopards may still take individuals. At Boni-Dodori, predators such as Lion *P. leo*, Leopard, Caracal *Caracal caracal*, African Wild Dog *Lycaon pictus* and Spotted Hyaena *Crocuta crocuta* all co-occur with Aders's Duiker (T. Wachter pers. comm.). A parasite taken from an animal in Zanzibar was described as *Tricholipeurus pakenhami* (Pakenham 1984).

Conservation IUCN Category: Critically Endangered A4cd. CITES: Not listed.

Aders's Duiker has undergone severe long-term population declines in both Kenya and Zanzibar (Tanzania) due to habitat loss and hunting pressure. In Zanzibar there has been a large amount of deforestation and forest degradation, particularly over the last 30 years, as the human population has increased. Much of the habitat loss has been driven by a demand for domestic fuelwood by a rapidly expanding urban population. This has led to extensive loss of habitat for Aders's Duikers but also severe habitat fragmentation. Habitat destruction is probably the most significant threat to the species' survival on Zanzibar, and one that is unlikely to be solvable in the short term. Jozani-Chwaka Bay N. P., which was gazetted in 2004, includes important but only small parts of suitable habitat for Aders's Duikers as does the proposed Kiwengwa-Pongwe F. R.

In Kenya, the Arabuko-Sokoke Forest is one of the last major remnants of lowland forests on the East African coast. Illegal wood-cutting has led to the deterioration of the species' habitat and contributed to the decline of the population. Kanga (2003b) reported that levels of wood-cutting increased between the surveys he carried out in 1998 and 2002. It is likely that habitat destruction will constitute the most difficult threat to address in terms of the species' future security in Arabuko-Sokoke (Kanga 2003b). The discovery, then, of a significant population of Aders's Duiker in the Boni-Dodori forest to the north improves the conservation prospect for the species, and highlights the need for improved management efforts in the Boni-Dodori forest (Andanje *et al.* 2011b).

Aders's Duikers are traditionally hunted in Zanzibar but an increase in hunting pressure likely followed the revolution of 1964 after which enforcement of the wildlife laws became largely non-existent (Finnie 2004). It would appear that, partly as a result of

hunting, the mini-antelope populations of Zanzibar (especially Aders's Duikers) have undergone long-term declines (for example, see Williams *et al.* 1995, Kanga & Mwinyi 1999). The Department of Forests and Non-Renewable Natural Resources began to address the hunting situation in Zanzibar in 1994, through community-based conservation initiatives. Although hunting has now come under an increasing level of control in Zanzibar (both at the village and governmental level) it remains a significant threat up to the present (Finnie 2002).

In the Arabuko-Sokoke Forest, trapping is common. In 1991, more than 2600 households lived within 2 km of the forest and at least 33% carried out hunting and/or trapping (FitzGibbon *et al.* 1995). It is thought that the high level of snare-trapping in the Arabuko-Sokoke Forest represents a significant threat to the continued existence of Aders's Duikers in this forest (Kanga 1995, 2002, Finnie 2004) as the species is a favoured target because of its sweet meat, which fetches a good price at market. Kanga (1995) stated that when hunters found an area where they suspected Aders's Duikers occurred, they would saturate the pathways with a large number of traps. Hunters told Kanga that Aders's Duikers were often caught in the 1970s, but that since the 1980s their hunting success with this species was low. However, Kanga's (1995) observations can be contrasted with FitzGibbon *et al.*'s (1995) assertion, without documentation, that trapping for duiker species in 1991 was well within sustainable limits. The impact of hunting on the Aders's Duiker population that may exist in the vicinity of the Boni-Dodori forests is unknown.

Measurements

Cephalophus adersi

HB (unsexed): 714 (630–780) mm, n = 14

T (unsexed): 111 (60–138) mm, n = 14

E (unsexed): 78 (75–87) mm, n = 14

Sh. ht (unsexed): 404 (375–440) mm, n = 14

WT (♂♂): 9.2 (8.7–10.2) kg, n = 9

WT (♀♀): 9.0 (6.8–10.1) kg, n = 5

Zanzibar (Kanga & Mwinyi 1999)

Wilson (2001) noted that Kanga & Mwinyi (1999) failed to indicate how their measurements were taken, and draws attention to the doubtful reliability of their measurements of the hindfoot (mean = 452 mm). Wilson (2001) gave the measurements of two adult ♂♂ as TL: 823–830 mm; T: 100–122 mm; E: 73–81 mm; HF c.u.: 195–214 mm; Sh. ht: 400–420 mm; and WT: 8.5–10.7 kg. Measurements for three ♀♀ were TL: 790–846 mm; T: 120–131 mm; E: 68–76 mm; HF c.u.: 210–225 mm; Sh. ht: 410–435 mm; and WT: 10.5–12.4 kg.

Maximum recorded horn length for this species would appear to be that of a ♂ captured in Jozani Forest in 1999, measuring 5.3 cm and reported by Kanga & Mwinyi (1999). The longest pair recorded by Wilson (2001) was 4.8 cm, on an adult ♂ killed by hunters and measured by the side of a road near Jozani Forest, which exceeds the 3.8 cm pair recorded by Rowland Ward from the Arabuko-Sokoke Forest

Andrew Williams

***Cephalophus rubidus* RWENZORI RED DUIKER**

Fr. Céphalophe de Rwenzori; Ger. Rwenzoriducker

Cephalophus rubidus Thomas, 1901. Proc. Zool. Soc. Lond. 1901 (2): 89. 'Ruwenzori District'.Rwenzori Red Duiker *Cephalophus rubidus*.Lateral view of skull of Rwenzori Red Duiker *Cephalophus rubidus*.

Taxonomy This species has been treated as a subspecies of *C. natalensis* (Schwarz 1914) and as a subspecies of the Black-fronted Duiker *C. nigrifrons* (St Leger 1936, Ansell 1972, Groves & Grubb 1981). Because this species occurs on the same Rwenzori mountain range as another race of the Black-fronted Duiker (*C. n. kivuensis*), yet differs from it in features that suggest other affinities, Kingdon (1982, 1997) regarded this as a distinct high-altitude red duiker, proposing that it might have been pushed up into its present sub-alpine and upper montane forest habitat by the later arrival of the Black-fronted Duiker. Molecular studies have also indicated that *C. rubidus* is a distinct taxon with relatively old and ill-defined affinities with other red duikers, although admittedly the only material available for the analysis was a single tooth from a specimen in the Swedish Museum of Natural History (Jansen van Vuuren & Robinson 2001), which may itself be misidentified. Wilson (2001) was reluctant to consider *rubidus* a distinct species, and Grubb & Groves (2001) and Grubb (2005) both considered it a subspecies of *C. nigrifrons*. Synonyms: none. Chromosome number: not known, but given their conserved karyotype it is likely to be $2n = 60$ (B. Jansen van Vuuren pers. comm.).

Description A medium-sized duiker with a glossy rufous coat with long coarse hair on the neck changing to dense soft hair over the hindquarters. Black or dark brown blaze on the forehead. Zone

*Cephalophus rubidus*

of dark grey underlies uniform red tips of fur down mid-line of the back and neck, while underfur of the flanks is cream. Chin and belly white. Hindlegs almost black, dark brown markings on the joints of the forelegs. Tail bushy. Pedal and preorbital glands present. The horns, present in both sexes, reach 8–9 cm in length (Kingdon 1982).

Geographic Variation Currently believed to be restricted to the upper reaches of the Rwenzori Mts, no significant variation is known or likely. However, sightings of very russet duikers from the bamboo zone of the Bwindi forest in SW Uganda suggest a distinctive duiker in a relictual habitat once similar to that in which *C. rubidus* occurs on the Rwenzori Mts.

Similar Species

Cephalophus nigrifrons. Long-legged and long-hooved species from montane and lowland forest habitats. Kingdon (1982) suggested that *C. rubidus* and *C. n. kivuensis* (which occurs in the lower altitudes of the Rwenzoris Mts) might hybridize where their ranges overlap.

Distribution Endemic to Africa, where confined to the Rwenzori Mts (Kingdon 1982, Grubb & Groves 2001). Although it presumably occurs on the section of the Rwenzori Mts that lies within Virunga N. P. in DR Congo, the presence of this form in this country has not been confirmed (East 1999, Wilson 2001).

Habitat Mostly found in alpine and sub-alpine habitats between the snow/glacier line and bamboo zones, at altitudes of 1300–

4200 m. They occur along the margins of *Carex* tussock bogs, in afroalpine moorland dominated by *Helichrysum*, *Alchemilla*, giant groundsels *Dendrosenecio* and giant lobelias *Lobelia* and in heath 'woodlands' dominated by tree heaths, *Philippia* and *Erica*.

Abundance Data are scarce, but daylight sightings and hunter's middens reported before the mid-1960s suggest that it was once very abundant in its preferred habitats. East (1999) suggested that the population of the Rwenzori Red Duiker may number at least in the thousands.

Adaptations Apparently able to tolerate very low temperatures at night and frequent cold rain or snow, as well as periodic strong insolation during the day. The peculiarly soft, dense texture of the pelage on the body of this species would seem to be adapted to these peculiar conditions, although no attempt has been made to assess the insulating or water-proofing properties of the hairs. Activity periods are likely to be strongly influenced by the very frequent rain on the Rwenzoris.

This species is of some significance for our understanding of mammalian adaptation to an extreme habitat, especially as such situations are rare in Africa. As the only large mammal to inhabit the high, cold and wet afroalpine vegetation zones of the Rwenzori Mts it offers unique opportunities for the study of physiology, dietary habits and behavioural repertoires in a ruminant that has several apparent equivalents in temperate Eurasia, North and South America (notably Goral *Naemorhedus goral*, Chamois *Rupicapra rupicapra*, Pudu *Pudella mephistophiles* and Musk Deer *Moschus moschiferus*). Molecular studies imply that this species is likely to derive from a population of duikers that preceded the evolution of the specialized Black-fronted Duiker (Jansen van Vuuren & Robinson 2001).

While the legs and hooves of this species appear to be less specialized in their proportions than those of the Black-fronted Duiker, it is likely that less obvious physiological adaptations could be significant.

Foraging and Food No direct information is available, but the absence of fruit and abundance of afroalpine herbs (especially *Alchemilla*) and lichens in the sub-alpine zone suggest that these are possible staples. Rock-cress *Arabis alpina*, violets *Viola* spp. and ground orchids *Disa* spp. are also common, but other flowering plants are few

and small in size. Around bogs, the sedge *Carex petitiiana* as well as the nettle *Laportea alatipes* might be eaten; a few high-altitude grasses, the heavy rain-exposed bark and roots of plants both large and small are all likely forage. Along the lower margins of its habitat the fruits of *Rubus* might be important and herbs such as goose-grass *Galium*, sorrels *Rumex* spp., wild parsley *Peucedanum* spp. and borage *Cynoglossum* spp. are very abundant and probable foods.

Social and Reproductive Behaviour Casual observations suggest that these duikers are generally solitary except when juveniles or subadults accompany their mothers or ♂♂ are accompanying an oestrous ♀.

Reproduction and Population Structure Nothing is known about the timing of breeding or any other aspect of reproduction in this species.

Predators, Parasites and Diseases Known predators include African Golden Cats *Profelis aurata* and probably Leopards *Panthera pardus*. Large, migratory eagles sometimes fly over the Rwenzori Mts, but are not likely to be any more than a rare hazard.

Conservation IUCN Category: Endangered B1ab(iii); C2a(ii) (listed as *C. nigrifrons rubidus*). CITES: Not listed.

A very vulnerable species owing to the ease with which it can be snared and the increase in illegal hunting within Rwenzori Mountains N. P., Uganda, the species' only known protected area stronghold. This species has long been a highly desirable quarry for Bakonjo hunters from the inhabited foothills. As noted earlier, the species presumably occurs on the section of the Rwenzori Mts that lies within Virunga N. P., but the presence of this form within DR Congo requires confirmation.

Measurements

No reliable measurements are available. Grubb & Groves (2001) gave mean GLS as 172 ± 4.2 mm ($n = 3$) for ♂♂ and 180 mm for a single ♀.

Jonathan Kingdon

Cephalophus leucogaster WHITE-BELLIED DUIKER

Fr. Céphalophe à ventre blanche (Céphalophe du Gabon); Ger. Weusbauch Ducker

Cephalophus leucogaster Gray, 1873. Ann. Mag. Nat. Hist., ser. 4, 12: 43. 'West Africa, Gaboon' (Gabon).White-bellied Duiker *Cephalophus leucogaster*.Lateral and dorsal views of skull of White-bellied Duiker *Cephalophus leucogaster*.

Taxonomy Type specimen named from an immature animal collected by Du Chaillu in Gabon. Rode (1943) mistakenly lumped *leucogaster* and *ogilbyi* as subspecies of the Bay Duiker *C. dorsalis*. Ansell (1972) included the form *arrhenii* as a subspecies of the Bay Duiker, but this form is actually attributable to *C. leucogaster* (Grubb & Groves 2001). Synonyms: *arrhenii*, *seke*. Chromosome number: not known, but likely $2n = 60$.

Description Pale, sandy-coloured 'red duiker' with a distinctive narrow black dorsal patch, broadest in the middle back. A sleek animal with short dense hair, and gracile build, this species is one of the more delicately built of the forest duikers. Sides of face pale rufous; forehead contains a strong admixture of black hairs, darkening toward the nose producing a distinctive dark frontal blaze. Back of ear pinnae rufous admixed with dark hairs on the outer surface, and variably fringed with light hair on the upper rim and black hairs toward the base of the rim. Inner surface of ear with black patch on lower third of the ear. Both sexes have a coronal tuft of upright, bright rufous hairs between the horns. The dark dorsal patch begins as a narrow dark streak at the base of the neck, intergraded with dark rusty hairs over the shoulders, widening into a nearly pure black, distinctively marked, dorsal patch, widest in the middle of the back, where it sharply contrasts with the pale sandy-coloured sides, narrowing again and ending in a point just above the tail. Neck and sides pale rufous, sprinkled with darker hairs dorsally, and white hairs ventrally. Chest, abdomen and inside of upper legs pale cream, becoming nearly pure white on the lower abdomen. Limbs pale rufous admixed with darker hairs on outer surface on front legs and shoulder. Rear hocks with indistinct black patches. Lower limbs, from metacarpals distally, black. Tail pale rufous-sandy colour at base and along upper surface, with large brush of long black hairs, many with the distal third white-tipped. Preorbital glands, producing a greyish exudate, are present in both sexes, and run from under the eye toward the muzzle. Inguinal glands and pedal glands present in both sexes. Inguinal secretions

are rusty-coloured and are visible on the white ventral surface of some animals. There is little sexual dimorphism: ♂♂ and ♀♀ have similar pelage, but adult ♀♀ average between 8% (Congo) and 11% (Ituri Forest, NE DR Congo) larger body mass than adult ♂♂ (see Measurements). Pelage of newborns differs from adults in being overall pale grey, with less distinctive dorsal patch. This pelage is replaced by adult colouring before weaning.

Cranium with broadened toothrow and palate, though the skull is not as robust or broad as in the Bay Duiker *C. dorsalis*. Horns present in both sexes, stout and strongly annulated at base, and variably over three-quarters of their length, turned inwardly at the tips in older ♂♂.

Geographic Variation

C. leucogaster leucogaster: range of the species, except NE DR Congo.

Colour darker and redder. Dorsal stripe narrow (e.g. between 21 and 84 mm on the Cameroon coast); slightly smaller in size.

C. leucogaster arrhenii (includes *seke*): NE DR Congo. Colour paler, browner. Dorsal stripe broader (in Ituri 80–156 mm wide); size slightly larger.

Similar Species

Cephalophus ogilbyi. The White-legged Duiker (*C. o. crusalbum*) is partially sympatric with White-bellied Duiker in W Gabon. Distinguished by its overall more russet colour and white patches on its legs.

C. dorsalis. Broadly sympatric in Gabon. Larger and overall darker in colour and with the dorsal band widest over the rump, not in the middle of the back.

C. callipygus. Sympatric in western central Africa. More rufous; dorsal patch widest over the rump.

C. weynsi. Sympatric east of the Ubangi R. Deeper rufous in colour and lacks the black dorsal patch.

Distribution Endemic to the central African lowland forest zone, and apparently restricted to forest below 1000 m. The White-

bellied Duiker ranges in the west from S Cameroon (south of the Sanaga R.), through Gabon, Equatorial Guinea, N and SW Congo (where the species is reported in the forest savanna complex along the Atlantic coast), and extreme SW Central African Republic (East 1999, Wilson 2001). The provenance of museum specimens north of the Sanaga R. remains uncertain (P. Grubb, in Lamarque *et al.* 1990, Grubb *et al.* 2003). The species is found again with certainty in NE DR Congo in the Ituri Forest, Maniema and North Kivu. It is uncertain if the species ever occurred north of the Mboumu R. into the forest blocks of SE Central African Republic (for example, East [1999] and Wilson [2001] both map its possible occurrence from Bangassou Forest, from whence there are no confirmed records). There are no records from Cabinda (Angola) (Crawford-Cabral & Veríssimo 2005), but it may occur, perhaps ranging into the Bas-Congo province in DR Congo.

The species' occurrence in DR Congo's central cuvette is also hypothetical (von Richter *et al.* 1990, Wilson 2001). Schouteden (1947) shows four records west of about 24°E along the Congo R., including two from locations on the left bank of the river, but it is uncertain if these specimens originated from these locations. A skin reportedly of this species has been reported from Salonga N. P., but no details are known, and the skin was apparently not examined; more recent surveys of animals taken by local hunters in the park failed to produce any evidence of the species (von Richter *et al.* 1990, Hart *et al.* 2008). There is no further evidence of the species' occurrence south of the Congo R.

The White-bellied Duiker is not known to range east of the lowland forest block bordering the Albertine Rift, although it was thought possible that it may exist in the Kayonza Forest, in W Uganda (Kingdon 1982). It may still occur in the forests west of the Semliki R. in DR Congo. The range of the White-bellied Duiker, with distinct western and eastern block populations, resembles that of another small forest ungulate, Bates's Pygmy Antelope *Neotragus batesi*.

Habitat The White-bellied Duiker is restricted to areas of extensive, intact closed tropical moist forest. It occurs in upland, terra firma, primary forest and older secondary forests. It is absent from areas of recent clearing and disturbance. The species does not occur in swamp forests and does not range into gallery forest or the forest–savanna ecotone north of the main forest block. Its characterization by Malbrant & Maclatchy (1949) as a common species of secondary forest and savanna ecotone and not of deep forest has not been supported by subsequent research. In the central Ituri Forest, radio-collared individuals frequented areas of open understorey, and tended to avoid dense stands of herbaceous thickets. In the Ituri Forest and the Nouabale–Ndoki area of N Congo this is one of the characteristic species in the monodominant *mbau/limbali* forests, a closed-canopy formation dominated by *Gilbertiodendron dewevrei*. Fruit and seed availability in monodominant forests is strongly seasonal with periods of very low availability juxtaposed by brief pulses of abundance during the supra-annual mast flowering and seed production by the dominant *G. dewevrei* (Hart 1985). In the Ituri Forest, where six species of frugivorous duikers, and the Water Chevrotain *Hyemoschus aquaticus* co-occur, population densities of all species except the White-bellied Duiker are lower in large monodominant stands than in the more productive, and seasonally less variable, mixed-canopy formations (Hart 1985, 2001). For White-bellied Duikers, the monodominant forest appears to represent a competitive refuge from the more densely occupied mixed-forest areas, where combined densities of all small ungulates can reach 45–50/km². In large monodominant stands, in contrast, total small ungulate densities are about half this value, and the White-bellied Duiker's nearest competitor, the similarly sized, diurnal Weyns's Duiker *Cephalophus weynsi*, is absent.

Abundance A little known species over much of its range, the White-bellied Duiker is reported as uncommon or rare in most areas where it occurs. Dubost (1984) reported the species comprising less than 11% of all individuals reported in hunter catches in E Gabon (Makokou area). Elsewhere in Gabon, the species is most frequently reported in Lopé N. P., but is uncommon and poorly known elsewhere (Blom *et al.* 1990). White-bellied Duikers were represented by only 2 of 198 skulls collected in SW Central African Republic (Wilson 2001). Colyn *et al.* (1987) report the species as the least common among duikers in surveys of the Kisangani bushmeat markets. The species appears to be more common in the Ituri Forest where densities of unhunted radio-collared populations averaged about 4.5/km² in mature mixed forest and about 6/km² in monodominant *Gilbertiodendron dewevrei* forest, contributing about 15% and 35% of the total small ungulate biomass in mixed and monodominant forest, respectively (Hart 2000, 2001). East (1999), assuming average population densities of 2.0/km² where it is known to be common/abundant and 0.2/km² elsewhere, estimated the total population at 287,000 individuals.

Adaptations The White-bellied Duiker is a diurnal species that occupies large home-ranges. The species has long legs, a gracile build and a broadened, but lightly built dental arch and palate. These adaptations are associated with a trophic niche specifically adapted to widely dispersed high-quality food patches. This specialization provides the White-bellied Duiker with a

relative advantage over more generalist duikers in monodominant forests where food resources can be uncommon and patchy, and are successfully exploited by the duiker that 'gets there first'. In the Ituri Forest, radio-collared adults ranged widely over annual home-ranges that averaged 63 ha in mixed forest and 58 ha in mbau forest. These home-ranges were comparable in area with those of the larger nocturnal Bay Duiker, and nearly twice the area of the similarly sized diurnal Weyns's Duiker. Radio-collared animals regularly patrolled widely dispersed, known fruit sources, and frequently accompanied troops of primates. While other duikers also feed beneath primates, White-bellied Duikers actively seek and follow moving troops to a much greater extent than other more sedentary duiker species. They feed not only on fallen fruit parts, but more remarkably are coprivorous, foraging selectively on primate faeces when these contain concentrations of nutrient-rich seeds, and in particular *Landolphia* spp. The relatively broad mouth and wide maw indicate that the species is capable of ingesting large-sized fruits. However, unlike the Bay Duiker, which has a still broader tooththrow, the dentition of the White-bellied Duiker is less robust, and lacks the developed cranial supports for expanded musculature to deal with coarse foods. It would seem that aggressive intra-specific conflict is sufficiently rare given the light build of the skull and lack of reinforced cranial boss. The wide ranging and wandering movements of the White-bellied Duiker would appear to obviate the need for armoured defences typical of some of its immediate competitors, such as Weyns's Duiker, which occupy smaller more intensively defended territories.

Foraging and Food The diet is dominated by fruits and seeds. Gautier-Hion *et al.* (1980) and Dubost (1984) recorded that fruit comprised almost three-quarters of stomach contents collected in Gabon. In captive feeding trials, White-bellied Duikers invariably selected fruits over foliage, even when these contained relatively higher levels of fibre (Molloy & Hart 2002). Hart (1985) found the White-bellied Duiker to be among the most dedicated frugivore of all the forest duikers in the Ituri Forest, with ripe fruits, unripe fruits and edible seeds comprising from 80% to 100% of rumen contents in all but the most extended periods of fruit and seed dearth. Seasonally dominant dietary items included seeds of *Landolphia* spp., and the unripe and still soft aborted fruits of *Kalinedoxa gabonensis* and *Irvingia grandifolia*. These relatively uncommon and ephemeral, but high-quality, foods were less frequently found in the diets of other duiker species. Like other duikers, White-bellied Duikers feed on caesalpinaceous mast when this is available. Fungi and fallen flowers picked up from the forest floor dominated diets during periods of low fruit availability. In common with other frugivorous duikers, the White-bellied Duiker disperses seeds of a number of species of forest trees (Feer 1995). These tree species have characteristically large, heavily armoured seeds, which duikers spit out undamaged when they ruminate. A number of these trees appear to be specialized for ungulate dispersal and the fruits are not regularly eaten by other frugivores. In the Ituri Forest, two of these species, *Donnella pruniformes* and another unidentified Sapotaceae, were characteristically eaten and seeds dispersed by White-bellied Duikers. Both tree species are uncommon, and produce large, soft, latex-rich fruits in small numbers over extended periods that are

optimally exploited by this species' wide-ranging, patrol-foraging strategy.

Social and Reproductive Behaviour Male and female home-ranges overlap, and pairs are perhaps drawn together by the noise made by the primates that both sexes seek to accompany. Nevertheless, sexes often range separately. Radio-collared juveniles often travelled in company with their mothers; however, both sexes disperse from maternal home-ranges at the onset of sexual maturity.

Reproduction and Population Structure A wide seasonal spread of birth and pregnancy records in the Ituri Forest implies that some breeding goes on throughout the year. Seven of nine estimated birth months occurred during the late rains (Aug–Nov), when fruits are seasonally most abundant, a pattern also found in some other duikers in Gabon (Dubost & Feer 1992). In the Ituri Forest, about 60% of 20 adult ♀♀ examined were pregnant. Gestation period has been estimated at six months (Dubost & Feer 1992). Females produce a single young. The weights of two full-term foetuses were 1300 and 1500 g.

Predators, Parasites and Diseases White-bellied Duikers are killed by Leopards *Panthera pardus* in the Ituri Forest (Hart, J. A. *et al.* 1996); however, the species is not among the most selected prey. Per capita annual predation of radio-collared White-bellied Duikers was lower than for nocturnal duikers, such as Bay Duikers and Yellow-backed Duikers *C. silvicultor* (Hart 2000). Serological surveys of duikers in the Ituri Forest revealed potentially significant exposure to bluetongue, epizootic haemorrhagic disease, infectious bovine rhinotracheitis and leptospirosis (Karesh *et al.* 1995). This study also recorded several ixodid tick species, including *Haemaphysalis parvula*, *Ixodes cumulatimpunctatus* and a *Rhipicephalus* sp.

Conservation IUCN Category: Least Concern. CITES: Not listed.

White-bellied Duikers appear to be rare or declining in many areas of their range. The species is extremely vulnerable to over-hunting and is one of the first species to drop out of the small ungulate fauna in areas subject to heavy snare pressure. Some populations may have become locally extinct in recent time with the advent of uncontrolled hunting and the bushmeat trade. In Ituri Forest, indigenous Mbuti hunters regularly catch White-bellied Duikers on net drives. Since the persistence of hunting is often determined by the frequency of capture of more abundant species such as the Blue Duiker *Philantomba monticola*, White-bellied Duikers could be hunted to local depletion or extirpation, even when already rare (Hart 2000). The species' wide-ranging movements over large home-ranges expose it to higher risk by snare capture than more sedentary species. Important protected areas for this species include Lopé N. P. (Gabon), Monte Alén N. P. (Equatorial Guinea), Dzanga-Ndoki N. P. (Central African Republic), Odzala N. P. and Nouabalé-Ndoki N. P. (Congo) and Kahuzi-Biega N. P., Maiko N. P. and Okapi Faunal Reserve (DR Congo) (East 1999). Management of the bushmeat trade in Okapi Faunal Reserve, a stronghold for White-bellied Duikers, would improve overall prospects for the species' conservation (Wilkie *et al.* 1998).

Key References Hart 1985, 2000, 2001; Wilson 2001.**John A. Hart*****Cephalophus natalensis* NATAL RED DUIKER**

Fr. Céphalophe du Natal; Ger. Natal-Rotducker

Cephalophus natalensis A. Smith, 1834. S. Afr. Quart. J. 2: 217. South Africa, KwaZulu–Natal, ‘Port Natal’ (Durban).Natal Red Duiker *Cephalophus natalensis*.Lateral view of skull of Natal Red Duiker *Cephalophus natalensis*.

Taxonomy In a revision of the duikers, Grubb & Groves (2001) included Harvey's Duiker *C. harveyi* as a single subspecies of the Natal Red Duiker *C. natalensis* (and see Jansen van Vuuren & Robinson 2001 and Hassanin *et al.* 2012). Ansell (1972) considered Harvey's Duiker *C. harveyi* and Weyns's Duiker *C. weynsi* as conspecific with *C. natalensis* and he offered a provisional list of 11 subspecies (including 'walkeri' from Malawi, which was actually a *Sylvicapra*; see Grubb 1988, 2005). Excluding these extralimital or mistaken forms, Ansell still retained four described subspecies of *C. natalensis* (as defined here). Following Swynnerton & Hayman (1951), Kingdon (1982, 1997) and East (1999), we provisionally treat *C. natalensis* and *C. harveyi* as separate species and recognize two subspecies within *C. natalensis* (following Meester *et al.* 1986). Synonyms: *amoenus*, *bradshawi*, *lebombo*, *robertsi*, *vasei*. Chromosome number: 2n = 60 (Robinson *et al.* 1996b).

Description A small duiker, often giving a first impression of being an all-over, uniform red. Although there is substantial regional and individual variation, the upperparts of the body are typically a deep chestnut-red, the lower part of the flanks and underparts pale chestnut, and there is a prominent crest of long, bushy, chestnut-coloured hair on the top of the head, which often conceals the horns. The sides of the muzzle, the sides and underparts of the neck, and the inner upper

surfaces of the limbs range from tawny or pale fawn to a rich red, only marginally lighter than the upperparts. The lower jaw behind the black or brown chin is always white and white or cream sometimes extends onto the upper throat. Ears short and rounded with a fringe of black hair on the outside margins; insides with three alternating black and white, rather 'smudged' markings. The back of the neck varies in colour with animals from the southern part of the range tending to uniform red while those in the north are more variable, sometimes having the entire nape light or dark grey. The pasterns and hind part of the hocks are also variable, sometimes red but more commonly darker in colour, with a tinge of dull violet or grey. The upperparts of the tail are the same colour as the back, darkening towards the whitish tip. Preorbital glands are present as a perceptible swelling below and in front of each eye. The gland exudes secretion along a streak of black skin that is studded with a row of small pores (Mainoya 1978); the secretion is a clear sticky fluid with a faint aromatic odour, the chemical constituents of which have been investigated by Burger *et al.* (1988). Interestingly, the preorbital gland secretions of the Natal Red Duiker and Common Duiker *Sylvicapra grimmia* contain two major constituents absent from the preorbital gland secretion of the Blue Duiker *Philantomba monticola*. Pedal glands are present, and discussed in detail by Mainoya (1978); there are no inguinal glands.

Horns, present in both sexes (those of ♂♂ twice the length of ♀♀), are short, straight, with coarse basal rings and longitudinal striations, but smooth towards the tips.

Geographic Variation

C. n. natalensis (including *amoenus*, *lebombo*): S and NE KwaZulu–Natal, E Mpumalanga and possibly S Mozambique. General description as above with strong erythrismic tendency.

C. n. robertsi (including *bradshawi*, *vasei*): Mozambique, north of the Limpopo R. northwards through S Malawi to SE Tanzania. Specimens

from Mozambique tend to be more orange/rufous in colour on the upperparts of the body than their counterparts from KwaZulu–Natal. In addition, the head is darker and there are slight traces of a dark frontal blaze, not present in animals from KwaZulu–Natal (Wilson 2001). Grey napes are also more common (J. Kingdon pers. comm.). Comparing specimens from lowland STanzania (south of the Rufiji R.) with specimens of *C. natalensis* from many other parts of their range, Swynnerton & Hayman (1951) had no hesitation in allocating them to *C. n. robertsi*.

Similar Species

Cephalophus harveyi. Larger red duiker ranging from N Malawi, NE Zambia, through suitable forested areas of C and NE Tanzania to SE Kenya and S Somalia. Legs dark grey to brownish-black; mid-facial zone blackish; crest with more black in it. Bolder, more strongly contrasting facial and ear patterns. For intermediate-looking animals along the interface between *C. natalensis* and *C. harveyi*, see discussion in next section.

Distribution Endemic to Africa. The Natal Red Duiker formerly occurred widely in coastal and riverine forests and thickets from SE Tanzania to NE KwaZulu–Natal. The species' distribution within this range is patchy and discontinuous and the clearing of forests and thickets to make way for agricultural development has destroyed much suitable habitat. Natal Red Duikers still occur locally in forest patches and coastal scrub in SE Tanzania, while in Mozambique they are still believed to occur widely in the eastern, coastal parts of the country, as well as in a few scattered localities inland; they are reported to occur at high densities in Maputo G. R. Their distribution range extends southwards through Mpumalanga and the Limpopo Province of South Africa (in the Soutpansberg), Swaziland, to KwaZulu–Natal, where they occur mainly in the north-eastern parts (East 1999, Wilson 2001, Skinner & Chimimba 2005). The southernmost limit of distribution has been given as extending as far

south as Pondoland (Bowland 1990) and even to George (Skead 1980); Rowe-Rowe (1994) shows the species occurring in small isolated populations along the coast south to about Oribi Gorge at about 31°S. Today they probably do not occur much further south than Durban. There are no confirmed records of this species from Zimbabwe (Smithers & Wilson 1979, Wilson 2001). East (1999) shows the species occurring in NE Zambia and N Malawi, but these records relate to Harvey's Duiker, the Natal Red Duiker being known only from S Malawi (Ansell 1978, Ansell & Dowsett 1988).

Red duikers from the area between the Ruvu and Rufiji valleys in E Tanzania approach *C. harveyi* in colouring and this area may represent a hybrid zone (Kingdon 1982). A similar hybrid frontier is implied by Wilson's (2001) observations on the Nyika Plateau in N Malawi where animals he observed looked like intermediates between *C. natalensis* and *C. harveyi*. The relationship between these very closely related duikers awaits a scientifically rigorous resolution.

Habitat Throughout their range, Natal Red Duikers are associated with forests and dense thickets, occurring in riverine forest and in thickly wooded ravines and dense coastal bush. In NE KwaZulu–Natal they occur up to about 200 m elevation (Rowe-Rowe 1994). They are independent of water; in KwaZulu–Natal, only one of the home-ranges of the duikers studied by Bowland (1990) had a perennial water supply.

Abundance The only reliable density estimates available for Natal Red Duikers are from KwaZulu–Natal, where Bowland (1990) recorded densities varying from 1 ind/0.5–1.0 ha in favourable habitat (such as at St Lucia) to 1 ind/2.5–5.0 ha in less favourable areas. East (1999) estimated the total population to stand at about 42,000, but noted this could be an underestimate. Rowe-Rowe (1994) gave the population size for KwaZulu–Natal as between 2000 and 3000 animals; the largest population in this province occurs in Greater St Lucia Wetland Park (1000). A substantial part of the range of this species occurs in Mozambique, where an overall recovery in wildlife populations is likely to include this duiker.

Adaptations Natal Red Duikers are diurnal, with peaks in activity at dawn and dusk, and little evidence of nocturnal activity (Bowland 1990, Wilson 2001), a pattern that is confirmed by the frequency of their bones in the debris below nests of the diurnal Crowned Eagle *Stephanoaetus coronatus* in STanzania (J. Kingdon pers. comm.). They are shy and secretive, and if disturbed seldom stand for more than a few seconds before bounding away into thick bush, often emitting a hoarse alarm 'whistle'. They are said to display a remarkable jumping ability; De Vos (1979) reported an instance of two adults clearing a 1.6 m high fence.

Metabolic rates are high, and energy requirements are met by utilizing easily digestible and fermentable plant parts while less digestible parts (lignin, cellulose) are poorly digested due to the fast digesta passage rates (Faurie & Perrin 1995, Perrin *et al.* 2003). The rumen has been described as similar to that of the Blue Duiker, displaying many adaptations typical of concentrate selectors, including a densely, evenly papillated rumen for maximum nutrient absorption (Faurie & Perrin 1995). High rates of food intake, frequent rumination and rapid fermentation ensure efficient supply of energy and nutrients (Perrin *et al.* 2003).

Cephalophus natalensis

Foraging and Food Natal Red Duikers are browsers and frugivores, feeding primarily on leaves (fresh and fallen), wild fruits and flowers, and shoots of low-growing shrubs. An analysis of the contents of 19 stomachs from KwaZulu–Natal found that dicotyledonous leaves had a relative occurrence of 66%, seeds and fruits 25% and flowers 1% (Faurie & Perrin 1993, Bowland & Perrin 1998). Although Gagnon & Chew (2000) reported a very small percentage (1%) of monocotyledons in the diet (and see Sponheimer *et al.* 2003b), Prins *et al.* (2006) recorded between 15% and 20% of monocots in the diet.

Bowland (1990) directly observed Natal Red Duikers eating the freshly fallen leaves of *Cussonia sphaerocephala*, *Strychnos spinosa*, *Celtis africana*, *Ficus stuhlmanii*, *Sapium integerrimum*, *Harpephyllum caffrum*, *Barringtonia racemosa*, *Apodytes dimidiata*, *Acacia robusta* and *Ziziphus mucronata*. Heinichen (1972) recorded them feeding on *Dichrostachys cinerea*, *Strychnos madagascariensis*, *Gardenia cornuta*, *Azima tetracantha*, *Asparagus falcatus* and *Justicia protracta*. Other species recorded from the examination of stomach contents include *Justicia* sp., *Commelina africana* and *Grewia* sp. (Heinichen 1972). Elevated water and protein content of leaves influence the food choice of Natal Red Duikers, but there is no evidence that condensed tannin concentrations influence leaf choice, since some highly preferred species have tannin concentrations exceeding 18% while other rejected leaves have concentrations of less than 2% (Faurie & Perrin 1993, Bowland & Perrin 1998, Perrin *et al.* 2003). Wilson (2001), after Bowland (1990), provides a detailed list of dietary items in the diet of Natal Red Duikers recorded in southern Africa.

Prins *et al.* (2006) investigated niche segregation among three small antelopes – Natal Red Duikers, Common Duikers and Sunis *Nesotragus moschatus* – in a coastal savanna woodland/forest mosaic in S Mozambique to determine whether they exhibited any obvious differences in diet to avoid competition. Some 80 dietary items were recorded being used by Natal Red Duikers. On average, only about 10% of the food items used by all three small bovids were specific to one species only. Diet overlap was considerable in the wet season, but the use of exclusive species was significantly larger in the dry season, and significantly larger for the Natal Red Duikers (Prins *et al.* 2006). Likewise, Blue and Natal Red Duikers are sympatric in many localities, with home-ranges of the two species often overlapping. Both generally have similar diets, and they exhibit no temporal separation since both are diurnal, with only subtle differences in spatial utilization (e.g. Natal Red Duikers sometimes forage beyond the forest margin) (Perrin *et al.* 2003).

Social and Reproductive Behaviour Natal Red Duikers are primarily solitary, although it is not uncommon to encounter a ♀ with her offspring, or pairs or small groups of three to five (♂♂ sometimes form temporary associations in the absence of a ♀). Home-ranges usually cover an area of 2–15 ha in size, and decrease in size with an increase in population density and availability of food resources. Communal dung heaps are used to demarcate the boundaries. The secretion from the preorbital glands is also dabbed onto stems and branches as a means of marking the home-range. However, there is no evidence of territoriality (as in Blue Duikers) and home-ranges may overlap by as much as 80–100%; there was also extensive overlapping of core areas of home-ranges (Bowland 1990, Bowland & Perrin 1995).

Vocalizations include an alarm whistle, and a loud ‘tchie-tchie’ sound, which is louder and more penetrating than that of the Suni (Heinichen 1972). Natal Red Duikers are known to ‘thump’ or ‘alarm stamp’ prior to fleeing.

Natal Red Duikers have been recorded in association with Vervet Monkeys *Chlorocebus pygerythrus*; the monkeys were seen actively grooming a duiker, which itself solicited grooming on several occasions (Borland & Borland 1979).

Reproduction and Population Structure Breeding occurs throughout the year, and three-month-old lambs have been observed in Feb, Jul and Aug (A. E. Bowland pers. obs.); in captivity, young are also born throughout the year, with no discernible peak (Spence 2003). A single young is born; captive animals had an average mass at birth of 979 g ($n = 2$) and an inter-birth interval of 236 days (range 222–273, $n = 5$; Spence 1991). Gestation period is in the order of 7 months. Bowland, in Rowe-Rowe (1994), gives age at first conception at 18–24 months, but a captive ♀ conceived when just under a year old (Spence 1991). Bowland (in Rowe-Rowe 1994) gives a potential life-span of 8–9 years; Weigl (2005) gives a longevity record in captivity of 15 years.

Predators, Parasites and Diseases Natal Red Duikers, in particular infants or juveniles, are likely to fall prey to a number of medium to large carnivore species (e.g. Roche 2003), as well as birds of prey (such as the Crowned Eagle; Wilson 2001) and African Rock Pythons *Python sebae*. Very little was known of the helminth parasites of Natal Red Duikers until the studies of Boomker and co-workers in KwaZulu–Natal (Boomker *et al.* 1984, 1991d). The latter authors summarized what was known at the time, listing 17 species of nematodes, two species of cestodes (*Moniezia benedeni* and *Stilesia hepatica*) and trematodes (paramphistomes). Ectoparasites in Natal Red Duikers have been investigated by various authors, primarily in KwaZulu–Natal; Horak *et al.* (1991a) examined 20 duikers from two reserves in NE KwaZulu–Natal and recorded the following ixodid ticks: *Amblyomma marmoreum*, *Haemaphysalis leachi*, *H. parvata*, *Rhipicephalus appendiculatus*, *R. maculatus*, *R. muehlensi* and *R. evertsi*. In addition, they recovered two species of lice (*Damalina* sp. and *Linognathus* sp.).

Conservation IUCN Category: Least Concern. CITES: Not listed.

Natal Red Duikers have disappeared from large parts of their former range, largely as a result of the loss of suitable habitat in the face of expanding human settlement and agriculture, combined with the impacts of hunting. None the less, despite what is likely to be a gradual population decline across much of their range, they are not likely to be threatened as a species, and remain well represented by healthy populations in a number of protected areas, such as Selous G. R. (Tanzania), South Vipya F. R. (Malawi), Maputo G. R. (Mozambique) and Greater St Lucia Wetland Park, Hluhluwe–iMfolozi and Ndumo G. R. (South Africa) (East 1999).

Michael Hoffmann & Anthony E. Bowland

Cephalophus harveyi HARVEY'S DUIKER

Fr. Céphalophe de Harvey; Ger. Harveyducker

Cephalophus harveyi (Thomas, 1893). Ann. Mag. Nat. Hist., ser. 6, 11: 48. Kahe Forest, Moshi District, Tanzania.

Harvey's Duiker *Cephalophus harveyi*.

Thomas named the species for Sir Robert G. Harvey, a member of the hunting party which took the type specimen.

Taxonomy Treated as a subspecies of Natal Red Duiker *C. natalensis* by some authors (Heyden 1968, Ansell 1972, Groves & Grubb 1981, Grubb & Groves 2001, Wilson 2001, Grubb 2005; and see Jansen van Vuuren & Robinson 2001 and Hassanin *et al.* 2012), Kingdon (1982) considered that subsuming this very distinctive population in *C. natalensis* risked obscuring the complex evolutionary history of red duikers. None the less, likely hybrids between *C. harveyi* and *C. natalensis* are known from some of the lowland areas where their ranges appear to overlap (Kingdon 1982). Wilson (2001) considers animals from N Malawi on the Nyika Plateau as intermediate between Harvey's Duiker and the

Natal Red Duiker, commenting that the red duikers he saw in Selous G. R. were very similar to these duikers. Synonyms: *bottegoidi*, *keniae*. Chromosome number: not known, but likely to be $2n = 60$ as in *C. natalensis* (B. Jansen van Vuuren pers. comm.).

Description A richly russet-red duiker with the red of the rump and back becoming lighter below. The dorsal portion of the head shows a very distinct black band that covers the bridge of the nose and becomes wider above the eyes. The centre of the crest is also black and this line is continued down the back of the neck where it gives way to a dark freckle. In southern parts of its range this melanistic tendency extends to the dorsal portion of the neck, shoulders and, in the same area, the legs can be entirely dark sepia brown. Hundreds of camera-trapping photographs of Harvey's Duikers from several sites in the Udzungwa Mts show that there is large variation in the extent of these dark portions of the pelage between individuals within the same area (Rovero *et al.* 2005, F. Rovero pers. obs.). By contrast, animals from Mt Kenya tend to be more consistently red. As with the Natal Red Duiker, preorbital glands are embedded in a large swelling below and in front of each eye, the external expression of which comprises a black streak of skin studded with a row of small pores (Mainoya 1978). Pedal glands are present, and discussed in detail by Mainoya (1978); there are no inguinal glands.

Geographic Variation Populations in the northern part of their range (Kenya and N Tanzania) differ from those in SC Tanzania, but the boundaries or clinal areas between them remain to be elucidated. It may eventually be possible to characterize these two populations as subspecies. Three names have been applied to this duiker: *harveyi* from Kilimanjaro, *keniae* from Mt Kenya and *bottegoidi* from lowland coastal forest on the extreme northern edge of its range. These names should be treated as synonyms until their taxonomic status has been assessed.

Lateral view of skull of Harvey's Duiker *Cephalophus harveyi*.

Similar Species

- Cephalophus nigrifrons*. Lowland forest block and montane isolates on Mt Kenya, Mt Elgon and the Aberdares. Long-legged, long-hooved species with dark, finely freckled pelage.
- C. natalensis*. A primarily southern African duiker, reaching its northerly limit in the Rufiji Valley, STanzania. Smaller; legs slightly grey or not at all; facial mid-line in front of eyes darker.
- C. weynsi*. Mainly found in central Africa and Uganda extending as far as the Mau forest in Kenya. A larger species with longer, more arched muzzle and duller orange-red colouring. Kingdon (1982) suggested some red duikers from the Mau massif in Kenya might be hybrids between Weyns's Duiker and Harvey's Duiker.
- C. adersi*. Restricted to Zanzibar and the East African coast (notably the Arabuko-Sokoke Forest and Boni-Dodori forests, but also, perhaps, other East African isolated coastal forest pockets). Smaller, with white underbelly, white freckling on the lower limbs, and a broad white band on the rump.

Distribution Endemic to Africa. Patchily distributed through various forest types in the moister eastern parts of C and SE Kenya and NE and C Tanzania and, marginally, in extreme S Somalia (including, formerly, the lower Shebelle and Juba Rivers where now probably extinct) and N Malawi (Wilson 2001). There is a single record of this species from the Zambian side of the Nyika Plateau (Ansell 1978; mapped by East [1999] as *C. natalensis*).

Red duikers seen in the Hareenna Forest on the Bale massif (Hillman 1988a, Yalden *et al.* 1996) and another population in Omo N. P. in SE Ethiopia (Schloeder & Jacobs 1996) probably represent this species (East 1999), although the Omo duikers could be Weyns's Duiker *C. weynsi*, which occurs in the Imatong Mts of S Sudan, some 400 km to the south-west of Omo (East 1999, Wilson 2001; and see Grubb *et al.* 2003).

Habitat Found in both moist coastal forests and riverine gallery forests in the eastern parts of its range. It ascends into montane forests on Mt Kenya, the Aberdares and the Eastern Arc Mts in Kenya and Tanzania (see below). There it is found in both drier and moister forest types but predominantly in the vicinity of permanent water. In the Udzungwa Mts, Tanzania, it has been recorded in miombo woodland at 400 m; in dry, *Commiphora*-dominated bush at 1400 m; also up to about 2200 m in mixed upper montane forest and bamboo thickets (F. Rovero pers. obs.) and may well range to the highest forested slopes of Mt Luhomero to about 2400 m. It has also been reported as widespread in the highest Forest Reserves of the Uluguru Mts, which range to over 2400 m (Doggart *et al.* 2004).

Abundance Data scarce, but observations suggest that the species may be more abundant on the moister eastern or windward sides of

Cephalophus harveyi

massifs and scarcer on the drier western rain-shadow sides. Assuming an average population density of 2.0/km² in favourable areas and 0.2 in other parts of its range, East (1999) estimated a total population of 20,000 individuals, but notes that this could be an underestimate. A sharply downward trend in the overall population is evident in the rapid clearance and human settlement of its preferred riverine habitat.

Extensive camera-trapping and line transect censuses conducted in the Udzungwa Mts indicated high variation in the density of Harvey's Duikers even within relatively close and similar forest sites, presumably related to a combination of past and current hunting pressure and habitat features. Highest densities of about 13.3/km² were recorded in Matundu Forest in ground-water semi-deciduous forest at 300–500 m within Udzungwa Mountains N. P. However, in areas of the same forest where hunting had occurred, the density decreased to 8.2/km², and in the highly disturbed Uzungwa Scarp forest density dropped to about 2.1/km² (Rovero & Marshall 2009). Similarly, in Mwanihana Forest, at an altitude of 300–1000 m, the density resulted in the range of 4.8–9.5 ind/km² for moderately disturbed and undisturbed forests within the National Park (Rovero & Marshall 2009). These results confirm that East's (1999) average density estimations for favourable areas might be underestimates and that more data are required before a sound, overall estimation can be attempted.

Adaptations Contemporary molecular studies suggest that the closest relatives of the *harveyi*/*natalensis* group are the swamp-forest adapted Black-fronted Duiker *C. nigrifrons* and woodland adapted Red-flanked Duiker *C. rufilatus* (Jansen van Vuuren & Robinson 2001). Since both the latter species have moved into habitats that are atypical of other duikers, the very generalized Harvey's Duiker could be a passable model for their common ancestral type.

Until very recently Harvey's Duikers were abundant in the montane forests of East Africa and neighbouring coastal areas. This abundance and the absence of a clearly defined habitat preference confirms that this species fills the niche of medium-sized frugivorous antelope within

Cephalophus harveyi

Cephalophus harveyi

Cephalophus harveyi

Cephalophus harveyi

Cephalophus harveyi

the bushes *Acokanthera frisorum* and *Warburgia ugandensis* are also eaten. *Parinari excelsa* is dominant in some montane areas and *Ficus*, *Cordia* and *Lannea* spp. are widespread; all are known foods. Within its range the following are known sources of fruit and/or leaves: *Annona senegalensis*, *Anthocleista grandiflora*, *Tabernaemontana pachysiphon* and species of the genera *Bridelia*, *Canthium*, *Coccinia*, *Diospyros*, *Euclea*, *Grewia*, *Mammea*, *Parkia*, *Poliscias*, *Rhus*, *Sapium*, *Strychnos*, *Trema* and *Uapaca* (Kingdon 1982, T. Jones & F. Rovero unpubl.).

Digestion in the forestomachs has not yet been investigated. However, the strict preference for dicotyledonous leaves and fruits likely results in a high rate of volatile fatty acid production in the rumen. This is indicated by anatomical features such as a dense papillation of the mucosa to enhance absorption and inconspicuous thin rumen pillars (Hofmann 1973) resulting in a short rumen retention time, and a paucity of rumen protozoa (Hoppe *et al.* 1981). This contrasts with a surprisingly large capacity of the rumen, which is atypical for dicotyledon selectors and more typical of grass-eating antelopes.

Harvey's Duiker is primarily diurnal. In the Udzungwa Mts, activity pattern of this species, as indicated by camera-trapping times, resulted in 98% of more than 350 photographs being taken between 07:00h and 20:00h. Activity peaked between 07:00h and 10:00h and between 15:00h and 18:00h, and decreased significantly between 12:00h and 15:00h (F. Rovero pers. obs.).

Social and Reproductive Behaviour Little is known, but the species resembles other red duikers in being mostly solitary, although Wilson (2001) observed three adult male red duikers (here considered to be Harvey's) together on the Nyika Plateau; in the same region, he recorded an adult Gentle Monkey *Cercopithecus mitis* grooming a female duiker. The solitary habit of this duiker has been confirmed from both direct observations and camera-trapping in the Udzungwa Mts, with only occasional (fewer than 10%) observations and photographs of pairs (T. Jones & F. Rovero unpubl.). Harvey's Duikers have often been seen foraging below trees occupied by colobus monkeys and moving in association with the predominantly ground-foraging Sanje Mangabey *Cercocebus sanjei*; they are also groomed by this mangabey species (T. Jones & F. Rovero unpubl.). Other than facilitating access to food resources (i.e. fruits dropped by the monkeys), this behaviour must also increase anti-predator vigilance.

As with some other red duikers, Harvey's Duiker utters a shrill, fluty whistle when disturbed. If these animals live in a mosaic of territories (whether exclusive or overlapping), as is supposed, the most likely function of such calls is to inform conspecific neighbours as to the whistler's movements as well as alert them to disturbance. It is not known how much information these whistles might contain about the identity of the caller or the nature of the disturbance.

Reproduction and Population Structure Wilson (2001) recorded newborns on the Nyika Plateau in Dec, Mar, Aug and Feb. There is no other published information.

Predators, Parasites and Diseases Known predators include Leopards *Panthera pardus*, notably in the Udzungwa Mts (Rovero *et al.* 2005). Predation by Crowned Eagles *Stephanoaetus coronatus* has been recorded in the Udzungwa Mts (F. Rovero & A. Bowkett unpubl.); other potential predators are Lions *Panthera leo* and Spotted Hyenas *Crocuta crocuta*. Round (1968) documented cestodes from the genera

Moniezia and *Cysticercus* and a nematode (*Setaria* sp.) from Harvey's Duiker. Hoppe *et al.* (1981) recorded a number of species of the protist *Entodinium*.

Conservation IUCN Category: Least Concern. CITES: Not listed.

Harvey's Duikers are declining due to hunting and destruction of habitat. East (1999) notes that this species is heavily hunted throughout its Tanzanian and Kenyan range, where animals are hunted with dogs in several areas; wire snares are probably the largest cause of mortality through most of its range. The species has lost most of its habitat in Somalia along the lower Shebelle and Juba Rivers. Clear evidence of decreased abundance related to habitat degradation and hunting resulted from comparison of line-transect and camera-trapping data across contrasting sites in the Udzungwa Mts (Rovero & Marshall 2004, F. Rovero pers. obs.).

Important protected areas with known populations of Harvey's Duikers include Aberdare N. P., Mt Kenya F. R., Arubuko-Sokoke, Boni, Dodori, Tana River and Shimba Hills National Reserves (Kenya), Bush Bush N. P. (Somalia), Bale Mountain N. P. (Ethiopia) and Mikumi, Udzungwa, Kilimanjaro, Lake Manyara and Arusha National Parks (Tanzania) (East 1999, Wilson 2001).

Cephalophus rufilatus RED-FLANKED DUIKER

Fr. Cephalophe à flancs roux; Ger. Rotflankenducker

Cephalophus rufilatus Gray, 1846. Ann. Mag. Nat. Hist., ser. 1, 18: 166. 'Sierra Leone, Village of Waterloo'.Red-flanked Duiker *Cephalophus rufilatus*.Dorsal and lateral views of skull of Red-flanked Duiker *Cephalophus rufilatus*.

Taxonomy In the nineteenth century, several taxonomists confused this species with *Sylvicapra grimmia coronatus* (Sclater & Thomas 1899). A densely haired neck and coarse coat ally this species with other coarse-haired red duikers. Jansen van Vuuren & Robinson (2001), using mtDNA, found a consistently close relationship with the Black-fronted Duiker *Cephalophus nigrifrons*, in spite of very different proportions, morphology and habitat (and see Hassanin *et al.* 2012). They found a slightly more distant relationship with the Natal Red Duiker *C. natalensis*, which has similar proportions and dimensions, and the larger Harvey's Duiker *C. harveyi*. Two subspecies are usually recognized (St Leger 1936, Ansell 1972, Kingdon 1997), with the Chari R. thought to mark the boundary between them. Grubb & Groves (2001), who did not list subspecies, noted that two types of colouring are found at the extremities of its range: pale ochraceous with dorsal stripe sharply marked in the west, and darker, redder, with dorsal stripe more diffuse towards the eastern end of its range, and that skins from intervening areas show intermediate colouring. Size also varies rather sporadically. Synonyms: *cuvieri*, *rubidior*. Chromosome number: $2n = 60$; the X chromosome is a metacentric (Hard 1969).

Description A prettily coloured, relatively short-legged duiker with bright orange-red on the face, neck and flanks, dark brown or grey limbs and similarly coloured dorsal 'patch'. It belongs to the coarse-haired duiker group and its pelage, notably on the neck and throat, resembles that of the Black-fronted Duiker. The shiny black nose is broad and prominent. A dark line down the mid-line of the face is subject to much individual variation in breadth and colour. Likewise, the length and thickness of hair growing vertically from the crown varies individually, but is mostly black in colour. Underside of chin white, posterior surface of ear black, anterior surface lined with short white hairs except for black band close to lower margin. Underside light reddish. Tail with black tuft and its very frequent movements are always from side to side. Long, narrow pedal glands present on both fore- and hindfeet. Inguinal glands absent. Preorbital glands well developed in both sexes. Rostrum is long and narrow, and the frontals are evenly convex as far forward as the proximal nasals, as far back as bases of horns, which are raised up (Grubb & Groves 2001).

Geographic Variation

C. r. rufilatus: Senegal to Chari and Benue Valleys. Back and legs light grey.

C. r. rubidior: Chari R. to Nile Valley. Back and legs dark grey.

Similar Species

Cephalophus nigrifrons. Niger R. to East Africa. A larger, long-legged, long-hooved swamp-forest and mountain dwelling red duiker.

Philantomba maxwelli. Senegal to Cross R. A smaller, forest-dwelling duiker of overall dull brown colour.

P. monticola. Cross R. to East and south-eastern Africa. A smaller, forest-dwelling duiker of overall grey-brown colour.

Distribution Endemic to Africa, ranging from S Senegal, Gambia and Guinea-Bissau through to the Nile Valley in SW Sudan in forest-savanna mosaics north of the main forest block (East 1999, Wilson 2001). Formerly widespread in NW Uganda, as far east as the Albert Nile (Kingdon 1988, East 1999); a small relic population was discovered on the eastern side of the Nile in Bugungu G. R., immediately south of Murchison Falls N. P. (Allan 1996). The boundaries of its range are poorly defined and the species has been recorded in the southernmost regions of several 'Saharan' States (SW Mali, SW Niger and extreme S Chad). Not recorded from Liberia. Dowsett (1993) rejected all records from Gabon and Congo, though Grubb *et al.* (2003) remark that a supposed record of this species from the coastal lowlands of SE Gabon deserves further investigation.

Habitat A diurnal species finding refuge in forest edge, forest relics and riverine thickets, but also commonly emerging into open savanna and woodland. Heringa (1990) reported a distinct preference for riverine woodlands and thick vegetation close to permanent sources of water such as springs within rocky areas. In Nigeria it prefers places with rocky outcrops and forest outliers, even dry valleys within savanna, riparian or forest areas but never in high forest (Agbelusi 1992). In Mole N. P., Ghana, this duiker was

*Cephalophus rufilatus*

found in open savanna woodland in which tree cover averaged 30% (range 5–65%); the main trees were *Burkea africana* and *Terminalia avicennoides* together with other typical woodland trees such as *Gardenia*, *Lannea*, *Pterocarpus*, *Piliostigma*, *Grewia* and *Isoberlinia* spp. (Schmitt & Adu-Nsiah 1993). Wilson (2001) found them to be abundant in open savanna in Central African Republic in a region where there were tens of thousands of small termite mounds. In some regions the replacement of primary forest with farm bush and other secondary vegetation has enabled this species to expand its range (East 1999).

Abundance Data are scarce, but the species is generally widespread over most of its range. Estimates of density vary: Wilson (2001) recorded densities of 3–4/km² in prime habitat in Mole N. P., while Fischer & Linsenmair (2001a) estimated densities of 0.45/km² in 1995 in Comoé N. P., Côte d'Ivoire (though these declined to 0.14/km² in 1998). Heringa *et al.* (1990) estimated densities of less than 0.1/km² from ground surveys in Burkina Faso. This was the second most commonly observed antelope in the National Park of Upper Niger in Guinea, with a density of 2.6/km², although it had none the less declined by 50% since a previous census in 1997 (Brugière *et al.* 2005). East (1999) estimated total population numbers at 170,000.

Adaptations The Red-flanked Duiker is unusual in being an inhabitant of relatively open woodlands and savannas, degraded forests and riverine wooded environments. In this adaptation to drier, more exposed environments the Red-flanked Duiker has followed a similar evolutionary trajectory to the Common Duiker *Sylvicapra grimmia*. However, this adaptation has involved much less departure from the general red duiker morphotype. Molecular studies confirm that the Red-flanked Duiker (and its genetic sibling, the Black-fronted Duiker *C. nigrifrons*) diverged very much later than the bush duiker, which split away from other species quite early in the duiker radiation (Jansen van Vuuren & Robinson 2001).

The discovery of genetic affinity between the less specialized Red-flanked Duiker and swamp-adapted Black-fronted Duiker offers special opportunities for the study of evolutionary history and adaptive radiation in duikers. One question concerns habitat. The Black-fronted Duiker has long legs and elongated, splayed hooves that parallel those of another swamp-dwelling antelope, the Sitatunga *Tragelaphus spekii*. Distribution patterns for both species suggest that their ancestral populations originally adapted to swamp forests bordering lakes and rivers running immediately north of the Equator (Kingdon 1982). As the Red-flanked Duiker is distributed along the furthestmost northern tributaries of the same system both *rufilatus* and *nigrifrons* can be viewed schematically as 'outliers' that have been displaced onto the northern and southern margins of an ancestral range. In this construction their common ancestor was likely to have inhabited a long east–west forest belt running north of the Equator. This is a zone that currently supports a considerable diversity of duikers, all of which are ecologically partitioned by size, food and habitat type (Gautier-Hion *et al.* 1980, Kingdon 1982). Within this partitioned community, the Black-fronted Duiker has departed furthest from the generalized duiker type, whereas the Red-flanked Duiker has not. Instead, the latter's distribution implies a sort of evolutionary 'displacement' out onto the northern margins of duiker habitats with minimal external change to show for it. None the less, both species are likely to possess inconspicuous but substantial physiological adaptations and among these is an observed difference in scent glands. The Red-flanked Duiker is without glands in the groin, whereas the Black-fronted Duiker has developed large, deep inguinal glands.

Understanding this divergence has the potential of throwing light on the overall functions of scent glands in antelope biology, a topic that is still deeply problematic. Antelopes belonging to several lineages have developed inguinal glands and the emission of their secretions is unequivocally directed at conspecifics where they augment other olfactory signals. Unlike facial, pedal and excretory scents, where animals betray a direct interest in the scent and may deliberately mark places or other animals, inguinal glands are generally cryptic in expression. Exactly what purposes these glands serve is uncertain, but they are known to signify excitement and presumably assist conspecifics to identify sex, age and condition and then track the individual. Although pedal glands are best suited to the last task, constant switching of the tail might help disperse inguinal scent along trails. It is resting places or 'forms' (possibly urine puddles too) that must be the main scent-depositories. When a previously glandless lineage develops such glands there is the distinct implication of a change in social structure or a heightened need for intra-specific contacts. The principal external cost of developing such very odoriferous scents is facilitating predators that track their prey by scent: a selective agency that is greatly reduced in densely obstructed, boggy habitats.

In lacking inguinal glands, the Red-flanked Duiker resembles a majority of duiker species and it is likely that this is the original condition for these predominantly solitary animals. A careful and detailed comparison of Red-flanked Duiker social behaviour with that of Black-fronted Duikers might reveal currently unknown aspects of social behaviour in the latter. In any event, there is much still to be learned about communication and the evolution of social structures in duikers and antelopes in general. The preorbital glands are wiped on a wide variety of sites, vegetable and mineral, including termite mounds (Wilson 2001). The same site is often wiped with both sides of the face.

Foraging and Food Red-flanked Duikers feed on the fruit, flowers and foliage of numerous trees, shrubs and herbs. Some of their foods consist of large cumbersome fruits, others are little more than berries or seeds and every size of fruit in between. In Bangangai, Sudan, on the outermost borders of its range, Hillman (1982) noted fallen fruits, flowers, dry leaves, root tubers and the meat of dead animals. In the Toumodi area, Côte d'Ivoire, stomachs ($n = 15$) of duikers killed in and around forest-cleared farms contained the fruits of 21 different plants that were typical of the forest/savanna mosaic, with preference given to *Phoenix reclinata*, *Nauclea latifolia* and *Ficus capensis*, although other species consumed included *Combretum racemosum*, *Griffonia simplicifolia*, *Alchornea cordifolia*, *Phyllanthus discoideus*, *Anthocleista djalensis*, *Carapa procera*, *Antiaris africana*, *Ficus mucosa*, *Macuna pruriens*, *Canthium vulgare*, *Blighia sapida*, *Malacantha alnifolia* and *Solanum* spp. They also contained cultivated plants such as mangoes, cassava, cocoa and pawpaw as well as raphia and oil palm dates (Hofmann & Roth 2003).

In Mole N. P., these duikers have been recorded feeding on the figs of eight species of *Ficus* as well as fallen fruit of large trees, in particular *Uvaria chamae*, *Xylopia parviflora*, *Elaeis quineensis*, *Nauclea latifolia*, *Pavetta crassipes* and *Anthocleista vogelii* (Wilson 2001). In Nigeria, this duiker was found to mainly browse the leaves of shrubs, such as *Piliostigma thonningii*, *Pterocarpus erinaceus*, *Annoa senegalensis*, *Grewia arborea*, *Landolphia oweriensis*, and *Vitex domiana* (Agbelusi 1992). Such flexibility in diet suggests an ability to survive fruitless periods or areas with few fruits by switching to browse and may help explain why this species thrives outside true forest.

Red-flanked Duikers commonly rise onto their hindlegs to reach plant parts above their heads. They pay close attention to monkeys and exploit dropped waste beneath the primates' food trees (Wilson 2001).

Social and Reproductive Behaviour Red-flanked Duikers are solitary, resident animals living in spaced-out territories at densities of about 3–4/km² (Wilson 2001). Male and female territories overlap, but each sex spends most of its time on its own. Of 386 observations in Mole N. P., 325 were of solitary animals, 47 were male–female pairs and ten were of ♀♀ with their young. In the same area, Wilson (2001) found two animals that had 5–7 different resting places within an area of 2 ha. Middens were prominent landmarks in this habitat and Wilson (2001) found 90% of them deposited on open ground, well away from vegetation. Unlike some other antelope species, faeces were not piled up on top of each other and anything between 15 and 80 single deposits, of varying age, were found scattered over an area of 15–50 m². The sexes have distinctively different urination postures, ♂♂ with their hindlegs stretched out behind while ♀♀ bunch up and lower their hindquarters to the ground.

In captivity, ♂♂ are almost continuously interested in ♀♀ (even attempting to mount ♀♀ not in oestrus), approaching the ♀ from the rear with body stretched out and exhaling with a snort while following the ♀ (Dubost & Feer 1988). The ♀ utters a short moan as she exhales and ♂♂ exhibit flehmen when sampling her vulva or

urine (Wilson 2001). A captive pair copulated four times in 40 min and oestrus lasted for a day and a half (Wilson 2001).

Reproduction and Population Structure There is no information on timing of parturition in the wild. Gestation period has been cited as 223–245 days (Schweers 1984). Based on records from captivity, birth-weights average 1.0 kg (range 0.8–1.2 kg) and weaning takes places at 93–98 days (Wilson 2001), although the latter author also notes a record of 58 days. A captive ♀ gave birth at 26 months (Hayssen *et al.* 1993). Animals in captivity have survived more than 15 years (Weigl 2005).

Predators, Parasites and Diseases Martial Eagles *Polemaetus bellicosus* and Crowned Eagles *Stephanoaetus coronatus*, pythons and various carnivores, notably Lions *Panthera leo*, Leopards *Panthera pardus*, Servals *Leptailurus serval* and jackals *Canis* spp. are all likely predators. Dipeolu & Akinboade (1984) recorded the ixodid ticks *Amblyomma variegatum* and *Boophilus decoloratus* from animals in Nigeria, while Ntiemoa-Baidu *et al.* (2005) recorded the following ixodid tick species from Red-flanked Duikers in Ghana: *Haemaphysalis parvula*, *Ixodes muniensis*, *I. moreli*, *Rhipicephalus simpsoni* and *R. ziemanni*.

Conservation IUCN Category: Least Concern. CITES: Not listed.

This species is declining due to hunting, but, as East (1999) remarked, has shown much resilience to both hunting and the spread of settlement and probably still occurs reasonably widely throughout much of its historical range. The species is common in many protected areas and reserves (about half of the total population occurs in and around protected areas), including Niokolo-Koba N. P. (Senegal), National Park of Upper Niger (Guinea), Comoé N. P., Haut Bandama Fauna and Flora Reserve and Marahoue N. P. (Côte d'Ivoire), Mole, Bui and Digya National Parks (Ghana), W N. P. (Benin), Bouba Ndjida, Bénoué and Faro National Parks (Cameroon), and Manovo–Gounda–St Floris and Bamingui–Bangoran National Parks (Central African Republic) (East 1999).

Cephalophus nigrifrons BLACK-FRONTED DUIKER

Fr. Céphalophe à front noir; Ger. Schwarzstirnducker

Cephalophus nigrifrons Gray, 1871. Proc. Zool. Soc. Lond. 1871: 598. 'Gaboon' (Gabon).Black-fronted Duiker *Cephalophus nigrifrons* adult male.Lateral and palatal views of skull of Black-fronted Duiker *Cephalophus nigrifrons*.

Taxonomy Five subspecies have been recognized (see Ansell 1972), with four confined to montane areas of eastern Africa and the nominate race found in the forests of the Congo Basin. The Rwenzori Red Duiker *Cephalophus rubidus* has been included as a subspecies of *C. nigrifrons* (St Leger 1936, Groves & Grubb 1981), although Kingdon (1982) considered *rubidus* to be a full species (and see Grubb 1993c, Kingdon 1997). Jansen van Vuuren & Robinson (2001) presented molecular evidence supporting the recognition of the species as distinct, although the only material available for the analysis was a tooth from a specimen in the Swedish Museum of Natural History. Wilson (2001) was reluctant to consider *rubidus* a distinct species, and Grubb & Groves (2001) and Grubb (2005) both considered it a subspecies of *C. nigrifrons*. Grubb & Groves (2001) also described a new subspecies from the Itombwe Mts, west of the north end of L. Tanganyika, *C. n. hypoxanthus*. *Cephalophus fosteri* and *C. hooki* were considered evolutionarily distinct species by Cotterill (2003a). Synonyms: *apanbanga*, *aureus*, *claudi*, *emini*, *fosteri*, *hooki*, *hypoxanthus*, *kivuensis*, *lusumbi*, *mixtus*. Chromosome number: not known, but given their conserved karyotype it may be $2n = 60$ (B. Janssen van Vuuren pers. comm.).

Description A medium-sized red duiker, similar to other red duikers, but with relatively long legs. Crown and forehead black with black or very dark red or brown frontal blaze (the blaze that gives this species its name), and a black tuft of hairs between the ears. A well-developed preorbital gland runs from the eye towards the muzzle. Pelage glossy red with coarse body and neck hair, some hairs with black or darker red tips, with a darker back and rump grading to a paler red belly. The pelage is shorter in lowland areas, but long and shaggy in high-lying areas; similarly, montane animals are darker and more grizzled. The legs are darker than the body and tend to almost black at the hocks. Some animals have a large amount of black on the shoulders. Hooves are long and thinner than in any other duiker (Wilson 2001). Tail is the same colour as the rump, red or dark red with a white underside that is constantly flicked as the

animal is moving and feeding. The very young have a darker pelage colour, which is lost within a few weeks of birth (J. A. Hart pers. comm.). The pedal glands are large and there are virtually no hairs blocking the opening to the glands (Wilson 2001). Well-developed inguinal glands occur in most individuals, but are sometimes missing from *C. n. kivuensis*. Sexes similar with the ♂ slightly smaller.

The skull is narrower with the muzzle 'pinched in' so that the nasals obscure the maxillae in dorsal view (Grubb & Groves 2001). Both sexes have horns, which are black, short and straight, pointing backwards at about 45° to the vertical.

Geographic Variation

C. n. nigrifrons: from the Niger Delta and Mt Cameroon, lowland forest of SE Cameroon, Gabon and Congo through the lowland forests of the Congo Basin and N Angola to the Albertine Rift Valley. In lowland forest, almost solely found in swamp forest along streams and rivers. Shining chestnut-brown, with forelegs black as far up as the elbow, and hindlegs usually up to hock; chest black. Forehead generally black; chin yellow (sometimes white) (Grubb & Groves 2001). Hooves are particularly elongated because swamp forest is the main habitat they occupy.

C. n. kivuensis: mountains along the Albertine Rift from the Kahuzi Biega massif to the Rwenzori Mts. Very contrasting colouration, the limbs being grey-black and the facial blaze very black; hair thick and coarse; chin pale reddish, but more whitish in specimens from higher altitudes (Grubb & Groves 2001).

C. n. fosteri: confined to Mt Elgon at 2600–3700 m. Brownish colour, with face and sides of neck reddish, not grey; chin white; coronal tuft short, entirely black; hair thick and coarse; smaller in size than other subspecies (Grubb & Groves 2001).

C. n. hooki: confined to Mt Kenya at 2800–3300 m, and in the Aberdares. Chestnut or reddish-grey, with face and sides of neck greyer; chin reddish-white; face-blaze bordered by red stripe; coronal tuft short, entirely black; fur thick and coarse, and tail bushy;

Black-fronted Duiker *Cephalophus nigrifrons hooki*.

smallest of the subspecies after *fosteri*. This subspecies is supposedly ecologically separated (by altitude and habitat) from Harvey's Duiker *C. harveyi* on Mt Kenya (with Harvey's Duikers not occurring above the bamboo line), although it is unknown whether they interbreed at all at the interface of their ranges (Grubb & Groves 2001).

C. n. hypoxanthus: confined to the Itombwe massif in E DR Congo. Pale, light yellow-chestnut colour, with greyish legs rather than black; hair fairly long and very soft (more coarse in other highland races); chin white (Grubb & Groves 2001).

The four montane forms generally are found between 2000 and 3800 m on their respective mountains, while *C. n. nigrifrons* occurs at much lower altitudes. The Rwenzori Red Duiker generally occurs above the range of *C. n. kivuensis* on the Rwenzori massif (up to 4200 m).

Similar Species

Cephalophus rubidus. Restricted to the upper reaches of the Rwenzori Mts. Dark grey underlying red tips of the hairs down the mid-line of the back and neck. Underfur of flanks cream; very pale to white belly.

C. harveyi. Sympatric in the Aberdares and Mt Kenya. Black and white chin and whiter ears with black tips; belly pale cream or white; shorter legs.

C. rufilatus. Allopatric. Smaller in size, this species has a grey-brown back and grey-brown legs that contrast with the red-orange on the face, neck and flanks. White on lower jaws contrasts with black nose. This species has no inguinal glands.

C. ogilbyi. Sympatric in western central Africa (*C. o. crusalbum*) and presumably Nigeria/Cameroon (the nominate form). Paler pelage and in *C. o. crusalbum* with white legs; shorter legs.

Distribution Endemic to equatorial Africa. Widespread from SE Nigeria in the Niger Delta (where only recently confirmed; Powell & Grubb 2002), through the forests of S and SE Cameroon, south of the Sanaga R., mainland Equatorial Guinea, Gabon, SW and SE Central African Republic, Congo and N (Cabinda, Uige and Cuanza Norte Provinces) and NE Angola (Lunda Norte and Lunda Sul Provinces) eastwards across the Congo Basin to the Albertine Rift (East 1999, Wilson 2001, Crawford-Cabral & Veríssimo 2005). In Uganda they are known only from Mt Elgon and remnant forest on mountains along the Albertine Rift, including the Rwenzori Mts, Bwindi Impenetrable N. P. and the Virunga Mts, while in Rwanda and Burundi they are now restricted to Volcanoes N. P. and Nyungwe

Forest Reserves, and the Nyungwe-Kibira forest on the Rwanda–Burundi border. In Kenya they occur only in three widely separated populations, on Mt Elgon, Mt Kenya and in the Aberdares (East 1999, Wilson 2001).

Isolated populations of this species were recorded on Mounts Cameroon, Kupe and Manengube by Bowden (1986); however, Grubb *et al.* (2003) were not convinced these records relate to Black-fronted Duikers, and thought they may represent an undescribed species.

Habitat Found in lowland tropical forest in the Congo Basin from altitudes near sea level to more than 4000 m in montane forest and moorlands in East Africa. Typically occurs in swampy or waterlogged habitats along streams where its long hooves help it move around more easily. In the Ituri Forest, DR Congo, it was equally abundant in monodominant *Gilbertiodendron* forest as in mixed forest, although in both forest types it is confined to the courses of streams and rivers (Hart 1985, 2000). In the Virunga Mts there was a preference for wooded habitat with an open understorey dominated by dense herbs such as nettles up the sides, and in the saddle between the volcanoes (Plumptre & Harris 1995, Plumptre & Bizumuremyi 1996). On Mt Elgon it occurs in dense bamboo forest where it is probably not abundant (J. Kingdon pers. comm.), but in the Virungas this was not a preferred habitat and densities were low in bamboo (Plumptre 1991). On mountains there is less dependence on waterlogged areas than there is in the lowland forest although the long hooves are still present, implying that the original form may have occurred in lowland forest where its adaptations to waterlogged soils might have favoured its colonization of moist forested areas and spread up the mountains. There is some evidence that this species avoids predation by Leopards *Panthera pardus* by being better adapted to swamp forest in lowland areas where the supply of fruit is lower and animals survive on herbs (Hart 2000, 2001).

Abundance In the Virunga Mts, densities ranged from 5 to 22/km² across a range of different habitats (Plumptre & Harris 1995). In the

ABOVE AND RIGHT: Black-fronted Duiker *Cephalophus nigrifrons kivuensis* adult male facial features and forehead.

Ituri Forest, density was lower, at about 1.3–2.0/km² (Hart, J. A. *et al.* 1996, Hart 2000, 2001). Assuming average densities of 2/km² in high-density areas and 0.2/km² in low-density areas, East (1999) estimated the total population at around 300,000.

Adaptations The long hooves enable this species to inhabit swampy and waterlogged areas. J. A. Hart *et al.* (1996) have suggested that this gives it an advantage in keeping away from Leopards, one of its major predators. The foot-stamping that is typical of other duiker species appears to be absent in this species. It is possible that species-specific vocal signals may compensate. When feeding or moving, animals constantly flick their tails, exposing the white undersides that may be used to advertise their presence to others. The bone of the skull on the foreheads is thickened, probably to minimize the impact of head butting between individuals. Black-fronted Duikers are primarily diurnal, but occasionally are active at night.

Foraging and Food Diets vary where they have been studied. In the Ituri Forest, 29% of the diet determined from rumen contents was leaf material (primarily herbs) and the remainder was fruit and seeds, with some flowers and fungi (Hart 1985). Those fruits consumed tend to be fairly fibrous, such as *Ricinodendron heudelotti*, rather than fleshy. However, it was the most folivorous of all the duikers in the Ituri Forest and the only one to eat herbs. The diet varied seasonally depending on the availability of fallen fruit, and seed content increased dramatically in most years for *Gilbertiodendron dewevrei*. In Makokou, Gabon, rumen analysis indicated 73% of the diet consisted of fruit (mostly 1–3 cm in diameter) with the remainder consisting of leaves, flowers, petioles and fungi (Gautier-Hion *et al.* 1980); the Black-fronted Duiker was again the most folivorous duiker of those studied in Makokou (Dubost 1984). At higher altitudes (2900–3700 m) in the Virunga Mts there was very little fruit available and 80.7% of the diet consisted of leaves of herbs and grasses, with 14.8% lichen and 4.5% bark/roots based on faecal pellet analyses (Plumptre 1995). The low tannin and alkaloid levels in montane herbs probably allow this species to survive on such a drastically different diet and to live at high densities (Plumptre 1995). *Usnea* lichen was highly preferred, with individuals competing over pieces that fell to the

ground and standing on their hindlegs to reach lichen that was within reach. The desire for this lichen may be due to its reasonably high level of soluble carbohydrates (A. Plumptre unpubl.), which may substitute for those found in fruit consumed at lower altitudes. Diet in the Virungas did not vary seasonally as there was little variation in the availability of food.

Social and Reproductive Behaviour Generally solitary with occasional sightings of pairs (either mother–infant or male–female). They are territorial, using preorbital glands to mark territories, and tending to defecate near the boundaries of their territory. Territorial defence may be aided by the use of a thumping sound that appears to be vocal (Kingdon 1982), and a loud whistle-like call that is also used as an alarm call. Very occasionally two individuals will fight, which involves rearing up and butting heads together, pausing to recover and then repeating this, reminiscent of the way goats fight. Individuals have also been seen to snap at each other (Walther 1984). Fighting usually ends with a pursuit through the vegetation.

Anti-predator behaviour involves freezing, often in mid-stride, sinking down to the ground or sneaking away to hide in dense vegetation if they believe they have not been detected. If they know they have been detected they flee, giving a loud whistle, dashing through the vegetation with their head down for a short distance, often in a zig-zag manner to throw off any predator.

Like many ungulates, young when born are left concealed by the mother in dense vegetation and she returns to suckle at regular intervals.

Reproduction and Population Structure Nothing is known about reproduction of this species either in captivity or in the wild. Wilson (2001) mentions two lactating ♀♀ recorded in Feb and Mar

from the Central African Republic, and two pregnant ♀♀ in Dec. Longevity in captivity has been given as nearly 20 years (Jones 1982).

Predators, Parasites and Diseases Leopards are a major predator of all duiker species in the Ituri Forest and have a significant impact on their populations (Hart, J. A. *et al.* 1996). Leopards account for 87% of duiker mortality in areas where humans do not hunt in the Ituri Forest (Hart 2000, J. A. Hart pers. comm.). However, this species only formed about 1.7% of Leopard diet in the Ituri Forest, the lowest of any duiker species, despite being reasonably abundant, and occurred in only half of a calculated expected number of Leopard scats (Hart, J. A. *et al.* 1996). They also had the lowest mortality rate of any duiker species in the Ituri Forest (Hart 2000). Other large cats, such as African Golden Cats *Profelis aurata*, and African Rock Pythons *Python sebae* will also take this species. Large eagles such as the Crowned Eagle *Stephanoaetus coronatus* will take juveniles and very occasionally adults. Robust Chimpanzees *Pan troglodytes* and Nile Crocodiles *Crocodylus niloticus* occasionally take individuals.

Helminths recorded from Black-fronted Duikers include cestodes (genera *Avitinella*, *Stilesia*) and nematodes (*Bunostromum*, *Dipetalonema*, *Ochocera* and *Setaria*) (Round 1968, Bain *et al.* 1978, Chabaud *et al.* 1978). A study of the diseases and parasites found in wild duikers in the Ituri Forest showed that most Black-fronted Duikers in this forest contain gut parasites (Karesh *et al.* 1995). Of the five individuals sampled all had at least evidence of one parasite species in their faeces and for most parasites the percentage of individuals infected was higher for this species than the four other duiker species tested. Evidence of parasites in the blood included: 'bluetongue' virus, which was at a similar level to other species; epizootic haemorrhagic disease and infectious bovine rhinotracheitis, which were generally at a lower level than other species; and leptospirosis, which was at a higher level of infection compared with most of the other species sampled (Karesh *et al.* 1995). Some of these infections, particularly leptospirosis, could be transmitted to humans through the bushmeat trade in this species.

Conservation IUCN Category: Least Concern. CITES: Not listed.

Numbers of Black-fronted Duiker are probably declining across the range, mainly due to hunting, particularly with the opening up of the Congo Basin by timber extraction companies. The three subspecies confined to Mt Elgon, Itombwe Massif and Mt Kenya are probably at greater risk of extinction. This is particularly the case for *C. n. hypoxanthus* on the Itombwe Massif, which is not currently protected.

In central and West Africa this species is hunted heavily wherever it occurs in proximity to man. There is some evidence that red duikers

can accelerate their maturation in ♀♀ under low population densities but not as well as blue duikers can (Hart 2000). They are easily trapped, as there is some indication that they follow regular paths from the swamps to drier parts of the forest (Rahm & Christiaensen 1963, Wilson 2001). Data from Rwanda revealed that Black-fronted Duiker meat is significantly lower in price than domestic meat (Plumptre & Bizumuremyi 1996, Plumptre *et al.* 1997) and they were a favoured species for hunters. There was evidence that poaching of this species had increased in Volcanoes N. P. during and after the insecurity created by the civil war and genocide in Rwanda (Plumptre *et al.* 1997).

Protected areas important for the continued persistence of the species include Apoi Creek F. R. (Nigeria), Dja Faunal Reserve (Cameroon), Monte Allen N. P. (Equatorial Guinea), Lopé N. P. (Gabon), Dzanga-Sangha Forest Reserve and Bangassou Forest (Central African Republic), Nouabalé-Ndoki and Odzala National Parks (Congo), Kahuzi-Biega, Maiko and Virunga National Parks and Okapi Wildlife Reserve (DR Congo), Bwindi Impenetrable and Rwenzori Mountains National Parks (Uganda) and Volcanoes N. P. (Rwanda).

Measurements

Cephalophus nigrifrons

TL (♂♂): 1080 (1020–1120) mm, n = 6

TL (♀♀): 1090 (1040–1140) mm, n = 7

T (♂♂): 155 (130–160) mm, n = 6

T (♀♀): 150 (140–160) mm, n = 7

HF c.u. (♂♂): 295 (281–304) mm, n = 6

HF c.u. (♀♀): 296 (281–310) mm, n = 7

E (♂♂): 90 (87–94) mm, n = 6

E (♀♀): 91 (86–95) mm, n = 7

Sh. ht (♂♂): 560 (540–570) mm, n = 6

Sh. ht (♀♀): 560 (540–580) mm, n = 7

WT (♂♂): 13.8 (12.7–14.9) kg, n = 6

WT (♀♀): 14.0 (13.1–16.3) kg, n = 7

Cameroon, Central African Republic and Congo Republic (Wilson 2001)

Hart, J. A. *et al.* (1996) recorded the mean weight of two ♀♀ as 15.5 kg (range 15–16 kg) and 14.3 kg for two ♂♂ (14.0–14.5 kg). Maximum recorded horn length is 12.0 cm for a pair of horns from Ntem R., Cameroon (Rowland Ward)

Cephalophus ogilbyi OGILBY'S DUIKER

Fr. Céphalophe d'Ogilby; Ger. Ogilbyducker

Cephalophus ogilbyi (Waterhouse, 1838) Proc. Zool. Soc. Lond. 1838: 60. Equatorial Guinea, 'Fernando Po' (= Bioko).

Taxonomy Ogilby's Duiker, as described here, probably represents a species group that embraces three allopatric species. While acknowledging this probability we follow Wilson (2001) in provisionally continuing to treat this complex as a single species. The type of *C. ogilbyi* was described in 1838 from the island of Fernando Poo (Bioko); *C. o. crusalbum* was described in 1978 from Gabon and *C. o. brookei* in 1903 from Ghana. Brooke's Duiker *C. o. brookei* has been recognized as a full species by several recent authors (Grubb *et al.* 1998, Grubb & Groves 2001, Grubb 2005). *Cephalophus o. crusalbum* has been recognized as a full evolutionary species by Cotterill (2003a).

Molecular studies suggest that Ogilby's Duiker is an ancient relict duiker that has ambiguous genetic links with other duiker species, notably with Peters's Duiker *C. callipygus* (Jansen van Vuuren & Robinson 2001; and see Hassanin *et al.* 2012). Payne (1992) considered Ogilby's Duiker and Peters's Duiker to be particularly close, and Grubb (1978a) thought the population he named *C. o. crusalbum* was 'intermediate' between Peters' and Ogilby's Duikers. Wilson (2001) drew attention to the 'intergrading' of some Ogilby-like characteristics in individual Peters's Duikers, at or close to their zones of contact. This raises the possibility of occasional, or even sustained, long-term hybridization, past and present, between individuals or even entire populations. As ancestral duiker populations have been replaced by later ones the nature of that replacement could include various permutations of genetic admixture. As Ogilby's Duiker gives every sign of being a relictual form in the process of decline, the possibility of genetic admixture should be borne in mind. Unscrambling such mixed genetic backgrounds will be an interesting task for future molecular scientists. It is, therefore, appropriate to point out that the *C. ogilbyi* complex represents an enigmatic and puzzling taxonomic entity. Our uncertainties about the status of Ogilby's Duiker populations challenge science, yet their rarity, their relictual nature and their vulnerability to hunting may soon deprive scientists of important clues to the nature of duiker radiation. Synonyms: *brookei*, *crusalbum*. Chromosome number: not known.

Description A trim orange to mahogany-coloured duiker with chunky hindquarters and a bold black dorsal stripe (10–60 mm wide) that tapers to a point just above the tail. Nose and crown are black, but red or orange 'brows' of variable width may meet on the forehead. Horns may be partially obscured by short tufts of red or black fur. Pinnae are sepia behind and have narrow white margins with tracts of short paler hair in their forward aspect. On Bioko I., necks are well furred with soft but longish fur, while mainland populations tend to have short-haired darkish necks; hair on the neck is frequently reversed. Body colour extends down relatively long, slender legs, but *C. o. crusalbum* has off-white legs while *C. o. brookei* has narrow black lines or smears down the front of the limbs. Small lateral hooves are present. Inguinal, preorbital and pedal glands are all present. Tail narrow but ends in a distinct tuft that is sometimes quite large, like a pompom, with hairs up to 75 mm long (as in *C. o. crusalbum*).

Ogilby's Duiker *Cephalophus ogilbyi ogilbyi*.

The horns are short but peculiarly incurved and heavily corrugated and can occur on both sexes. The skull is characterized by the extreme inflation of the forehead behind the nasofrontal suture, such that the skull has a marked frontal boss, but which is reduced laterally so that the infraorbital foramina are not roofed over; the zygomatic arch is more curved than in the Black Duiker, flaring out in the middle (Grubb & Groves 2001).

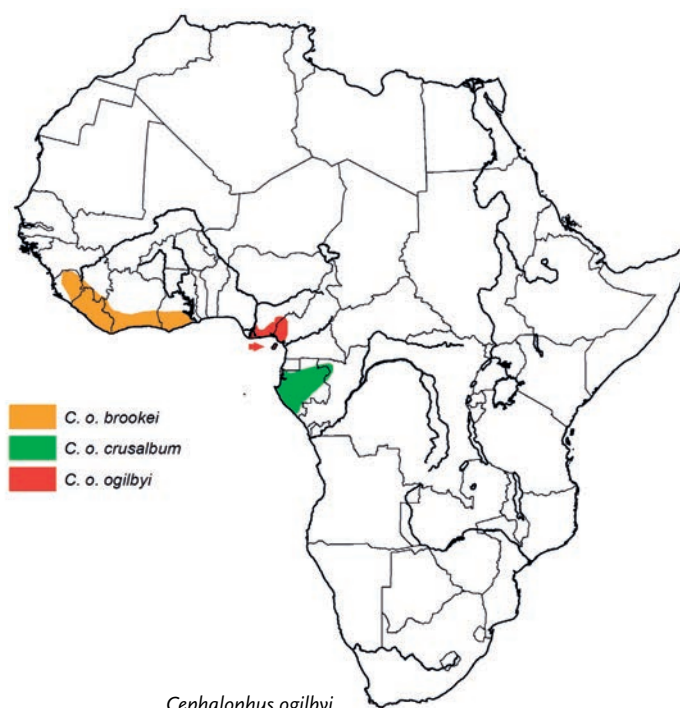

Geographic Variation

C. o. ogilbyi (Ogilby's Duiker): Bioko I., Equatorial Guinea, and Cameroon/Nigeria borderlands. Larger body size. Relatively uniform golden-rufous colouring overall but with whitish underside, throat and chin. Crisp, narrow, black mid-dorsal line. Neck pelage not noticeably shorter than rest of body. Heavily bossed forehead.

Brooke's Duiker *Cephalophus ogilbyi brookei*.

White-legged Duiker *Cephalophus ogilbyi crusalbum*.

Cephalophus ogilbyi

C. o. brookei (Brooke's Duiker): Sierra Leone, possibly SE Guinea, Liberia, S Côte d'Ivoire and Ghana, west of the Volta R.; Kingdon (1997) mistakenly described this population occurring in Cameroon. Pale golden colour with slightly redder rump; broad dorsal stripe narrows to a point above tail; red coronal tuft; neck hair very short; forehead not obviously bossed. Probably a distinct species.

C. o. crusalbum (White-legged Duiker): Gabon, mostly south of Ogooué R., and extreme NW Congo. Smaller body size; golden or orange-ochre torso, redder rump, but lighter on the flanks; somewhat greyer neck and face; neck hair very short; broad dorsal stripe; legs white from knee and hock to hoof, in contrast to all other duikers; tail orange-ochre with median stripe black and pronounced tail tuft; forehead not conspicuously bossed.

Similar Species

Cephalophus nigrifrons. Sympatric in Gabon and Congo (with *C. o. crusalbum*) and Nigeria/Cameroon (*C. o. ogilbyi*). A long-legged, long-hooved, dark red duiker with no dorsal band and a strong preference for swamp forest.

C. callipygus. Sympatric in Gabon (e.g. in Forêt des Abeilles and Lopé N. P.) and Congo. A large species with dark legs and extensive black dorsal stripe on upper rump. Hybridization may occur and *C. o. crusalbum* sometimes appears to be intermediate between *C. ogilbyi* and *C. callipygus* (see Grubb 1978a).

C. dorsalis. Sympatric throughout mainland range of Ogilby's Duiker. A broad-headed, short-faced, slender-horned, heavily built and usually dark red duiker, which is readily confused with Ogilby's Duiker. Nocturnal.

C. niger. A black duiker, restricted to Upper Guinea forests from SW Guinea to the Niger R.

Distribution Endemic to Africa, Ogilby's Duiker is distributed in four distinct populations. In West Africa it occurs in the forests of Upper Guinea, from Sierra Leone (where the only confirmed records are from the Outamba part of Outamba-Kilimi N. P. and Lalehun) through Liberia and S Côte d'Ivoire to Ghana, west of the Volta R. (Grubb *et al.* 1998, East 1999, Wilson 2001). May occur in SE Guinea, where reported from Ziama-Diécké F. R. by East (1999), but not by Butzler (1994). There is no recent information on the presence of this species in SW Ghana, and East (1999) noted that it had disappeared

from the Bomfobiri and Owabi wildlife sanctuaries where it occurred formerly. There is a break in distribution until reappearance (in the form *C. o. ogilbyi*) in the moist lowland forest in SE Nigeria and SW Cameroon. An isolated population occurs on Bioko I., particularly at higher altitudes. The white-legged form of Ogilby's Duiker, *C. o. crusalbum*, occurs in Gabon, mostly south of the Ogooué R., and is reported to occur in NW Congo (East 1999, Grubb *et al.* 2003). There is no record of this species from mainland Equatorial Guinea.

Habitat Found in all forest types, from sea level up to 2260 m and perhaps even higher on Bioko I. (Butynski *et al.* 2001), where it is the only large duiker species, and where it occurs in the *Schefflera* Forest Zone (ordinarily occupied by other species on the mainland). No clear specialization in forest type. Occurs in dense forest patches on the Guinea savanna edge in Sierra Leone (Grubb *et al.* 1998). Reported from a mixture of undisturbed high and also logged forests in Liberia (Wilson 2001). Found in forest patches within forest-savanna mosaic in northern part of Lopé N. P. in Gabon (East 1999). A different permutation of other duiker species is found in every one of the areas where Ogilby's Duiker occurs but there is virtually no overlap in range with 'main line' broad-spectrum red duikers (exclusive of Bay Duikers) (Kingdon 1982). The absence of any clear specialization in habitat or diet suggests that duikers of the *C. ogilbyi* complex represent relictual populations of an early lineage that may be in the process of succumbing to competition and genetic contamination from other forest duikers. The most notable of these is Peters's Duiker, which is almost allopatric and a very similar species. This similarity is most marked along the borderlands between the two species where occasional 'intermediate' specimens suggest that the 'relationship' between the two species may be complicated by long-term hybridization. In any event, the situation calls for further investigation. In Upper Guinea, where Black Duikers and Bay Duikers are the commonest large duikers, *C. o. brookei* was formerly widespread but never common (Grubb *et al.* 1998).

Lateral view of skull of Ogilby's Duiker *Cephalophus ogilbyi ogilbyi*.

Abundance Data are scarce, but during a survey conducted in 1990 in the Gran Caldera on Bioko I., Butynski *et al.* (2001) found evidence for their presence at the rate of 0.24 per linear transect km in suitable habitat. Figures from bushmeat markets and hunter interviews suggest an annual off-take of 4000 Ogilby's Duikers on Bioko I.; about 2/km² of forest habitat. A more localized estimate was 2250 from 160 km² (Fa *et al.* 1995). While it is not known how sustainable such off-takes are, East (1999) assumed an average density of 10/km² on Bioko I., 2/km² in other areas where the species is known to be common, and 0.2/km² elsewhere, and estimated a population of 12,000 animals on Bioko I. and in the Nigeria/Cameroon area. Elsewhere, he estimated 5000 individuals for *C. o. brookei* and 18,000 for *C. o. crusalbum*. It is worth noting that Wilson (2001), who conducted extensive survey work over a period of ten years in various parts of West Africa, only saw *C. o. brookei* in the wild once, in Kakum N. P., Ghana.

Adaptations A very generalized, but variable type of duiker; the possibility of a relictual status has been discussed above. There is also the possibility, raised by several authors (Grubb 1978a, Kingdon 1982, Wilson 2001), that hybridization may complicate our understanding of the duiker radiation, and of this species in particular. This possibility is central to any attempt at defining the adaptive niche of Ogilby's Duiker. There are several reasons to suspect that this duiker is a relict species in active decline and in the process of replacement by other species of the same generalized red duiker lineage. First is the lack of any distinct specializations. Second are peculiarities of its disjunct distribution, which lack any clear correspondence with vegetation or climatic zones. Third is a peculiar interdigitation in its distribution with that of the commoner Peters's Duiker, which implies competition, decline and retreat from the latter. Fourth, Ogilby's Duiker, from the margins of this 'frontier' zone, shows several characteristics that imply previous long-term hybridization. Likewise, some Peters's Duikers show variations in the form of their dorsal stripes that could be taken to imply hybridization between the two species. Fifth, current molecular evidence allies this species with several other species, including Peters's Duiker, and such ambiguities of affinity could imply both/either archaic status and/or a history of hybridization. The sixth reason to suspect an overall decline in the face of competition from other duiker species is the fact that the Bioko form is very common on the island, yet naturally rare in many of its remaining mainland sites. Unlike the long-haired island population, mainland duikers have short-haired necks that could imply genetic admixture because neck pelage is generally a clear distinguishing characteristic between two separate duiker lineages (Kingdon 1982). These and many other unanswered questions about the *C. ogilbyi* complex preclude any easy definition of the adaptive niche of this species.

The apparent restriction of bossed foreheads to Bioko duikers, combined with known recent high densities, suggest that this isolated species/subspecies lives in smallish, frequently defended territories. It is interesting to speculate whether frontal bossing once occurred in the ancestral populations of *C. o. brookei* and *C. o. crusalbum*. The anomalous occurrence of this physiologically expensive characteristic in just one population implies that reduced densities and less frequent conflict among mainland populations might have caused rapid atrophy in what might otherwise have been taken as a relatively immutable diagnostic characteristic (as tends to be the case in descriptions of the skulls of *C. weynsi*, *C. callipygus* and *C. niger*, all species that live at high densities).

Foraging and Food The ability of this duiker to range through all forest zones on Bioko I. implies a catholic diet and ability to adapt to different vegetation and rainfall zones. Like other duikers, it is known to feed on fruit, flowers and, presumably, foliage from the forest floor. Gautier-Hion & Gautier (1994) observed a subadult *C. o. crusalbum* eating the hard fruits of *Klainedoxa gabonensis*. The stomach contents of a specimen of *C. o. brookei* examined by Newing (2001) comprised 92% fruits and seeds, 7% vegetative parts and 1% flowers.

Social and Reproductive Behaviour A single adult ♂ that was radio-collared in Korup N. P., Cameroon, provided valuable information on the movements and activity (as determined from a mercury activity switch) (Payne 1992). The lucky capture of this individual followed a large number of fruitless drives and capture efforts in an area where Ogilby's Duikers were already acknowledged to be rare. The home-range of this ♂ was estimated to be 10.6 ha (as determined by the minimum convex polygon method). Within this home-range there was a small central area that was consistently and almost exclusively used for sleeping by this strictly diurnal duiker. By contrast, diurnal resting areas, mainly used between mid-day and 15:00h, were on the peripheries of the home-range. Peak activity was immediately after dawn (06:30–11:00h) and between 16:00h and 19:00h. Of 50 sightings, only three, thought to be mother-offspring pairs, were not solitary; this is in agreement with the findings of Gautier-Hion & Gautier (1994), all of whose observations were of solitary individuals or pairs.

In contrast to mainland species, which have been consistently described as rare and shy, Bioko duikers, when surveyed between Jan and Mar 1986, were abundant and vocal, implying a more complex social structure. They were frequently heard to make a loud 'wheet' call (Butynski *et al.* 2001) and East's (1999) estimate of 10/km² was probably realistic for the time of Butynski's surveys (and partly also due to the general absence of predators on duikers on Bioko; see Predators, Parasites and Diseases).

Reproduction and Population Structure Currently, there is no published information, but the dynamics of population structure are likely to differ radically between high-density *C. o. ogilbyi* on Bioko and very low density populations on the mainland. There is no indication of a breeding season.

Predators, Parasites and Diseases Leopards *Panthera pardus* may prey on Ogilby's Duikers in some mainland habitats, and African Golden Cats *Profelis aurata* are also likely to take young and possibly

adults, as are African Rock Pythons *Python sebae*. Young animals are probably taken by Crowned Eagles *Stephanoaetus coronatus*. Mandrills *Mandrillus sphinx* probably prey on young and infirm duikers (Lahm 1986, T. Butynski pers. comm.). Butynski *et al.* (2001) suggested that the main predators likely include Drill *Mandrillus leucophaeus* on Bioko, where hunters imitate the cry of an Ogilby's Duiker young to bring in Drill close enough to shoot.

Conservation IUCN Category: Least Concern (*C. o. crusalbum* – Least Concern; *C. o. brookei* – Vulnerable C1; *C. o. ogilbyi* – Vulnerable C1). CITES: Appendix II.

The main threats to Ogilby's Duikers are habitat degradation and overhunting, and on current trends these duikers will become extinct or will survive in a few well-protected areas. The effective protection of the Gran Caldera de Luba Scientific Reserve is crucial to the survival of this species on Bioko I. On the mainland, Upper Guinea populations of *C. o. brookei* have few remaining strongholds. Among them might be Sapo N. P. (Liberia) and Tai N. P. (Côte d'Ivoire), although hunters resident in Tai N. P. have been reported harvesting 1500–3000 tonnes of wild animal meat per year in parts of this park (Caspary *et al.* 1999) and heavy exploitation of bushmeat has been observed around Sapo N. P. (R. Hoyt pers. comm.). This form has also been recorded recently in Gola N. P. in Sierra Leone (Lindsell *et al.* 2011). *Cephalophus o. ogilbyi* occurs in Korup N. P. (Cameroon), where it is very rare (Payne 1992), and in Cross River N. P. (Nigeria); they are also present in several forest reserves in SW Cameroon, such as Mone and Ejagham (Forbeseh *et al.* 2007). The distinctive white-legged form is now known to be relatively widespread and numerous in Gabon, including protected areas such as Lopé N. P. and the Gamba complex of National Parks, as well as Odzala N. P. (Congo).

This species is hunted throughout its range, but with particular intensity in Bioko, where the bushmeat trade has been well studied over a period of years (Colell *et al.* 1994, Fa *et al.* 1995, 2000, Juste *et al.* 1995, Butynski *et al.* 2001). Of 94,616 wild animal carcasses brought to the bushmeat market in Malabo between the last quarter of 1997 and the first 10 months of 2006, 5.3% were Ogilby's Duikers and this species ranged between the fourth and seventh most common in the market over this period (W. Morra & G. Hearn

pers. comm.). This is similar to the 6% recorded between October 1990 and October 1991, when Ogilby's was the fifth most common species in the market at that time (Juste *et al.* 1995; and see Fa *et al.* 2000). These 1991 market harvest levels were clearly unsustainable (Fa *et al.* 1995), yet availability increased to 89% in 1996; in 1996, estimated daily abundance was about 3.4 carcasses per day (Fa *et al.* 2000). Since then, however, the availability of this species at the Malabo market has undergone a steady decline reaching 1.9 carcasses per day in 2006 (W. Morra & G. Hearn pers. comm.).

Colell *et al.* (1994) found that of animals taken by hunters in south-east Bioko, Ogilby's Duiker was the fourth most frequently collected species; 71% of these were shot and 29% were trapped. Less than 10% were consumed locally, the rest being taken to market, where prices as high as US\$14 per carcass were paid in 1986 (Butynski *et al.* 2001). As of 2006, the average price paid had increased to US\$94 (W. Morra & G. Hearn pers. comm.). The top priority for the conservation of Ogilby's Duiker on Bioko is to stop openly illegal hunting of this species in the two nominally 'protected' areas (T. Butynski pers. comm.).

Measurements

Cephalophus ogilbyi

HB: 850–1150 mm

T: 120–150 mm

E: 88 mm*

HF c.u.: 260 mm

Sh. ht: 550–650 mm

WT: 14.0–20.0 kg

Kingdon (1997); *single adult (sex not noted) from Bioko I. (T. Butynski pers. comm.)

Payne (1992) gave the weight of three adult ♂♂ from Korup N. P., Cameroon, as 18.0, 19.0 and 20.0 kg

Maximum recorded horn length is 12.3 cm for a pair of horns from Grebo, Liberia (Rowland Ward)

Key References Payne 1992; Wilson 2001.

Cephalophus weynsi WEYNS'S DUIKER

Fr. Céphalophe de Weyns; Ger. Weynsducker

Cephalophus weynsi Thomas, 1901. Ann. Mus. Congo Zool. 2 (1): 15. 'district des Stanley-Falls' (DR Congo, near Stanley Falls).

The duiker is named for Lt. Col. Auguste F. G. Weyns, a Belgian explorer for whom Weyns's Weaver *Ploceus weynsi* is also named.

Taxonomy Previously treated as a subspecies of Peters's Duiker *Cephalophus callipygus* (Kingdon 1982, East 1999, Wilson 2001), or even lumped variably in the past with the Natal Red Duiker *C. natalensis* (Ansell 1972) and Harvey's Duiker *C. harveyi* (Haltenorth & Diller 1980). Considered a distinct species by East *et al.* (1990), Groves & Grubb (1974), Grubb & Groves (2001) and Grubb (2005). Specific designation is supported by genetic analysis (Jansen van Vuuren & Robinson 2001; but see Hassanin *et al.* 2012). Three subspecies were recognized by Grubb & Groves (2001). Synonyms:

barbertoni, *centralis*, *ignifer*, *johnstoni*, *leopoldi*, *lestradei*, *rutshuricus*. Chromosome number: unknown, but likely 2n = 60.

Description A medium-sized, coarse-haired, rufous-coloured duiker, distinguished by its lack of a black dorsal back stripe. The species is variably darker, especially on the limbs, shoulders and underparts, especially in some eastern populations. Crown and forehead red to reddish-brown with a coronal tuft of thick, bright, rufous hairs located between the horns, and covering the horn base in both sexes. The crown is rounded and uplifted in a distinct vaulted boss. Sides of face and ears variably brownish-rufous. The lips are thickened, giving the animal a coarse appearance. Back, sides and abdomen bright rufous with hairs

LEFT: Weyns's Duiker *Cephalophus weynsi* adult female.
ABOVE: Lateral view of skull of Weyns's Duiker *Cephalophus weynsi* adult male.

longest on the rump. Neck and shoulder rufous, mixed with darker hairs, especially on the shoulder. Neck and shoulder hairs shortened and hair on the neck reduced, markedly in some populations, exposing the pale-coloured skin beneath. Pelage on limbs uniformly dark below the hocks, extending variably onto the upper limbs, chest, upper abdomen and shoulders in some populations and individuals. Lower abdomen covered with sparse pale hairs. Tail rufous at base, dark distally, with small dark tuft containing scattered white hairs. Preorbital glands are large, running from the eye towards the muzzle. Inguinal glands are well developed, producing a reddish secretion, which, in populations in the Ituri Forest in NE DR Congo, is sweet-smelling. Pedal glands are present on all four feet (Wilson 2001). Sexes are similar in colouration, and while ♂♂ are smaller than ♀♀, as is true in all forest duikers, sexual dimorphism is reduced; adult ♀♀ average less than 3% larger body weight than adult ♂♂. Pelage of newborns is overall brown, darker above and liberally grizzled with red hairs. The coronal tuft is present, even when horns occur only as buds. This pelage is replaced by adult colouration before the animal is weaned.

The skull has an elongated rostrum and is distinguished by the vaulted forehead and robust horn bases. Both sexes have horns, which are black, short, thickened and strongly annulated at the base and over two-thirds of their length. Horns, distinctly longer in ♂ than ♀, are often curved downward and inward at the tips.

Geographic Variation A variable species, with the taxonomic status of a number of forms, in particular east of the Albertine Rift and south of the Congo R., still uncertain (Wilson 2001). *Cephalophus w. weynsi* (including *leopoldi* and *centralis*), the most rufous form, ranges across DR Congo, on the right bank of the Congo R. east into the sub-montane forests of Kivu, south through Maniema and south Kivu to the forest limit. The forms in the montane forests of the Itombwe Massif, west of L. Tanganyika appear to be this race. Weyns's Duikers from the forest patches of SE Sudan and Uganda (west of L. Victoria) may also be attributable to this form, though some populations of the latter have been lumped as *C. w. johnstoni*. *C.*

w. lestradei, characterized by overall darker pelage, is reported from the sub-montane and montane forests along the eastern Albertine Rift, including Rwanda (Groves & Grubb 1974), and in the forests east of L. Tanganyika; however, the occurrence of this form, as well as the probably now extirpated *C. w. rutshuricus*, named from a now deforested area of eastern Kivu, and their relations to the nominate race on the west side of the Albertine Rift, are not well defined. The taxonomic status of a number of eastern forms, characterized by their smaller size and lumped as *C. w. ignifer* (Grubb & Groves 2001, Grubb 2005), and including duikers from Mt Elgon (*C. w. barbertoni*) through the forest patches of W Kenya, is also poorly known.

Possible hybrids between *C. weynsi* and *C. harveyi* are reported from the Mau escarpment (Kingdon 1982). Duikers south of the Congo R., ranging through the central cuvette to Kasai, and Sankuru have been attributed to this species; however, these forms have a black dorsal patch, and may be better grouped with *C. callipygus*.

Similar Species

Cephalophus callipygus. Allopatric, occurring only west of the Congo and Ubangui Rivers. All forms have a distinctive dark patch on the back and rump, which distinguishes them from Weyns's Duiker.

C. leucogaster. Sympatric east of the Ubangui R. Distinguished by paler colouring, and dark dorsal patch.

C. dorsalis. Sympatric in the east of its range, east of the Ubangui R. Broader-headed, shorter-muzzled, darker rufous, and with a distinct dorsal black patch.

C. harveyi. The species occurs mainly east of the Rift Valley in Kenya, but may hybridize with Weyns's Duiker along the Mau escarpment (Kingdon 1982, Wilson 2001). Black and white chin and whiter ears with black tufts; belly is pale cream or white; shorter legs.

Distribution Endemic to equatorial Africa. Widespread in DR Congo, including large areas of contiguous range north of the Congo R., from the Ubangui R. in the west, through the Ituri Forest to the limits of continuous forest on the western flanks of the Albertine

Rift, then south to the forest limits in Maniema, Kivu and possibly into northern Katanga province. The northern and southern range limits appear to be defined by the forest/savanna boundary on both sides of the Equator. The species' eastern distribution is more fragmented, with populations recorded historically from a number of lowland, sub-montane and montane forest islands in W Uganda, W Rwanda and Burundi, W Tanzania (Mahali Mts and Gombe), S Sudan (Imatong and Dongotona Mts), east to Mt Elgon and the forests of Kakamega and the Mau Escarpment in W Kenya. This species has not been recorded east of the Rift Valley in Kenya. Some eastern populations may now be seriously reduced or extinct.

Habitat In its lowland range in DR Congo the species is restricted to large blocks of closed forest and does not range far out into gallery forests or forest islands in the savanna ecotone. However, in East Africa, Weyns's Duiker occurs in relatively small and isolated forest remnants. Its limited occurrence at the forest edge in the north of its range may be due to the presence of Red-flanked Duiker *C. rufilatus*, which has specialized on the forest/savanna ecotone. In the Ituri Forest, Weyns's Duiker occurs widely in primary and older secondary forests, avoiding recent clearings and deep swamps. The species is common in mixed canopy forests, but is rare or absent from large stands of monodominant *Gilbertiodendron dewevrei* (Hart 2001). The species ranges from altitudes of 400 m to about 2000 m in forests of the Albertine Rift highlands, while east of the Albertine Rift, it occurs locally in sub-montane to montane forests up to 3000 m (reportedly on Mt Elgon; Haltenorth & Diller 1980).

Abundance In the Ituri Forest, Weyns's Duiker is the second most common duiker species after Blue Duiker *Philantomba monticola*. Densities of unhunted populations averaged 15 animals/km² (Hart 2000). East (1999) estimated a total population 188,000.

Adaptations Weyns's Duiker is a robustly built duiker with a strongly developed head and neck. Relatively large male body size, in association with the distinctive bony vaulted crown and reinforced horn bases, present on both sexes, but most developed in the ♂, are indicative of regular intra-specific combat. In the Ituri Forest, preorbital glands of Weyns's Duiker ♂♂ are often strongly swollen with visible exudates, suggesting frequent marking behaviour. Males, and possibly ♀♀, also mark by rubbing the coronal area against the stems of small trees. Animals that are excited or stressed show a red flush on the pale skin of the neck (which is exposed because the hair is so sparse). Weyns's Duiker has an elongated rostrum, and the tooth arch is not markedly widened, but the dentition is robust, and suggests the capacity to handle coarse foods. Relatively high rumen volume to body weight ratios also confirm the species' ability to digest a broad range of food quality (Hart 1985). Weyns's Duiker is diurnal, like the closely related Peters's Duiker (Wilson 2001).

Foraging and Food Ripe and unripe fruits are the most frequent foods in the diet of Weyns's Duiker in the Ituri Forest, comprising between 18% and 100% (mean = 69%) of a sample of rumens across the seasonal fruiting cycle (Hart 1985). In this same sample, foliage, primarily mature leaves fallen from the canopy, comprised the second most frequent food item (annual mean = 23%), with seeds, fallen flowers and fungi comprising the remainder of the diet. Many

Cephalophus weynsi

rumen contents contained small numbers of ants. It is not certain if these were ingested separately from other foods. Kingdon (1982) observed the species feeding on *Spathodea* flowers in W Uganda. In the Ituri Forest, fruits selected tend to be large to intermediate sized. Important plant families include: Irvingiaceae, Sapotaceae, Euphorbiaceae, Apocynaceae, Annonaceae, Ulmaceae, Sapindaceae and, seasonally, the mast seed-fall of dominant caesalpinaceous canopy species, *Julbernardia seretii* and *Cynometra alexandri*. The composition of Weyns's Duiker diets suggests that the species has a generalized foraging strategy, feeding on a range of species and food patch sizes in proportion to their availability (Hart 1985). Animals captured by hunters during periods of mast fruit seed-fall had layers of fat around their kidneys that were absent at other times of year. Several preferred fruit species (notably, *Klainedoxa gabonensis*, *Ricinodendron heudelotii* and *Irvingia grandifolia*) have large armoured seeds that Weyns's Duiker regurgitates intact during rumination. These species are adapted to ungulate and elephant dispersal (Feer 1995).

Social and Reproductive Behaviour Radio-collared Weyns's Duikers in mixed forest in the Epulu area, in the Ituri Forest, occurred in stable, highly cohesive and presumably related parties of 3–4 individuals. Two groups consisted of an adult male–female pair, accompanied by a subadult, and one group of four consisted of a pair accompanied by a subadult and another older animal of undetermined sex. The group of three (adult ♂ and ♀, with a subadult ♀) had individual core home-ranges that overlapped nearly completely over an entire year, and the animals often moved in spatial synchrony. Individual home-ranges in two other social groups also widely overlapped. These synchronized movements suggest strong territorial behaviour, with both sexes taking part in territorial defence. Radio-collared animals had average core home-ranges of 13 ha (adult ♂♂, $n = 4$) and 11 ha (adult ♀♀, $n = 5$), with total annual occupancy of 26–30 ha (adult ♂♂ and ♀♀, respectively) (J. A. Hart pers. obs.). East of the Albertine Rift, populations of Weyns's Duikers are most often observed as solitary

Weyns's Duiker *Cephalophus weynsi*.

animals (Kingdon 1982) or occasionally pairs; however, detailed information on home-range use and social behaviour are not available.

Development of group living in at least some populations of Weyns's Duikers is unusual in forest duikers, and separates this species from the closely related Peters's Duiker (Feer 1989a). In the Ituri Forest, the small individual home-ranges and defence of shared space, in combination with a generalized diet, may permit Weyns's Duikers to control areas of relatively higher overall food availability. However, intensive mate-guarding by adult ♂♂ is also not excluded as a driving factor. Group living may also contribute to anti-predator defence. Both ♂♂ and ♀♀ frequently utter whistled contact calls, in addition to loud bleating calls that they, as well as other duikers, utter when distressed. In the Ituri Forest, where Weyns's Duiker co-occurs with five other duiker species and the frugivorous Water Chevrotain *Hyemoschus aquaticus*, group living may provide this species with an advantage in inter-specific competition. In the Ituri Forest, White-bellied Duikers *C. leucogaster* occur in reduced numbers in areas where Weyns's Duikers are abundant in comparison with areas where they are uncommon or absent. Radio-collared White-bellied Duikers avoid areas controlled by Weyns's Duiker parties.

The commitment to social living has restricted this otherwise highly successful species from occupying some habitats. In the Ituri Forest, Weyns's Duikers are almost entirely absent from large areas of monodominant *Gilbertiodendron dewevrei* forest. Fruit resources in this forest are rare and widely dispersed over most of the year due to the low floristic diversity. This limitation is alleviated only during brief irregular periods of mast flower and seed production by *G. dewevrei*. The small, stable home-ranges of Weyns's Duiker, coupled with their reduced mobility, do not permit the species to take advantage of high-quality ephemeral food sources, unless these occur on the animal's home-range.

Reproduction and Population Structure In the Ituri Forest, 50% (11 of 22) of adult ♀♀ examined were pregnant over the course of a two-year study in a moderately to intensively hunted

area (Hart 1979, 2000, J. A. Hart pers. obs.). Pregnant ♀♀ were recorded in nearly every month. Seven of a total of ten lactating ♀♀ were recorded during the period Sep–Dec. This is the period of late rains, when fruit supplies are generally at their most abundant. One young is born at a time, and gestation period is not known. Two full-term embryos (1500 g and 1510 g) were recorded in Jun. Weigl (2005) reports longevity at 15 years in captivity. In the Ituri Forest, ♂♂ represented 42% of a total of 55 individuals captured. Of the 23 ♂♂, 52% ($n = 12$) were adults; in contrast, adult ♀♀ ($n = 24$), comprised 75% of a total of 32 ♀♀ captured ($n = 32$). The combination of skewed sex ratio, and younger cohort age, suggests higher mortality in ♂♂ in this population.

Predators, Parasites and Diseases Leopards *Panthera pardus* are the most important predator of Weyns's Duikers in the Ituri Forest; however, numbers killed are lower than would be expected given the species' abundance in the community (Hart, J. A. *et al.* 1996, Hart 2000). Diurnal habits and group living may contribute to reducing the extent of predation. African Golden Cats *Profelis aurata* are reported to capture this species occasionally (Y. Sugiyama pers. comm.). One carcass was reported from the nest of Crowned Eagles *Stephanoaetus coronatus* in Uganda (Skorupa 1989).

High frequencies of seropositive titres were recorded for bluetongue, leptospirosis and viral haemorrhagic fevers in a sample of animals tested in the Ituri Forest (Karesh *et al.* 1995). None of these individuals exhibited outward signs of disease; however, stressed animals frequently succumb to a herpes-like condition when brought into captivity, and latent infections may reduce overall fecundity. Helminths were found in the body cavity, often on the rumen surface of almost all freshly killed, butchered animals observed in the Ituri Forest (J. A. Hart pers. obs.).

Conservation IUCN Category: Least Concern. CITES: Not listed.

Weyns's Duiker is among the primary species hunted by the Mbuti net hunters in the Ituri Forest and populations may be severely reduced where hunting pressure is high (Hart 1979, 2000). Overall, however, this species, like the Blue Duiker, is among the more resilient species to human hunting pressure. Populations in some East African locations are at higher risk, especially in the isolated forest islands at the eastern edge of the range; at least one population in Nyungwe Forest, Rwanda, is suspected to be locally extinct. Otherwise, populations of the species occur in a number of protected areas, including Okapi Faunal Reserve and Maiko and Salonga National Parks (DR Congo), Kibale N. P. (Uganda), Mount Elgon N. P. (Kenya) and Mahale Mountains N. P. (Tanzania) (East 1999).

Measurements

Cephalophus weynsi

WT (♂♂): 17.1 (15.5–19.5.5) kg, $n = 12$

WT (♀♀): 17.5 (16.0–20.0) kg, $n = 22$

Cephalophus callipygus PETERS'S DUIKER

Fr. Céphalophe de Peters; Ger. Petersducker

Cephalophus callipygus Peters, 1876. Monatsb. K. Akad. Wiss. Berlin, p. 483. 'Africa occidentalis (Gabun)' (Gabon, Gabon River).

LEFT: Peters's Duiker *Cephalophus callipygus* adult male.
 ABOVE: Lateral view of skull of Peters's Duiker *Cephalophus callipygus* adult male.

Taxonomy Monotypic. Associated with the Natal Red Duiker *C. natalensis*, Aders's Duiker *C. adersi* and Weyns's Duiker *C. weynsi*, as a potential superspecies (Ansell 1972). Considered to be conspecific with the Natal Red Duiker (Wilson 1987) or not related (Groves & Grubb 1974). Weyns's Duiker has been described as a subspecies of Peters's Duiker (Kingdon 1982, 1997) or as a distinct species (Grubb & Groves 2001, Grubb 2005). The latter conclusion has been followed in this work. Molecular data have consistently placed Weyns's Duiker as a sister taxon to Peters's Duiker, within the 'West African red duiker' lineage (Jansen van Vuuren & Robinson 2001; and see Hassanin *et al.* 2012). Synonyms: none. Chromosome number: not known, but likely $2n = 60$.

Description Medium-sized duiker, with overall pale tawny pelage becoming red on the loins. The forehead and frontal crest is rich reddish in colour; the crest hair is forwardly curved. Sides of face greyish-fawn, and lips, chin and throat white. A fine black dorsal line begins in the middle of the back and widens on the base of the tail and croup. Underparts lighter coloured than the flanks. Legs darker than body, and there is a large blackish tail tuft. Females are about 12% heavier than ♂♂. There are large preorbital glands, covered with short rufous hair, present in both sexes, although those in ♂♂ are larger and more active; the slit is about 40 mm long, with 13–16 distinct large pores (Wilson 2001). Inguinal pouches not present. Well-developed pedal glands present. The newborn is darker in colour than adults, and Wilson (2001) notes that a newborn from the Central African Republic had the dark brown almost black dorsal stripe present extending down the back to the tail.

Horns present in both sexes, striated with massive transverse ridges, tips slightly converging and curving upward. Skull with strongly developed frontal boss as in Weyns's Duiker. Preorbital fossae deeper in ♂♂.

Geographic Variation None recorded.

Similar Species

Cephalophus weynsi. Allopatric sibling species, occurring in forests from

E DR Congo, east of the Cogo and Ubangui Rivers, to the western side of the Eastern Rift Valley. Darker pelage with longer dorsal stripe extending in a dark zone on withers; face with blackish tones. *C. ogilbyi*. The White-legged Duiker (*C. o. crusalbum*) is sympatric with *C. callipygus* in Gabon (e.g. Forêt des Abeilles) and NW Congo. Generally brighter colour with black dorsal line, black muzzle and marked dark brows; *C. o. crusalbum* has conspicuous white lower hindleg (Grubb 1978b, Gautier-Hion & Gautier 1994). J. Kingdon (pers. comm.) suggests that some individual specimens of Peters's Duiker with apparent *ogilbyi*-like characteristics might be wild hybrids between the two species. *C. leucogaster*. Broadly sympatric west of the Congo and Ubangui Rivers. Smaller in size, pale body with thick black dorsal stripe, underside sharply white. *C. dorsalis*. Sympatric nocturnal species, occurring in forests from Senegal to L. Tanganyika. Similar in size, but shorter-legged and smaller-headed, rich dark red body with black dorsal stripe and legs. *C. niger*. An entirely allopatric duiker from West Africa that resembles this species in morphology and size, but has glossy black pelage and lacks a black dorsal stripe.

Distribution Endemic to western central Africa in moist lowland forests of S and SE Cameroon, SW Central African Republic, mainland Equatorial Guinea, Gabon and N and SW Congo (East 1999, Wilson 2001). The Sanaga R. appears to be the northerly limit of distribution in Cameroon, although there are apparently museum specimens from north of the river (P. Grubb, in Lamarque *et al.* 1990). It is unlikely that this species occurs in extreme W DR Congo, east of the Ubangui R. and north of the Congo R., since there are large collections from this region in the Tervuren Museum in Belgium, which include other antelopes but not this species (P. Grubb, in von Richter *et al.* 1990).

Habitat Peters's Duikers inhabit moist lowland forest. They prefer primary forest, but are also present in logged forest, probably because they prefer heterogeneous undergrowth (Feer 1989a). In Gabon, Peters's Duikers mostly occupy mature forest, but have also been recorded in remote old secondary forest, riverine forest and seasonally

inundated terrain (Lahm 1993). In S Cameroon, Peters's Duikers occur in secondary forest and farm-bush (Fotso & Ngnegueu 1997).

Abundance Peters's Duiker is the second or the third most abundant duiker in undisturbed forests of NE Gabon, where densities can reach 25/km² (net capture Dubost 1979), 13–15/km² (net capture Feer 1988) and 6.7/km² (line transect Lahm 1993). In forests of S Central African Republic they rank third among duikers and densities are 0.9/km² (line transect) and 0.9–1.2/km² (net count Noss 1999). As a result of hunting, densities decrease near villages in NE Gabon (Lahm 1993), in S Cameroon (Muchaal & Ngandjui 1999) and S Central African Republic (Noss 1999). East (1999) estimated a total population size of about 382,000.

Adaptations When alarmed, Peters's Duikers may freeze before running for cover; they flee quickly at short distances, occasionally with barking. The median and distal segments of the hindleg are relatively longer than in the Bay Duiker *Cephalophus dorsalis* and correspond to the 'semi-runner' type of duiker (Feer 1988).

Living under a canopy with numerous fruit-plucking and fruit-dropping primates, bats and birds, this species is able to sustain a more frugivorous diet than other species of duiker. Dependence on a year-round fruit supply may explain why this species is mainly restricted to the consistently fruit-rich main forest block in west-central Africa while its very closely related sibling, Weyns's Duiker, occupies equivalent areas to the east of its range and the somewhat less closely related, but very similar Black Duiker *C. niger* occupies the main medium-sized duiker frugivore niche to the west of its range (J. Kingdon pers. comm.).

Peters's Duikers are active during the day, resting from around mid-day to late afternoon. As in other diurnal duiker species, the orbits are less dorsally oriented than in the nocturnal Bay Duiker. Females mostly prefer dense undergrowth, both for diurnal rest and for activity (Feer 1989a).

Foraging and Food One of the most frugivorous of duikers (Dubost 1984, Feer 1989b, Gagnon & Chew 2000, Wilson 2001). In two studies in Gabon (Dubost 1984, Feer 1989b), fruit comprised between 82.7% and 89.6% of the diet by dry weight based on examination of stomach contents. Leaves comprised between 7.9% and 10.0% of the diet, with petioles and stems following at 6.2%. Fruit and leaves were found in all stomachs in both studies. Flowers, fungi and animal matter (mostly insects) are found in fewer than 50% of samples and comprise less than 1% of the diet (Dubost 1984). Unweaned animals eat much less fruit than adults (52.7%) and more leaves (37.0%) (Dubost 1984). Fruit consumption is lowest from Mar to May (short wet season) whereas leaves are eaten significantly more throughout the rest of the year (Feer 1989b). Most of the fruit consumed are drupes or berries (77%), 1–5 cm in size (80%). Dubost (1984) identified 55 fruit species ($n = 20$ stomachs) and Feer (1989b) recorded 110 species ($n = 68$). The favoured species of fruits are *Xylopia hypolampra*, *Cylindropsis parvifolia*, *Canarium schweinfurthii*, *Klainedoxa gabonensis* (Dubost 1984) and *Dacryodes büttneri*, *Santiria trimera*, *Polyalthia suaveolens* and *Irvingia gabonensis* (Feer 1989b). During rumination, Peters's Duiker spit out intact protected seeds of ten plant species (Feer 1995). While foraging, the daily mean ranging distance in subadults and adults varies between 2600 m and 4090 m in ♂♂ and between 1870 and 4290 m in ♀♀ and decreases during the long wet season (Feer 1989a). Peters's Duiker increases its daily range when food resources become rare. Wilson (2001) mentions an interesting observation of this duiker deliberately hunting and capturing a Hartlaub's Duckling *Pteronetta hartlaubi*.

Social and Reproductive Behaviour Peters's Duikers are most often solitary (67% of observations, Feer 1988). Adult ♀♀ have stable home-ranges of ca. 40 ha. Male home-ranges are of similar size and include several overlapping ranges of ♀♀ and young. Adult ♂♂ are very intolerant of other ♂♂ in captivity and their home-ranges do not overlap. Female home-ranges are completely separated or overlapping when family bonds exist between them. Both sexes preferentially use locations situated near the perimeter of home-range. Males use a larger portion of their home-ranges on a daily basis than do ♀♀ (Feer 1989a). Males and ♀♀ frequently mark by scraping twig bark with their horns and depositing preorbital secretions (Dubost & Feer 1988). Middens or ritualized defecation were not observed. Social play, reciprocal allogrooming and marking of the partner were observed in captive animals (Dubost & Feer 1988).

Reproduction and Population Structure Histology suggests a sexual maturity at 17 months of age for ♂♂ and ca. 20 months for ♀♀. In Gabon, reproduction occurs all year round, although births peak twice a year at the beginning of the dry seasons when fruit availability or food qualitative richness is most favourable (Dubost & Feer 1992). Around 29% of ♀♀ over 20 months old are pregnant. This figure seems underestimated possibly because of a bias of the sample related to lower mobility, and thus less capture of some pregnant animals (Feer 1988). Two near-term fetuses measured by Wilson (2001) had masses of 2.7 kg and 2.9 kg. Weaning takes place when the maximum amount of fruit resources or leaves is available (Dubost & Feer 1992). In Gabon, a sample of 339 individuals from a moderately hunted population comprised 35% adults; ♂♂

accounted for 43.5% of adults. However, in a sample captured by nets, the proportion of ♂♂ was 27.3%, corresponding more to the observed social life pattern. Mortality of subadult and young adult ♀♀ is higher than in ♂♂ (Feer 1988).

Predators, Parasites and Diseases Peters's Duiker is potentially preyed upon by Leopards *Panthera pardus* (Hart, J. A. *et al.* 1996); hairs of red duikers were observed in a felid scat in Gabon (F. Feer pers. obs.). Diseases and parasites in the wild are unknown.

Conservation IUCN Category: Least Concern. CITES: Not listed.

The primary threats to the survival of the species are habitat loss due to human settlement and hunting (Lahm 1993, East 1999). Because Peters's Duiker prefers undisturbed primary forest, its future survival may be increasingly dependent on protected areas. At present the protected areas within which it is common, for example Dja Wildlife Reserve and Lobéké N. P. (Cameroon), Dzanga-Sangha Special Reserve and Dzanga-Ndoki N. P. (Central African Republic), Odzala and Nouabalé-Ndoki National Parks (Congo), Lopé, Ivindo, Minkébé, Loango and Moukalaba-Doudou National Parks (Gabon) and Monte Alén N. P. (Equatorial Guinea), receive unequal levels of protection and management.

Peters's Duiker is frequently the most abundant medium-sized duiker species in undisturbed areas, but its populations are heavily harvested. Peters's Duiker is especially affected by snare hunting. In the Central African Republic, Peters's Duikers accounted for 29% of all animals captured in snares, a level that appears to be unsustainable (Noss 1998a). In Gabon, the proportion of Peters's Duikers among duikers captured in snares is five times the proportion harvested with guns (Lahm 1993). In N Congo, they comprised 21% of all animals

killed with shotguns (Mockrin *et al.* 2011). In Dja Reserve they are the most frequently captured species and accounted for 48% of duikers hunted (Fotso & Ngnegueu 1997), but at another site in the same area this species accounted for 20% of duikers killed (Muchaal & Ngandjui 1999). In Gabon, Peters's Duikers comprised 9% of duikers caught by village hunters and trappers (Lahm 1993). In Congo, Peters's Duikers represent only 4% of duikers for sale in Brazzaville bushmeat markets (F. Feer pers. obs.) and is rarer in Pointe Noire (Wilson & Wilson 1991). Peters's Duiker ranks between third and fifth among the game species proposed in Libreville (Gabon) markets, with a mean number of animals sold ranging from 2.0 to 6.6 per day (Ntsame Effa 2005).

Measurements

Cephalophus callipygus

HB (♂♂): 977 (940–1060) mm, n = 11

HB (♀♀): 1025 (970–1090) mm, n = 14

T (unsexed): 120–150 mm

HF c.u. (♂♂): 251 (240–270) mm, n = 7

HF c.u. (♀♀): 250 (240–260) mm, n = 7

Sh. ht (♂♂): 532 (490–550) mm, n = 12

Sh. ht (♀♀): 549 (510–570) mm, n = 13

WT (♂♂): 19.6 (17.5–21.5) kg, n = 10

WT (♀♀): 21.9 (18.6–25.2) kg, n = 7

Gabon (Feer 1979, F. Feer pers. obs.)

Maximum recorded horn length is 14.9 cm for a pair of horns from Lomié, Cameroon (Rowland Ward)

Cephalophus niger BLACK DUIKER

Fr. Céphalophe noir; Ger. Schwarzducker

Cephalophus niger (Gray, 1846). Ann. Mag. Nat. Hist., ser. 1, 18: 165. 'Guinea', but apparently Ghana, Shama.

Black Duiker *Cephalophus niger*.

Taxonomy Seven years after Gray first named this species, Temminck described it under the name *Antelope pluto*. According to Grubb (2005), the type 'came from the Leiden Museum, one of a series from Chama (= Shama) and Dabocrom, Ghana, including the syntypes of *pluto*. Only the specimens from Dabocrom were retained in Leiden (Jentink, 1892) so presumably the type is from Shama.'

In morphology, size, behaviour and ecology this duiker is the Upper Guinea equivalent of Peters's Duiker *C. callipygus* and Weyns's Duiker *C. weynsi*. In colour and in a smooth neck and swollen nostrils it resembles the larger Abbott's Duiker *C. spadix* and Yellow-backed Duiker *C. silvicultor*. In some formulations of their mtDNA studies, Jansen van Vuuren & Robinson (2001) suggested that the *callipygus/weynsi* and *spadix/silvicultor* lineages were widely divergent whereas in other, more plausible, topologies they associated all these large, smooth-necked duikers in a single but complex cluster of species. Synonyms: *pluto*. Chromosome number: 2n = 60; the X chromosome is a submetacentric (Hard 1969).

Lateral view of skull of Black Duiker *Cephalophus niger*.

Description A heavily built, long-bodied, long-headed, glossy black duiker with swollen nostrils and relatively short stocky legs. Short hair on the face is often very thin or absent, probably abraded by frequent rubbing of the face and preorbital glands. Bridge of the nose black or dark brown graduating to a coronal tuft of dense reddish hair; rest of the face dull grey or, in some individuals, red. Lower jaw and upper throat off-white, dull cream or grey. Backs of ears dark brown, anterior surfaces with short, sparse off-white hairs. Neck black or brown, covered in short hair, and with thickened skin. Back intensely black, long and coarsely haired; legs, flanks and underside black or very dark brown with rufous tinge on upper, inner surfaces and on buttocks. Individual hairs have straw-coloured bases (Grubb & Groves 2001). Wilson (2001) comments that of 186 adults examined across the range of the species, only two exhibited any signs of small patches of white on them: a ♂ from Kumasi had a circle of white hair on the left hindleg near the tail, and another ♂ from Cape Coast in Ghana had three irregular patches of white hair on the left side between the front- and hindlegs. Tail brown and thinly haired except for a terminal tuft, which has a whitish tip. Juveniles similar in colour, but with less red on face and paler below (Grubb & Groves 2001). Sexes of similar size, although ♀♀ are on average larger, especially in mass (Wilson 2001); ♂♂ have longer, more robust horns. Wilson (2001) notes that the average preorbital gland of an adult ♂ was 500 mm long, with a single line of 35–50 pores, from which a white secretion could be squeezed; preorbital glands are smooth and the area surrounding the slit and pores is naked. Pedal glands are present on both fore- and hindfeet. No trace of inguinal glands has been found.

Grubb & Groves (2001) include among distinguishing characteristics of the skull: preorbital pits extending forward to premaxillae, and downward to molar alveoli; a well-defined groove between frontals, which are thickened and slightly convex; zygomatic arch straight; and supraorbital foramina often partly roofed over by lateral extension of frontal thickening.

Geographic Variation No significant variation has been recorded, but individuals vary in intensity of black and in the extent of rufous colour on head.

Similar Species

Cephalophus callipygus. An entirely allopatric duiker from western central Africa that resembles this species in morphology and size, but has rich red colouring and a black dorsal stripe.

C. ogilbyi. Brooke's Duiker (*C. o. brookei*) is sympatric from Sierra Leone to Ghana. A smaller, almost extinct sympatric duiker of reddish colour.

C. spadix. A larger, allopatric duiker from East Africa that closely resembles this species in colour, but is distinctly larger.

Cephalophus niger

C. silvicultor. A much larger sympatric species with prominent yellow back.

Distribution Endemic to Africa, occurring in forested and formerly forested areas from near Kindia in SW Guinea and eastwards through Sierra Leone to the Niger R.; there are no confirmed records from Benin or from Burkina Faso (East 1999, Wilson 2001). There is no indication that the species has ever occurred east of the Niger R., and reference to the species occurring in Cameroon (Jeannin 1936) are in error; similarly, records from Boshi–Okwango forests on the Nigerian border with Cameroon cannot be accepted (Anadu & Green 1990). It is particularly common and successful in the central parts of its range, from Liberia to Ghana, but is rare or declining both east and west of this heartland.

Habitat Primarily found in disturbed and secondary forest, but also inhabits forest galleries, thickets and is especially common in secondary 'farm-bush'. Black Duikers are also found, albeit more rarely, in primary rainforest (Jeffrey 1974). In Liberia, Peal & Kranz (1990) described them favouring secondary bush and riparian habitats. In Côte d'Ivoire, the Black Duiker was one of the two most frequently observed species in mixed farmland mosaics (along with Maxwell's Duiker *Philantomba maxwelli*), and the least frequently observed of the five small- and medium-sized species present in closed-canopy forest (Newing 2001). In a study of 251 carcasses in Ghanaian markets and 41 sightings, Wilson (2001) recorded the majority from various categories of secondary vegetation; less than 10% came from unlogged high forest. Of a smaller sample of 46 records, Anstey (1991) found only 13% in high forest. Wilson (2001) attributes these habitat preferences to a greater variety of food plants and to the denser cover growing under a felled or partial canopy. Of special interest is the role of an American invasive hemp-like species, *Chromolaena odorata*, which forms dense thickets after forests have been cleared. For Black Duikers the attraction of these 'Akyempong

weed' thickets seems to be the cover they provide as the plant did not feature in an exhaustive study of Black Duiker diets (Wilson 2001).

Abundance The Black Duiker's preference for regrowth after forest felling probably led to initial increases in abundance throughout the former forest zones of Upper Guinea, but intensification of agriculture and the spread of vehicles, road networks, markets, firearms, spotlights and snares, all in the service of an increasing human population, eventually offsets initial increase. Once regarded as extremely abundant in Sierra Leone, where eight species of duiker were known, Stanley (1925) reported 'by far the commonest are the black duiker and Maxwell's duiker (the bushgoat and fritambo of the Creoles), which are found everywhere in Sierra Leone where there is plenty of cover, preferably forest regrowth'. By 1990 this species had become restricted to isolated pockets where it continued to decline (Teleki *et al.* 1990). In Liberia, Anstey (1991) considered it the most widely sighted duiker, and the second most frequently recorded in bushmeat markets in Liberia. In Côte d'Ivoire, Newing (2001) recorded the species as being very common in secondary habitats. Wilson (2001) suggested that the Black Duiker was more common in Ghana than anywhere else in West Africa, and the second most common forest duiker in the country after Maxwell's Duiker. This species is still abundant in many other parts of its range and a density of 2/km² in the more favourable localities has been suggested by East (1999), who estimated the total population to be about 100,000.

Adaptations There are interesting questions raised by a switch from predominantly red to black colouring in several lineages of duikers. Within the *callipygus/weynsi/niger* complex, melanistic colouring occurs in the far west and far east of their range. Both Peters's Duiker and Weyns's Duiker are vividly coloured red duikers, but one race of the latter, *C. w. lestradei*, and occasional individual variants from other parts of this species' range are very dark brown or nearly black (a change in colouring that seems to derive from extensions of the very variable black dorsal stripe). It has been reported that the Black Duiker is nocturnal (Sclater & Thomas 1899) or crepuscular (Wilson 2001), and it could be argued that dark colouring might represent a type of crypsis appropriate to this activity, with predation by Leopards *Panthera pardus* providing the principal selective pressure. However, captives in Monrovia Zoo were found to be active at night only 24% of the time and 69% during the day (Newing 2001), and other authors (Dunn 1991, Anstey 1991, and see Hoppe-Dominik *et al.* 2011) have recorded diurnal activity, so the link between dark colouring and nocturnal habits seems unlikely. An alternative explanation could be that visual communication has some intra-specific utility for bright red duikers that live at high densities in relatively open undergrowth, whereas equally large numbers of duikers living in denser vegetation rely more on auditory, olfactory or indirect clues to regulate intra-specific contacts. If this is so, then dark colouring could be characterized as a sort of 'cancelling out' of the visual channel, except at very close quarters, where ear and face markings can enhance expressions and intention movements.

This species shares with both Peters' and Weyns's Duikers a strongly reinforced forehead that is especially thick in ♂♂. This peculiarity implies adaptation to exceptionally severe concussion during intra-specific fighting. The special development of this reinforcement in

♂♂ makes it less plausible that it evolved to break open large, hard fruits or even to butt fruit-bearing trees. These might, of course, be secondary benefits of hard-headedness. To date neither aspect of behaviour has been confirmed, but there are widespread hunter's stories of this species felling banana *Musa paradisiaca* and pawpaw *Carica papaya* trees to get at the fruit (Wilson 2001). Assuming that the selective pressure favouring reinforcement of the forehead was the ability to withstand head-butting, especially among ♂♂, the frequency of confrontations implies either a naturally high density of territorial ♂♂ or a high level of competition for ♀♀. What little is known of all three species supports the former explanation. A significant difference, however, is that Peters' and Weyns's Duikers inhabit well-developed, multi-species mature high forest whereas the Black Duiker prefers thick secondary growth, a preference that places it closer to Abbott's Duiker and the Yellow-backed Duiker. This suggests that the Black Duiker occupies an ecological position in between the two giant duikers and the larger red duikers of the main forest block. This conclusion has some support from the molecular trees of Jansen van Vuuren & Robinson (2001) and there is the implication that with phylogenetic enlargement of duiker body sizes there may have come a point where high-quality diets might have had to give way to less selective, broader-band feeding habits, especially in disturbed or secondary forests. If that is the case, the Black Duiker's biology might illustrate some of the conditions that favoured increase in the size of duikers.

Black Duikers are well known for digging up subterranean plant parts and for employing their sharp hooves to slash and break up edible roots. Among the tubers regularly excavated and eaten by Black Duikers are those of the introduced exotic cassava *Manihot esculenta*. As these tubers are known to harbour strong toxins in their unprocessed state it is clear that the Black Duiker has a natural resistance to certain plant poisons (Wilson 2001).

Foraging and Food Fallen fruits, flowers and leaves from the forest floor, as well as bulbs, rhizomes, fungi, bark and occasional animal matter, make up the diet. In Liberia, Black Duikers have been recorded following Western Pied Colobus *Colobus polykomos* for canopy waste, presumably mostly leaf and stem material. The bulk of their diet is fruit, and every one of 131 stomachs retrieved from Ghanaian markets and examined by Wilson (2001) contained pieces of fruits or whole fruits and seeds. Figs *Ficus* spp. were a major food throughout the year, as were *Nauclea latifolia*, *Canthium vulgare*, *Lecaniodiscus cupanoides*, *Blighia sapida* and *Solanum* spp. Other more seasonal fruits were *Cola gigantea* (May, Jun and Sep–Dec), *Anchomanes difformis* (Nov–Mar), *Griffonia simplicifolia* (Oct–Mar), *Musanga cecropoides* (Feb–Mar), *Alchornea cordifolia* (Feb–Apr), *Phyllanthus discoides* (Jun–Aug), *Antholeista djalensis* (Mar–May) and *Canavalia ensiformis* (Sep–Nov).

This spread of wild fruits was augmented by visits to cultivated crops; in 35 of the stomachs, the bulk of the food was from cultivation. The most important of these were: oil nut palm dates *Elaeis guineensis*, avocados *Persea americana*, cassava, coffee *Coffea canephora*, new cocoyam *Xanthosoma* sp., cocoa *Theobroma cacao*, pawpaws, bananas and cow-itch *Mucuna pruriens*. As a very high proportion of these food plants are exotic to Africa, it is clear that Black Duikers have a naturally catholic diet and, in spite of intensive hunting, have found some benefits from partial forest clearance and low-intensity

agriculture. Wilson (2001) found animal matter in 15% of his sample and he also recorded Black Duikers feeding on an open sea-side beach where he thought minute shells (perhaps salt-retaining types?) were the attraction. In total, Wilson (2001) recorded some 27 species of fruit or cultivated crops eaten. In a similar study, Hofmann & Roth (2003) examined 57 stomachs and recorded a total of 33 different types of fruit eaten. Their study also confirmed that Black Duikers frequent cultivated lands for feeding and are not dependent on primary forest habitat for food; leaves of cassava were found in 53% of stomach samples, and leaves of *Alchornea cordifolia* in 18% of stomachs. Black Duikers are believed to play an important role in the dispersal and germination of small seeds, such as *Solanum verbascifolium* (Alexandre 1982). Newing (2001) found that Black Duiker mouths and teeth could break open food items up to a diameter of 6 cm.

Social and Reproductive Behaviour A territorial and mainly solitary species: of 53 sightings made by Wilson (2001), 39 were of single animals, ten were of male–female pairs (three accompanied by an infant) and four were of ♀♀ with young. Duikers in general are known to respond to bleat-like calls and this susceptibility is widely exploited by hunters. The Black Duiker appears to be particularly responsive to artificial lures blown on whistles that are cut from fern stems in Liberia (Wilson 2001). What attention-getting calls could signify in the social and spatial structures of a solitary species remains to be elucidated.

Reproduction and Population Structure Although pregnant ♀♀ have been recorded in every month of the year, Wilson (2001) recorded a very marked birth peak between Nov and Jan (the wet season) based on reproductive tracts of 106 sexually mature ♀♀ collected mainly in Ghana. Of the ♀♀ examined, 72.6% were either pregnant or lactating and of these nearly 10% were both pregnant and lactating. Females are capable of conceiving at one year of age (Wilson 2001). Such fecundity helps explain how Black Duikers have managed to survive very high mortality rates from the bushmeat trade in West Africa. Although ovulation had taken place in both ovaries, Wilson (2001) found that single foetuses were always implanted in the right horn of the uterus; he found that neonates weighed between 1.65 and 2.31 kg at birth (with no difference between the sexes). Captive Black Duikers weigh 1.4–2.2 kg at birth, doubling in weight after the first month (Barnes *et al.* 2002). Weaning occurs at between 80 and 108 days (Wilson 2001). Captive animals have lived to more than 14 years (Weigl 2005).

Predators, Parasites and Diseases Lions *Panthera leo*, Leopards and African Rock Pythons *Python sebae* are known predators (Wilson 2001, Bodendorfer *et al.* 2006). Young may be predated upon by

Servals *Leptailurus serval*, African Golden Cats *Profelis aurata*, Eagle-owls *Bubo* spp., Martial Eagle *Polemaetus bellicosus* and Crowned Eagle *Stephanoaetus coronatus*. Ntiemoa-Baidu *et al.* (2005) recorded the following ixodid tick species from animals in Ghana: *Haemaphysalis parvata*, *H. leachi*, *Ixodes muniensis*, *I. moreli*, *I. aulacodi*, *Rhipicephalus ziemanni*, *R. simpsoni* and *Amblyomma compressum*.

Conservation IUCN Category: Least Concern. CITES: Not listed.

Their adaptability to degraded and secondary forests has enabled Black Duikers to withstand settlement better than other medium-sized forest duiker species in West Africa, and while they have been eliminated from the more densely settled parts of their range they still occur relatively widely within their historical range. They also show resilience to hunting and remain locally common; they have been recorded as extirpated from several reserves in Ghana (e.g. Digya N. P. and Kalakpa Resource Reserve; Wilson 2001), but in fact do still persist in these areas (R. J. Dowsett pers. comm.). Dunn (1991) noted that long after all primates had been shot out in parts of Liberia, the Black Duiker persisted. None the less, East (1999) has warned 'If current trends continue, including a complete lack of effective protection and management over most of its range, its status will eventually decline to threatened.' Black Duikers are well represented, generally in stable numbers, in protected areas such as Sapo N. P. (Liberia), Western Area F. R. (Sierra Leone), Taï N. P. and Comoé N. P. (Côte d'Ivoire) and Bia, Nini-Suhien and Kakum National Parks (Ghana).

Cephalophus spadix ABBOTT'S DUIKER

Fr. Céphalophe d'Abbott; Ger. Abbottducker

Cephalophus spadix True, 1890. Proc. U.S. Natl Mus. 13: 227. 'High altitudes on Mt. Kilima-njaro, frequenting the highest points' (Tanzania, Mt Kilimanjaro; at 2400 m according to Grimshaw *et al.* 1995).

Abbott's Duiker *Cephalophus spadix*.

The common name is after W. L. Abbott, an American naturalist and explorer who spent 1888–89 in the Kilimanjaro district, collecting zoological specimens.

Taxonomy According to Sclater & Thomas (1899), F. True suggested that '*C. spadix* was closely allied to *C. niger* and even possibly identical with it'. Roosevelt & Heller (1915) suggested that it was more closely related to the group of giant duikers of which the Yellow-backed Duiker *C. silvicultor* is typical, and Hattenorth (1963) considered Abbott's Duiker a subspecies of *silvicultor*. Kingdon (1982) indicated that Abbott's Duiker was closely related to the Yellow-backed Duiker and probably represented a relic of an ancestral population. Wilson (2001) interpreted the skull morphology to suggest that Abbott's Duiker is primitive with respect to both the Yellow-backed Duiker and the Bay Duiker and considered it a near-perfect morphological ancestor. A cladistic analysis that considered 41 morphological characters highlighted the monophyly of the *silvicultor* group and, within this, a split between *dorsalis* versus *jentinki* / *silvicultor* / *spadix* (Grubb & Groves 2001). Molecular phylogeny of seven duiker species representative of four supposed adaptive lineages has confirmed the existence of a distinct, giant duiker lineage that includes *silvicultor*, *spadix* and *dorsalis* (Jansen van Vuuren & Robinson 2001). Synonyms: none. Chromosome number: not known.

Description A large, stocky duiker with a glossy, dark brown pelage, especially on the back, flanks and upper legs. Neck and face are paler, greyer brown. A prominent russet hair tuft between the ears is dense, tinged with black and usually lighter basally. Throat, ventrum and inner thighs are sometimes paler brown, with white fur in the genital area. The extent of the paler ventral hair can vary between individuals within the same population (T. Davenport & S. Machaga unpubl., F. Rovero pers. obs.). The wedge-shaped head ends with a broad, flat-

Lateral view of skull of Abbott's Duiker *Cephalophus spadix*.

fronted nostril pad that overhangs the mouth (as with Yellow-backed Duikers). The rhinarium is shiny black. Ears are rounded with naked and grey-pinkish inner surfaces. Lower parts of the legs are slightly darker brown to almost black and end in black hooves, the front ones longer than the hind ones. Tail short, dark grey to black on the outer, dorsal portions and paler grey to white on the inner surfaces and tip. A six-month old juvenile from West Usambara appeared uniformly paler brown than adults, including head and neck, and had a darker brown dorsal stripe. The skin of a juvenile from Mount Rungwe exhibited longer fur than adults (T. Davenport & S. Machaga unpubl.).

Kingdon (1982) mentioned 'a hint of the yellow-back of *silvicultor* is visible in the form of a small grey patch above the root of the tail', and Grubb & Groves (2001) mention a 'vague dark dorsal stripe' and note that two skins in the British Museum show what may be rudiments, or precursors, of the *silvicultor* dorsal markings at the base of the tail. Wilson (2001) found no signs of such markings in two adult ♀♀ examined and no markings were evident on at least four individuals camera-trapped in the Udzungwa Mts (F. Rovero pers. obs.). However, in three of five skins from Mt Rungwe, a very slight, approximately 5 cm-wide, darkening of hair along the spine from the lower neck to the rump is visible, although there is no obvious grey patch above the root of the tail (T. Davenport & S. Machaga unpubl.).

Both sexes possess horns (8–12 cm long), which are mostly hidden in the hair tuft. Horns are without any conspicuous thickening at their base.

Geographic Variation No subspecies have been described and no geographical variation is reported. The coat colour of a captive adult pair from West Usambara appeared remarkably darker brownish, almost black, with less evident, contrasting paler underparts, than several individuals camera-trapped in the Udzungwa Mts (F. Rovero pers. obs.); the same is true of Mt Rungwe animals (T. Davenport & S. Machaga unpubl.). It is likely that variation in coat colour occurs within populations as much as between populations.

Similar Species

Cephalophus niger: Allopatric species from West Africa. Considerably smaller, the body is black with more contrasting paler neck and head, and similar reddish hair tuft.

C. silvicultor: Allopatric species from the Guineo-Congolian forests. Slightly larger, greyish-brown with a vivid cream-coloured patch on the back.

Distribution Endemic to Africa, being confined to a few isolated forested massifs in N, E and SW Tanzania (Kingdon 1982, 1997, East 1999). It is currently reported from Mt Kilimanjaro, W Usambara Mts, Rubeho Mts, Udzungwa Mts and Mt Rungwe (Wilson 2001, Moyer 2003, F. Rovero pers. obs.), as well as the forests of Livingstone (now part of Kitulo N. P.), Irungu, Irenga, Ndukunduku and Madehani in the Southern Highlands (Wilson 2001, Machaga & Davenport 2004, T. Davenport & S. Machaga unpubl.). Surveys in the Udzungwa Mts have extended their known distribution to nine discrete forests (Jones & Bowkett 2012). However, recent work in Madehani failed to record the animal (T. Davenport pers. obs.). In the Uluguru Mts, the most recent published record is from Swynnerton & Hayman (1951), and no signs were obtained during extensive surveys in the last few years (Frontier-Tanzania 2005), including a camera-trap survey in Uluguru North F. R. in 2005 (F. Rovero & A. Bowkett unpubl.). A previously unknown population of Abbott's Duiker, estimated at a maximum of 50 individuals, was discovered in 2006 in a montane forest locally called 'Ilole', in the southern Rubeho Mts (Rovero *et al.* 2008), while no records are reported from other forests of this area (Doggart *et al.* 2006, F. Rovero pers. obs.). Among other highland forests of Tanzania, Abbott's Duiker was not reported to occur from recent surveys in North Pare, South Pare, Nguru, Nguu, Ukaguru and Mahenge Mts (Tanzania Forest Conservation Group unpubl., Frontier-Tanzania unpubl.).

The historical distribution also included forests on the Rift Wall near Babati in C Tanzania, forests above L. Manyara, the Poroto Mts and Mfrika Scarp in the Southern Highlands (Rushby & Swynnerton 1946, Swynnerton & Hayman 1951), as well as Mporoto, Mpara, Sawago and Njombe Forest Reserves and possibly Mbeya Range (T. Davenport & S. Machaga unpubl.). However, it is probable that they have been extirpated from all these sites (Rovero *et al.* 2005). Reports of this species being present in Sierra Leone and Ghana are clearly in error, and likely refer to Black Duiker *C. niger* (see references in Grubb *et al.* 1998).

Habitat Typical habitat is montane and sub-montane moist forest; in Mt Kilimanjaro it is reported as commonest between 1300 and 2700 m (see Grimshaw *et al.* 1995) in forest and high-altitude swamps, scrub and moorland. In the Udzungwa Mts, Abbott's Duiker has been recorded as low as 300 m in Matundu Forest, a large, lowland and semi-deciduous forest (Rovero & Marshall 2009), as well as on the highest peak (Mt Luhombero, 2600 m; Rodgers & Swai 1988). It has been camera-trapped on several occasions in semi-deciduous to evergreen forests with dense understorey in Matundu and Mwanihana forests at 500–800 m in Udzungwa Mountains N. P. (Rovero *et al.* 2005, F. Rovero pers. obs.). On the Uzungwa Scarp it has been sighted on bamboo-dominated ridges at 1700 m (J. Fjeldså pers. comm.). It is known from disturbed and secondary montane forest and bamboo forest to 2500 m and occasionally plateau grassland to 2800 m on Mt Rungwe and in Livingstone–Kitulo in the Southern Highlands (T. Davenport & S. Machaga unpubl.). These records suggest that Abbott's Duiker, if undisturbed, occurs also in lowland, semi-deciduous forest with clearings and large areas of secondary vegetation.

Abundance Abbott's Duiker is one of the rarest duiker species (East 1999). However, there is very little information to infer reliable estimates of population densities. It is sighted too infrequently to be counted using diurnal, line-transect methods (Rovero & Marshall 2004), while camera-trapping is proving a potentially useful technique (Rovero *et al.* 2005). East (1999) used comparative data to derive a conservative estimate of 1 individual per km² in optimal habitat. Camera-trapping data from the Udzungwa Mts fed into a regression equation relating sighting rates to estimated densities obtained for Harvey's Duiker *Cephalophus harveyi* suggest maximum densities of 1.3 Abbott's Duikers per km² (F. Rovero pers. obs.). Albeit preliminary, this figure matches the estimation given by East (1999). From in-forest follows, tracking, habitat suitability analyses and hunting surveys, it is estimated that there are fewer than 40 individuals throughout Mt Rungwe and Livingstone (T. Davenport & S. Machaga unpubl.). East (1999) and Moyer (2003) gave total population size in the range of 1500–2500 individuals based on estimated area of occupancy. However, these did not account for the dramatic decline of Abbott's Duiker due to hunting in potentially suitable habitat, especially over the last decade (e.g. Uzungwa Scarp F. R., Mt Rungwe and Livingstone, West Usambara Mts and West Kilimanjaro). Therefore, although the total population size is unknown, it is probably less than 1500 individuals (Rovero *et al.* 2005).

Adaptations This is an extremely secretive species, occurring at low densities and very rarely seen even where it is considered relatively common. Furthermore, it appears to be mainly nocturnal and crepuscular (F. Rovero pers. obs.), and capture times of 25 photographs from several sites in Udzungwa Mts N. P. show that 52% were taken at night, 16% from 06:00h to 07:00h and from 18:00h to 19:00h, and 32% in the day (F. Rovero pers. obs.).

Foraging and Food Kingdon (1997) indicates that the diet of this species includes fruits, flowers, green shoots and herbage, and that it has been recorded browsing the leaves of a balsam (*Impatiens elegantissima*). In the Udzungwa Mts, it has been seen browsing both on understorey leaves in closed forest and on marshy vegetation in forest clearings (T. Jones & F. Rovero pers. obs.), and one individual was camera-trapped

with a large frog in its mouth (Rovero *et al.* 2005). Wilson (2001) reports Abbott's Duikers on the lower slopes of Mt Kilimanjaro crop-raiding and feeding on sweet potato leaves and tubers, bananas, cassava leaves and cowpeas; he also saw an adult Abbott's Duiker eating pieces of green moss from rocks. In the Southern Highlands on Mt Rungwe, Abbott's Duikers have been reported eating various balsams *Impatiens* spp., the climbing herb *Begonia meyeri-johannis* and beans from local shambas (Machaga & Davenport 2004).

Social and Reproductive Behaviour There is an almost complete lack of behavioural notes on Abbott's Duiker. All sightings and camera-trap records are of single individuals except for one mating pair (see below) and a ♀ with a two-month-old juvenile (Wilson 2001). It is likely that Abbott's Duiker is mainly solitary, as claimed by all hunters of the species in the Southern Highlands (T. Davenport & S. Machaga unpubl.) and as reported for the Yellow-backed Duiker (Kingdon 1997). When disturbed, no alarm vocalization is usually emitted (T. Jones pers. obs.), in contrast to other forest antelope species. In the Udzungwa Mts, an adult Abbott's Duiker was briefly observed following a large group of Sanje Mangabeys *Cercocebus sanjei*, which were foraging on the forest floor (T. Jones pers. obs.).

Reproduction and Population Structure A camera-trap photograph of a mating pair was taken on 27 Jan in Mwanihana Forest, Udzungwa Mts (F. Rovero & T. Jones pers. obs.). Wilson (2001) reports two births that occurred in Aug/early Sep and suggests that as Abbott's Duikers are found mainly in wet and fairly moist habitats they may not have a fixed breeding season, and as claimed by hunters in the Southern Highlands (T. Davenport & S. Machaga unpubl.). A pair kept in captivity was observed mating on 28 May, and a birth occurred on 13 Jun, these observations being recorded in different years (J. Beraducci pers. comm.).

Predators, Parasites and Diseases The main non-human predator of Abbott's Duiker is the Leopard *Panthera pardus* (Wilson 2001, Rovero *et al.* 2005, D. Moyer pers. comm.). In the Udzungwa Mts, Lions *Panthera leo* and Spotted Hyenas *Crocuta crocuta* are also potential predators. Juveniles are probably preyed by Crowned Eagles *Stephanoaetus coronatus* and pythons *Python* spp.

Conservation IUCN Category: Endangered C2a(i). CITES: Not listed.

Wilson (2001) reports Abbott's Duikers as having been quite common until the early 1960s and mentions frequent records of hunted animals from several sites until the late 1980s. There is little doubt that increasing hunting, habitat destruction, alteration and fragmentation have caused a dramatic decline in the last few decades in the abundance of most populations and probably their extirpation from many areas. This is the case of small/marginal forests in the Udzungwa Mts (Kigogo, Mufindi Scarp East and Mufindi Scarp West Forest Reserves; Moyer 2003), many sites in the Southern Highlands, and Chonwe Forest in the Uvidunda (Bismark) Mts. Near-extinction is probably occurring in the Uluguru Mts, Uzungwa Scarp F. R., Kising'a-Lugalo F. R., New Dabaga-Ulang'ambi Forest in the Udzungwa Mts and throughout the Southern Highlands (Bowkett *et al.* in press).

A comprehensive survey of duiker hunting was carried out in Mt Rungwe and the adjacent Livingstone forest in 2003 (Machaga

& Davenport 2004, T. Davenport & S. Machaga unpubl.). All 114 hunters interviewed reported having seen Abbott's Duiker. Some 77% hunt for domestic purposes, whereas 23% hunt for commercial purposes. Abbott's Duiker is not sought after for medicinal properties, but its skin is used in making drums. In 2003, an Abbott's Duiker carcass was valued in the villages at \$US20–30, although only 3% of hunters successfully trapped one that year. The vast majority used snares and the number of snares laid per hunter ranged from 300 to 1000. All hunters had noted a dramatic reduction in the number of Abbott's Duikers caught, especially over the last decade, and only 5% said hunting was still worthwhile.

The heavy hunting pressure in unprotected forests has probably left the Kilimanjaro and Udzungwa populations as the two strongholds of this species, while in other areas it most likely persists at very low densities. The current distribution on Mt Kilimanjaro is not known, but the area is mainly protected as a national park. Udzungwa Mountains N. P. holds a healthy population of Abbott's Duikers, while the species' presence in adjacent, unprotected forests such as Uzungwa Scarp F. R. is severely threatened by recent and alarming increases in levels of poaching (Moyer 2003, Rovero *et al.* 2005, 2010). However, a recent, preliminary study on the genetic structure of the Udzungwa population found that genetic diversity values are low relative to Harvey's Duiker in the Udzungwa Mts or published values for other mammal species (Bowkett *et al.* in press). This may be the result of habitat fragmentation and the resulting isolation of small subpopulations. In the West Usambara Mts, heavy hunting is seriously threatening the survival of this population, and recent interviews of hunters indicate that Abbott's Duikers might be left only in Shume-Magamba F. R. (F. Rovero pers. obs.). The situation in the East Usambara Mts is reported to be even more critical (Moyer 2003), and Abbott's Duiker is very likely to have been extirpated there already. Livingstone Forest, now part of Kitulo N. P., is the only Southern Highland habitat that is currently being effectively managed, although moves to upgrade the protected area status of Mt Rungwe are under way (T. Davenport pers. obs.).

Unless major conservation efforts are urgently applied within the next few years, Abbott's Duiker will probably become restricted to the Udzungwa Mts and Mt Kilimanjaro (Moyer 2003). Thus, coordinated survey work should be carried out throughout its range to assess current status and distribution. Conservation and education initiatives should also be instigated as a matter of priority. Current work in the Southern Highlands employing hunters in environmental education initiatives in exchange for stopping hunting has met with some success. It is too early to say if this will have a significant positive impact on Abbott's Duiker populations, although it may prove a valuable model for conservation at other sites.

Major conservation management measures that would enhance the protection of Abbott's Duiker are increased protection to include important forests in the Udzungwa Mts currently poorly protected, in particular Uzungwa Scarp, Iyondo and Matundu (Sumbi *et al.* 2005). The expansion of Kilimanjaro N. P. to annex lower altitude forests has been recently gazetted. Also necessary is the inclusion of Mt Rungwe within the new Kitulo N. P. and greater law enforcement enacted in those areas that are currently not adequately protected (such as Southern Highland forests, Usambara and Uluguru Mts). Critical forest connections, such as the degraded Bujingijila corridor linking Mt Rungwe to Livingstone Forest in Kitulo, must be adequately

protected. The ca. 25 km² of moist montane forest in the Rubeho Mts, where a new population of Abbott's Duikers was discovered in 2006, does not benefit from any legal protection, and therefore measures to give protected status to this forest should be urgently considered.

Measurements

Cephalophus spadix

HB (♂): 1240 mm, n = 1

T (♂): 110 mm, n = 1

HF (slot) length (♂): 50 mm, n = 1

E (♂): 1190 mm, n = 1

Mt Rungwe, Tanzania (T. Davenport & S. Machaga unpubl.)

HB (♂): 1330 mm, n = 1

T (♂): 135 mm, n = 1

E (♂): 112 mm, n = 1

Sh ht. (♂): 710 mm, n = 1

WT: 58.0 kg, n = 1

Mt Kilimanjaro, Tanzania (Wilson 2001)

Kingdon (1982) gave the following measurements: HB: 970–1400 mm;

T: 80–130 mm; Sh. ht: 660–740 mm; WT: 50.0–60.0 kg

Maximum recorded horn length is 11.1 cm for a pair of horns from the Usambara Mts, Tanzania (Rowland Ward)

Cephalophus silvicultor YELLOW-BACKED DUIKER

Fr. Céphalophe à dos jaune; Ger. Riesenducker

Cephalophus silvicultor (Afzelius, 1815). Nova Acta Reg. Soc. Sci. Upsala 7: 265, pl. 8, fig. 1. 'Habitat in montibus Sierra Leone & regionibus susuensium fluvios Pongas & Quia adjacentibus frequens'; since restricted to Sierra Leone, vicinity of Freetown (Grubb *et al.* 1998).

Yellow-backed Duiker *Cephalophus silvicultor*
adult female myology and skeleton.

Yellow-backed Duiker *Cephalophus silvicultor*.

Taxonomy The type species of the genus, this species was described at a surprisingly early date for a tropical forest duiker. The reason was that the botanist Adam Afzelius, a pupil of Linnaeus, provided an illustrated account to the Swedish Royal Scientific Society on his return to Sweden after serving in Sierra Leone between 1792 and 1794. Ansell (1972) recognized three subspecies (the nominate form, *C. s. ituriensis* and *C. s. ruficrista*), but noted that their validity was in some doubt. St Leger (1936) had earlier only considered *ituriensis* as distinct, though Hill & Carter (1941) and Ansell (1960b) both recognized *ruficrista* (and which they considered to include the form *coxi*, which St Leger included in the nominate form). Haltenorth (1963) recognized *ruficrista*, but not *ituriensis*, and included *coxi* in the nominate form. More recently, a comprehensive review by Grubb & Groves (2001) recognized four subspecies, including the description of a new subspecies. The correct spelling of the species name is *silvicultor*, not *sylicultor*, which is an incorrect subsequent spelling (Grubb 2004). Synonyms: *coxi*, *curticeps*, *ituriensis*, *longiceps*, *melanoprymnus*, *punctulatus*, *ruficrista*, *sclateri*, *silvicultrix*, *sylicultor*, *thomasi*. Chromosome number: $2n = 60$; the X chromosomes are submetacentric, while the Y chromosome is assumed to be a small acrocentric (Hard 1969, Robinson *et al.* 1996b).

Description The largest of the duikers, dark brown, with a vivid cream-coloured patch on the back. The long wedge-shaped head has a grey muzzle and cheeks ending in a shiny black rhinarium. Pale off-white colouring on the throat and lips is very variable in extent but tends to blend into the darker body colour without sharp demarcation. Eyes and ears are relatively small. Facial vibrissae are not obvious, nor do they grow out of light-coloured patches. Preorbital glands are large and prominent and can measure 44 mm with as many as 15 large pores (Wilson 2001). A coronal tuft of red or maroon hair, of variable length and conspicuousness, sticks up between the horns. Neck covered in short hair, variable in extent of pale throat

colouring. The skin in this area forms a thickened 'neck shield'. The yellow dorsal triangle is variable in its extent, tonality and colour. Although there are no obvious glands beneath this triangle, the entire coat, which is sleek but softly haired, is slightly oily, presumably due to secretions by sebaceous and apocrine glands. The triangle begins just behind the shoulder blades and widens, ending on the croup. Behind this long-haired triangle is a short-haired light coloured area, which Grubb & Groves (2001) call a 'haunch spot', and which varies, both individually and regionally, in its colour (yellow to pale grey or white) and extent. Body and legs are very dark brown, almost black in some individuals. Tail very short and thinly haired except for a wispy terminal tuft. Sexes of similar size and colour, but ♂♂ tend to have thicker horns and larger preorbital glands. Pedal glands are present on both fore- and hindfeet. Inguinal glands absent.

Horns slightly arched, with no or very small inner ridges, and possessed by both sexes, measuring up to 21 cm. Relative to Jentink's Duiker *C. jentinki* and the Bay Duiker *C. dorsalis*, the skull has a more convex frontal region; the supraorbital foramina are not sunk into channels, and the lateral nasal processes are usually conspicuous. The rostrum is narrower, but shorter than in Jentink's Duiker. Median pillars are commonly developed on the buccal sides of the cheekteeth (Grubb & Groves 2001).

Geographic Variation

C. s. silvicultor (including *silvicultrix*, *punctulatus*, *sclateri*): formerly from Senegal and Gambia to Niger R. Very large; brown with greyish tones, and with broad yellow dorsal triangle; no 'haunch spot'.

C. s. longiceps (including *melanoprymnus*, *thomasi*, *ituriensis*): from Niger R. to Congo R. and eastwards to extreme S Sudan and Western Rift Valley. Somewhat smaller than *C. s. silvicultor*, and darker to blackish-brown, with narrower dorsal triangle; 'haunch spot' absent, rare or weakly developed.

Dorsal and lateral views of skull of Yellow-backed Duiker *Cephalophus silvicultor*.

C. s. curticeps: predominantly montane form between Western and Eastern Rift valleys, including in E DR Congo, Rwanda, Burundi, Uganda and SW Kenya. Smallest of the subspecies, very dark brown coat (similar to *C. s. longiceps*), dark golden-ochre dorsal triangle; 'haunch spot' present, usually well developed.

C. s. ruficrista (including *coxi*): extensive area south of lower Congo R. to N Angola, and Zambia; some intergradation with *C. s. longiceps*. Similar in size to *C. s. longiceps*, but colour lighter (light to dark brown) and dorsal triangle broader; 'haunch spot' always present.

Similar Species

Cephalophus spadix. A large allopatric duiker that resembles this species in colour and conformation but lacks a dorsal triangle.

C. jentinki. Sympatric in Sierra Leone, Liberia and SW Côte d'Ivoire. A large, grey-bodied duiker of similar size but much stockier build, with black head and neck and white shoulder halter.

C. niger. A smaller, partially sympatric black duiker that lacks a dorsal triangle.

C. dorsalis. Broadly sympatric. A squat red duiker with short broad head; smaller than *C. silvicultor*.

Distribution Endemic to Africa, the Yellow-backed Duiker has the widest distribution of the forest duikers (Ansell 1972, Wilson 2001). Originally, the species ranged from SW Senegal through all West African countries to extreme S Chad, the Congo Basin and east to SW Sudan and SW Uganda, from the northernmost extensions of gallery and riverine forests (almost up to the Sahel) to equivalent forest extensions in N Angola (including Cabinda) and Zambia, east of the Zambezi R. and north of the Muchinga Escarpment (East 1999, Wilson 2001). It is rare in primary forest of DR Congo, but is present in 800–1000 m montane forest in the Bélinga mountains, NE Gabon (G. Dubost pers. comm.). Its equivalent habitats east of the Gregorian Rift are occupied by its close relative Abbott's Duiker *C. spadix*. It has also been recorded from montane forest and bamboo in the Mau Forest in SW Kenya (Kingdon 1982, Hillman *et al.* 1988, East 1999), and is reportedly present on Mt Elgon (Kingdon 1982), although no museum specimens are available to corroborate this (Grubb *et al.* 2003).

Within their range Yellow-backed Duikers are still common in some localities, but in other parts they have undergone significant

Cephalophus silvicultor

declines or are now absent. They are now considered extinct in Gambia (East 1999), although whether they actually ever formerly occurred is uncertain (Grubb *et al.* 1998, 2003). Malbrant & Quijoux (1958) recorded Yellow-backed Duikers from S Chad, but there is no recent information on their occurrence in this country. They also were thought to have been extirpated from Rwanda (East 1999), but have been confirmed as surviving in Nyungwe N. P. (F. Mulindahabi & A. Vedder pers. comm.). In Uganda, East (1999) recorded them surviving with certainty only in Bwindi Impenetrable Forest N. P.

Habitat An animal of lowland and montane primary and secondary forest, riverine galleries and many permutations of forest–savanna mosaics, including secondary swidden 'farmbush', the borders of plantations and, in montane areas, bamboo groves and steep forested valley slopes. It is typically an ecotonal species and survives well in narrow riverine strips and fragmented woods. Often found close to deep swamps, perhaps seasonally. During very dry periods small aggregations have been reported around salt-licks. Throughout its range it lives only in strips or pockets of suitable habitat, where it can be quite numerous. Yellow-backed Duikers in densely forested NE Gabon exhibited strong associations with riparian habitat, and to a lesser extent with old secondary forest and advanced fallowing fields (Lahm 1993). In Tāi N. P., Côte d'Ivoire, Newing (2001) observed this species only in secondary forest.

Abundance The density of these large duikers varies enormously, partly due to habitat preferences and natural constraints that limit them to quite specific localities and partly to very high levels of predation by human hunters over the greater part of their range. In a particularly choice locality in forest–savanna mosaic in Lopé N. P., Gabon, Tutin *et al.* (1997) estimated a density of 2.1/km². Elsewhere, in the National Park of Upper Niger, Guinea, Brugière *et al.* (2005) recorded individual and group densities of 0.79/km² and 0.69/km², respectively; Prins & Reitsma (1989) estimated 0.26/km² in coastal

Yellow-backed Duiker *Cephalophus silvicultor*.

forest/savanna of SW Gabon, while in the heavily poached Comoé N. P., Côte d'Ivoire, Lauginie (1975) estimated $0.09/\text{km}^2$. Lahm (1993, 1997) had encounter rates of $0.005/\text{km}$ and $0.03/\text{km}$ for this species in hunted and non-hunted areas, respectively, of densely forested NE Gabon, and $0.32/\text{km}$ in an unexploited logging concession now part of Lopé N. P. In the Ituri Forest, DR Congo, where these duikers are naturally rare (but even so opportunistically hunted on a regular basis), densities ranged from $0.1\text{--}0.7/\text{km}^2$ near settlements and $0.5\text{--}1.6/\text{km}^2$ in remote areas (Hart, J. A. *et al.* 1996, Hart 2000). As the largest duiker, it consumes a greater proportion of widely dispersed large-sized fruits than smaller species (Dubost 1984). Comparing the relationship between the body weights and known home-ranges of some duiker species, Feer (1988) suggested that its home-range size may attain 200 ha. East (1999), assuming a density of $1.0/\text{km}^2$ where Yellow-backed Duikers were common and $0.1/\text{km}^2$ elsewhere, arrived at an overall population estimate of 160,000 animals.

Adaptations Among the most striking peculiarities of the Yellow-backed Duiker are its pale dorsal triangle, its considerable size (up to 70 kg), its ability to make an explosive and intimidating thumping noise, and its rather bovine appearance. Dubost (1979) estimated that its body is proportionally heavier than the diurnal duikers, but less than the strictly nocturnal species.

Especially interesting is the fact that it has a black dorsal stripe at birth, as do young and adults of its closest relative, Abbott's Duiker. Nocturnal duikers tend to be dark-coloured and it is possible that the common ancestral population of Abbott's Duiker and Yellow-backed Duiker was predominantly nocturnal. However, both species are essentially crepuscular, being most active both before and after dawn and dusk but intermittently active at other times of the day and night as well. When quietly browsing or resting back hairs lie flat and are not particularly conspicuous (even while fleeing). This is partly due to the freckled forest light and the existence of other light streaks, such as stems and trunks and partly because the surrounding dark pelage 'encroaches' on the dorsum when the coat is sleeked down. However, the dorsal hairs are elongated, erectile and in this condition are able to catch the light and make the back the single most arresting feature of the animal. Evolution of the near-white dorsal triangle is clearly linked to sending a signal to other forest dwellers, the most susceptible being members of the same species. What sort of information could such a vivid pattern have in a mainly solitary species?

Dorsal hair is raised whenever there is a disturbance that has put an animal on the alert. This is often described as 'alarm' behaviour, but the observations of J. Kingdon (pers. obs.) and those of Wilson (2001) suggest that an animal on the alert is generally static and closely monitoring its surroundings. It may even approach to investigate. It is during this phase of active interest that the back is hunched in readiness to run and the hair is at its most erect and conspicuous; S. Lahm (pers. obs.) observed this behaviour during both day and night surveys in Gabon. There are four likely main sources of disturbance: the first, and probably the most frequent, are neutral agents such as falling branches or monkeys' noisy leaps. The second is any animal or event with a potential for harm, such as a hunter or Leopard *Panthera pardus*. The third is another Yellow-backed Duiker. The fourth is any potential competitor, such as duikers of other species, Red River Hogs *Potamochoerus porcus* or Mandrills *Mandrillus sphinx*. Species-specific signals of this sort are only likely to have selective value when received by animals belonging to the last two categories (and a conspicuous back can easily address either). Because an alert animal typically bunches its back, the yellow patch effectively enlarges and advertises the highest part of a big black body mass (thereby emphasizing the signaller's height and bulk). This can simultaneously identify and intimidate, particularly if accompanied by the 'humming' sound peculiar to Yellow-backed Duiker.

Competing duikers and some smaller carnivores can immediately see that they are dwarfed by a Yellow-backed Duiker, while conspecifics have the choice of approaching or fleeing. There is, as yet, no evidence that the dorsal triangle overlies a glandular area but the entire animal is faintly greasy and the hairs may well serve as dispensers for a generalized body odour with all the information that entails. Overall the most likely function of this pattern is to invite retreat from an animal that has been selected to advertise its height and bulk and back this with an alarming 'thump'. Dubost (1980) suggested that this species uses fewer visual signals than strictly diurnal duikers, but more than nocturnal species.

Morphology and genes unite in suggesting that the Yellow-backed Duiker is an end-of-the-line species, one of the most recently evolved of duikers. That conclusion is also consistent with the idea that all duikers have derived from a diminutive ancestor and that the living radiation of duikers represents a protracted adaptation to the very varied opportunities offered by fruit-fall in the diverse forest habitats of Africa (Kingdon 1982).

Where duikers belong within the larger radiation of bovids is a contentious topic that has a bearing on the strikingly 'bovine' appearance of this large duiker. Duikers have been seen as occupying an ambiguous position in the primary divide between bovines and antilopines. Most authors have placed them within the latter (as in this volume), but Gentry (1992), Groves & Schaller (2000) and Grubb & Groves (2001) noted the resemblance between duiker skulls and those of the Asian Four-horned Antelope *Tetracerus quadricornis* and other Asian boselaphines. They suggested that duikers might be as close to the bovines as to any other antilopine group and therefore proposed recognition of a new subfamily Cephalophinae to reflect a supposed intermediate position and relative distinctness from both Bovinae and Antilopinae.

As cattle and buffalo have evolved into ever larger forms they have acquired that complex of characteristics and appearance that we sum up in the vernacular term 'bovine'. It is therefore interesting that the

Yellow-backed Duiker *Cephalophus silvicultor*.

evolutionary enlargement of this duiker species seems to parallel that transformation in the Bovinae and that this has led some scientists to doubt the duikers' affinity with other antelopes.

Foraging and Food Fallen seeds, fruits, berries and the bark of shrubs, fungi, ground moss and many herbs. In montane areas, waterberry *Syzygium*, dog plum *Ekebergia* and yellow-wood *Podocarpus* are favoured fruits (Kingdon 1982). Wilson (2001) emphasized that this species shows a marked preference in lowland forests for dry fruits, pods and seeds, which accounted for 79% of the diet, leaves, shoots and traces of animal matter making up the balance of his central African sample (three stomachs). Wilson (2001) recorded them having ingested large pieces of *Piliostigma thonningii* pods (and leaves), *Gardenia* sp. fruits and *Swartzia madagascariensis*. Gautier-Hion *et al.* (1980) recorded 71.3% fruit, 28.6% leaves and 0.1% animal matter in four stomachs in Gabon. Dubost (1984) found ten fruit species and two *Eremospatha* spp. as preferred foods in four stomachs.

Feer (1995) also found them feeding on mature fruits, noting *Irvingia* spp. and *Detarium macrocarpum*. He recorded 30 species in 23 stomachs with large quantities of pulp, and recorded duikers swallowing fruits of up to 4.7 cm diameter. Small seeds passed through the digestive system unharmed, but several fruits were chewed so thoroughly that their seeds were actually destroyed: these were *Chrysophyllum* spp., *Mammea africana*, *Pseudospondias longifolia* and *Ricinodendron heudelotii*. The most important species by order of decreasing frequency were: *Panda oleosa*, *Polyalthia suaveolens*, *Irvingia* spp. and *Gambeya beguei* (F. Feer pers. obs.). In the south of its range, forest/savanna ecotonal species such as *Pseudolachnostylis dekindtii*, *Oncoba spinosa*, *Swartzia madagascariensis* and *Canthium venosum* are recorded foods (Ansell 1960b); other records are of African Mangosteen *Garcinia* and Duiker-tree *Sapium* fruits. It was mentioned as a crop raider of maize shoots and cassava leaves in five of 218 villages sampled in Gabon (Lahm 1994).

Yellow-backed Duikers may also take carrion (Dekeyser & Villiers 1955), and one captive duiker was observed to capture, kill and eat pigeons (Kranz & Lumpkin 1982). Wilson (2001) recorded the remains of a lizard from one stomach, those of a chameleon from another in Congo, and reported that they would readily eat newly hatched tortoises. This species has also been observed feeding on a Forest Buffalo *Syncerus caffer nanus* carcass (L. White pers. comm.) and fresh Leopard *Panthera pardus* scat (P. Henschel, pers. comm.) in Gabon, and a White-nosed Guenon *Cercopithecus nictitans* carcass in Congo (N. Shah pers. comm.). Mbuti pygmies in DR Congo described its diet as comprising fruits, leaves, insects and dead animals (Carpaneto & Germe 1989).

Of 23 Yellow-backed Duiker stomachs, four contained meat, bones and hair, and two contained the remains of pangolins (F. Feer pers. comm.).

Being both nocturnal and diurnal, there is no clear period of activity (Gautier-Hion *et al.* 1980, Newing 2001, Wilson 2001). It is physically adapted for rapid flight, unlike strictly nocturnal species such as the Bay Duiker and Water Chevrotain *Hyemoschus aquaticus*, which are relatively slow (Dubost 1979). The greater proportion of more diffuse large-sized fruits in its diet (compared with other duikers) may necessitate a 24-hour activity rhythm in a large home-range (Feer 1989b). Hart (2000) inferred that it is mainly nocturnal near human settlements. This may be a behavioural adjustment to avoid contact, as suggested by Lahm (1993) for this species and other large ungulates in hunted areas of Gabon.

Social and Reproductive Behaviour Although this appears to be a mainly solitary species and most records have been of single animals, Wilson (2001) found what he called 'bonded pairs' living in discrete home-ranges centred along a riverine forest strip in Mole N. P. in Ghana. The gallery was about 3.5 km long, but a 600 m dry break separated the two home-ranges. Both sexes mark their home-ranges with large preorbital glands but ♂♂ mark three times more often (Wilson 2001). Lying-up on termittaries or slight elevations on the forest floor suggests that they regularly monitor their surroundings and broken horns on female skulls suggests that ♀♀ may be actively intolerant of other ♀♀. Individuals lie up singly (very occasionally in pairs) between the buttresses of large trees, under fallen trunks or dense tangles, in 'forms', which show signs of regular use and where the duiker may shelter from rain (even entering the remnants of pit-sawyers' or hunters' lean-tos). As many as six such resting places can be found within a square kilometre. Given the absence of marked ridges on the inner side of the horns, this species probably does not scrape the bark of small trees, as do some other duiker species (G. Dubost pers. comm.). Courtship resembles that of other duikers: the ♂ tests the condition of the ♀ with flehmen and, if she is in oestrus, pursues her relentlessly, licking her but also butting and biting, and striking her with a foreleg. Meanwhile the ♀ grunts or bleats (Wilson 2001).

Reproduction and Population Structure Ansell (1960a) thought there was no fixed breeding season in Zambia, but reported a lactating ♀ in Mar and young in Oct and Dec. Ionides (1964) noted young in Kenya during Jan, and J. A. Hart (pers. comm.) recorded very young lambs in Ituri Forest in Jan and May. In Gabon, where births occur year-round in duikers, bats, rodents and other forest antelope, there are two peaks that differ among species (Brosset 1986, Feer 1988). The frugivorous duikers and Water Chevrotain generally had more births during the two annual dry seasons compared with rainy months in NE Gabon (Dubost & Feer 1992). S. Lahm (pers. obs.) saw small lambs in Jan (dry month) and Oct (wet month) in the same region and in Jun (wet-dry transition) in SW Gabon. Wilson (2001) found that even when ovulation originates from the left ovary, the foetus implants in the right horn of the uterus.

There has been much discussion about the length of gestation. Most authenticated captive records are between 210 and 282 days, but extremes of 151–310 days have been published (see Wilson 2001, and references therein). A single young is born. Captive birth-weights range between 2.3 and 6.1 kg (Wilson 2001); the young is born a dark umber colour with strong reddish tint, particularly on

Yellow-backed Duiker *Cephalophus silvicultor*.

the underparts and freckled flanks. The dorsum is jet black but begins to pale at 40 days, visibly whitening at five months and fully developed by seven months (Schürer 2002). It begins to eat plant material at about two months and is weaned by five months (Wilson 2001). In captivity, birth intervals range from 213 days to three years (Kranz & Lumpkin 1982). A captive ♀ at Miami Metro Zoo produced several young, the last of which was born when the ♀ was 18 years old. The ♂ of the pair was still alive in 2005 at age 23, the oldest known Yellow-backed Duiker in captivity (L. Rohr pers. comm.).

Predators, Parasites and Diseases Known to be taken by Leopards and pythons *Python* spp. and young are probably taken by Servals *Leptailurus serval*, African Golden Cats *Profelis aurata* and Crowned Eagles *Stephanoaetus coronatus*.

In N Congo, a considerable number of Yellow-backed Duikers and other bovids succumbed to an epidemic of a pneumonia-like disease possibly transmitted by biting *Stomoxys* flies (Stockenström *et al.* 1997; and see Elkan *et al.* 2009). A health evaluation of 77 duikers representing five species in the Ituri Forest revealed the presence of strongyles, trichurids, coccidia, *Moniezia* sp. and occasionally ticks (*Rhicephalus* spp., *Haemaphysalis parvata*, *Ixodes cumulatimpunctatus*). Many animals had positive antibody titres to leptospirosis serovars, bluetongue virus, infectious bovine rhinotracheitis and epizootic haemorrhagic disease (Karesh *et al.* 1995). The sample did not include any Yellow-backed Duikers, although the species is part of the local duiker community, and thus must be exposed to the same parasites and diseases. Dekeyser (1955) recorded the tick *Ixodes rarus*.

Conservation IUCN Category: Least Concern. CITES: Appendix II.

This species was formerly subject to strict taboos that once protected it in some parts of its range (Kingdon 1982). It is still considered non-preferred game in parts of central Africa, owing to its dark colour, scavenging habits and aggressive temperament when hunted (Carpaneto & Germi 1989, Lahm 1993). In Gabon, where it is also believed to be a 'were-animal', 17% of 144 villagers

sampled declared it to be non-edible (Lahm 2002). However, the Yellow-backed Duiker is now declining over most of its range due to intensive and unregulated hunting and the disappearance of taboos. It has disappeared from Gambia and is rare in Senegal, Guinea, Sierra Leone, Nigeria, Kenya and Uganda and over much of the peripheries of its range (Anadu & Green 1990, Anstey 1991, Wilson 2001).

Important protected areas include Ziama and Diécké Forest Reserves (Guinea), Gola Forests (Sierra Leone), Sapu N. P. (Liberia), Mbam Djerem N. P. and Lobéké N. P. (Cameroon), many of those in Gabon, including Odzala N. P. and Nouabalé-Ndoki N. P. (Congo), Monte Alén N. P. (Equatorial Guinea), Bwindi Impenetrable N. P. and Queen Elizabeth N. P. (Uganda), Kafue N. P. and Kasanka N. P. (Zambia), and Okapi Faunal Reserve (DR Congo). Comoé N. P. was once a stronghold for this species, but with 100–500 poachers operating on a daily basis in this park it had already become rare by the mid-1990s (Fischer 1997). Wilson (2001) regarded Yellow-backed Duikers as extinct in at least seven protected areas in which they formerly occurred, although subsequent surveys have confirmed that they do still occur in Digya N. P., and that they are present in Bui N. P. and Gbele Resource Reserve (R. J. Dowsett pers. comm.).

Although the species was described as easy to breed and hand-rear in captivity (Kranz & Lumpkin 1982), there were only 65 animals in about 23 North American zoological parks and eight known in international institutions in 2005. Within these captive groups a birth rate of 10 per year has been stable, and improved husbandry and population management practices in recent years have increased the Yellow-backed Duiker's survival potential in captivity (L. Rohr pers. comm.).

Measurements

Cephalophus silvicultor

TL (♂ ♂): 1420, 1460 mm, n = 2

TL (♀): 1620 mm, n = 1

T (♂ ♂): 120, 125 mm, n = 2

T (♀): 115 mm, n = 1

HF c.u. (♂ ♂): 295, 330 mm, n = 2

HF c.u. (♀): 350 mm, n = 1

E (♂ ♂): 116, 121 mm, n = 2

E (♀): 115 mm, n = 1

Sh. ht (♂ ♂): 748, 775 mm, n = 2

Sh. ht (♀): 730 mm, n = 1

WT (♂ ♂): 66.5, 68.6 kg, n = 2

WT (♀): 71.0 kg, n = 1

SE Central African Republic (Wilson 2001)

A ♀ from NE Gabon was subadult, yet weighed 74.5 kg (G. Dubost pers. obs.), so maximum weights (and other measures) probably exceed those shown here. It should be remembered that regional populations differ in body size, although the extent of this variation remains to be quantified.

Maximum recorded horn length is 21.2 cm for a pair of horns from Tchibota, DR Congo (Rowland Ward)

Cephalophus dorsalis BAY DUIKER

Fr. Céphalophe bai; Ger. Schwartzruckenducker.

Cephalophus dorsalis Gray, 1846. Ann. Mag. Nat. Hist., ser. 1, 18: 165. 'Sierra Leone'.

LEFT: Bay Duiker *Cephalophus dorsalis*.
 ABOVE: Lateral view of skull of Bay Duiker
Cephalophus dorsalis.

Taxonomy Named from a menagerie specimen from Sierra Leone; Gray named another specimen *C. badius*, which is now regarded as a synonym. Rode (1943) mistakenly lumped *leucogaster* and *ogilbyi* as subspecies of *C. dorsalis*. St Leger (1936) separated out *dorsalis*, based on horn characters. *Cephalophus dorsalis* is sympatric with both Brooke's Duiker *C. ogilbyi brookei* and the White-bellied Duiker *C. leucogaster*. Ansell (1972) included the form *arrhenii* as a subspecies, but this form is actually attributable to the White-bellied Duiker (Grubb & Groves 2001). Synonyms: *badius*, *breviceps*, *castaneus*, *kuha*, *leucochilus*, *orientalis*, *typicus*. Chromosome number: $2n = 60$; the X chromosome is a metacentric (Hard 1969, Robinson *et al.* 1996b).

Description Heavily built duiker with a red or yellowish-brown glossy coat, black or dark brown legs and a black dorsal mid-line. Also a dark brown mid-line down the chest and belly. Muzzle is reduced and strongly tapered. Eyes are larger, more prominent and higher in the skull and the entire head is broader and flatter than in any other duiker. The black dorsal line, which varies greatly in length and width and darkness, usually extends up the neck, over the crest and down the nose, especially in western populations, where much of the head can be black; however, the extent of black on face and back is very variable. Frontal crest reduced to some long hair at the base of horns. In common with some other duiker species, there are vibrissae on the muzzle and above the eye. These have black bases set in distinctive white flashes on the upper lip and upper eyelid. Chin and throat also white. Backs of the pinnae are black or brown; their fronts have white margins and some very sparse off-white hair inside. Hair on the shoulders is somewhat shorter than on the back and hindquarters. Legs black or brown, but sometimes show rufous streaks. Tail black with a white underside and somewhat tufted towards the tip. Deeply brown or black at birth,

rufous colouring appears between 5 and 6 months of age; the black dorsal stripe is only partly visible on the rump. Preorbital glands are relatively small compared with some other medium-sized duikers (Wilson 2001), although in Gabon the preorbital glands of ♂♂ were twice as large as in Peters' Duiker *C. callipygus*. Preorbital glands have 11–14 pores set in a straight line about 21 mm long (Wilson 2001). The inguinal glands are very distinctive, comprising deep, flask-like sacs in the lower flanks that exit from a narrow tube immediately inside the fold between thigh and abdomen. Their odour is said to be very disagreeable to the human nose. Pedal glands are large and active. Sexes are of similar size, although ♀♀ are slightly heavier. Preorbital glands are larger in ♂♂ than in ♀♀, as are the slender, cylindrical, parallel, spike-like horns.

Geographic Variation

C. d. dorsalis: Guinea, Guinea-Bissau and Sierra Leone to the Niger R. Grubb & Groves (2001) considered the boundary between the two forms to be the Adamawa Highlands in Cameroon. Redder body colour, black facial blaze and crest; dorsal stripe comparatively narrow. Smaller body size.

C. d. castaneus: east of the Niger R. to the Rwenzori Mts and Albertine Rift Valley and south to NE Angola. Darker body colour, redder face and crest. Larger body size. Grubb & Groves (2001) remark that there is considerable geographical variation in this subspecies. Hornless adult ♀♀ have been observed east of the Congo R.

Similar Species

Cephalophus ogilbyi. Sympatric across most of the range. A diurnal red duiker of similar size, and often confused with the Bay Duiker, but of paler red colour with a long narrow face and lighter-coloured legs.

C. leucogaster. Sympatric in central Africa north of the Congo R. A more gracile, pale-cream-coloured duiker with prominent white belly and two-toned legs.

C. callipygus and *C. weynsi*. Red duikers of similar size with long faces, prominently swollen foreheads and thick annulated horns.

C. silvicultor. Broadly sympatric. A larger, dark greyish-brown duiker with cream-coloured patch on lower back.

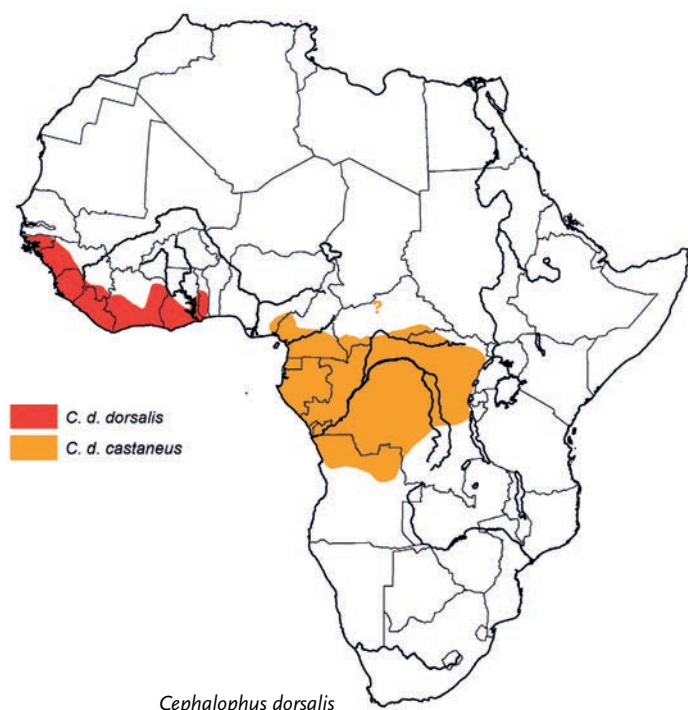

Distribution Endemic to Africa and closed-canopy areas within the rainforest block from Guinea-Bissau to the Rwenzori Mts, Albertine Rift Valley and L. Tanganyika, and south to NE Angola to about 11°S (Grubb *et al.* 1998, East 1999, Wilson 2001, Crawford-Cabral & Veríssimo 2005). The westerly limit is Guinea-Bissau, where East (1999) reported Bay Duikers from forest patches in five restricted areas of the mainland, including Cacheu R. and L. Cufada. In Guinea, they are recorded from the south-west and south-east, including Mount Nimba Biosphere Reserve and Ziamia and Diécké Forest Reserves, and then eastwards to Togo, where they were recorded in the forests of the Fazao and Togo mountains (East 1999). However, there are no confirmed records from Gambia (Grubb *et al.* 1998, 2003) or from Benin. There are also no records from Nigeria, west of the Cross R. (Grubb *et al.* 2003), their distribution continuing again east of the Cross R. in SE Nigeria, and then through S Cameroon, SW and SE Central African Republic, mainland Equatorial Guinea (being absent from Bioko I.), Gabon, Congo, east to the montane forests in E DR Congo. Fay *et al.* (1990) mentioned a doubtful record from Manovo–Gounda–St Floris N. P. in the north of Central African Republic, and another record from east of Bamingui–Bangoran N. P., but considered these as doubtful; however, Grubb *et al.* (2003) subsequently report on a specimen from N Central African Republic from Kabo, just south of the Chad border, and to the west of Gribingui–Bamingui Faunal Reserve. There is a single record from Uganda, below the north-western foothills of the Rwenzori Mts, but this area is now densely populated, and the

Bay Duiker probably no longer occurs in Uganda (Kingdon 1982, East 1999).

Habitat An inhabitant of the entire equatorial lowland rainforest block with a marked preference for high primary rainforest (Wilson 2001); also, if undisturbed, may occupy patches of forest within savanna mosaics. Within the rainforest zone Bay Duikers may visit edges of clearings and well-diversified areas with both dry and seasonally waterlogged areas (Dubost 1979). They generally avoid montane forests, although they are found in moist lowland forests on the slopes of the montane regions in E DR Congo. Very slow to recolonize felled or disturbed forest, but does occur in old farm-bush and old secondary forest (Fotso & Ngnegueu 1997, Wilson 2001). They seek out the most densely vegetated areas, piles of dead branches in forest gaps, the spaces between buttresses and large hollow logs to lie up in during the day, refuges that they freeze in and only leave when discovered (J. Kingdon pers. obs.).

Frontal view of Bay Duiker *Cephalophus dorsalis* (right) compared with Yellow-backed Duiker *C. silvicultor* to show former's larger eyes and shorter muzzle.

Cephalophus dorsalis

Abundance Estimates of home-range data in Makokou, Gabon, suggested densities of 7.5–8.7/km² in prime habitat (Feer 1988). In Makokou, Dubost (1979) calculated a density of about 19/km² (net capture). Lahm (1993) estimated by transect a density of 5.8/km². In S Central African Republic, the species ranks second among duikers, with densities of 0.3–6.6/km² (line transect and net count; Noss 1998b). Densities are 1.5/km² in the Ituri Forest (DR Congo) (Hart 1985) and 1.9/km² in Tāi N. P. based on night transect counts (Hoppe-Dominik *et al.* 2011). Using modest densities of 0.2–2.0/km², East (1999) calculated an overall population of 725,000 animals.

Adaptations Striking features of this species are the enlarged eyes and orbits, adaptations that are clearly related to improved night vision in an animal with very strictly nocturnal habits. Protrusion of the eyes on either side of a rather flat-topped head and dorsally oriented orbits are also likely to improve bifocal vision (Kingdon 1982, Feer 1988). However, the most significant peculiarity lies in the broad, flattened skull. When Bay Duiker skulls are compared with those of other duikers they show inflation of the zygomatic bones, outward bowing of the zygomatic arches, lateral expansion of the molar tooththrow (without equivalent modification of the premolars), widening of the mandibular condyles, and significant narrowing of the choanae so that the pterygoid bones are closer together. Taken all together this combination of

Palatal views of Bay Duiker *C. dorsalis* skull (above) and Black-fronted Duiker *C. nigrifrons* (below) to show broader molar teeth, greater mandibular traverse and enlarged masseter and pterygoid muscles.

characters signifies a significant amplification of the lateral element in chewing by introducing a wide lateral swing at the maxillary condyles (Kingdon 1982). This lateral action means that the duiker can grate or rasp fruits without cutting them open with a sharp vertical bite: a dangerous risk when seeds are protected by poisonous compounds. This risk might have exerted significant selection on anatomy and physiology during this duiker's evolution. The estimated mass of the masseter and zygomatic-mandibular muscle is large compared with duikers of similar size (such as *C. callipygus*). This, combined with broad upper and lower molars (Feer 1988), signifies more powerful jaws able to process hard fruits and seed.

The maxilla has also contracted, and this shortening of the maxilla, combined with a wide, elastic mouth and lips, allows the gape to widen to the point where a 7 cm fruit can easily be taken into the mouth and a 5 cm fruit can be bitten open. Few other duikers can cope with fruits that have large hard seeds and most prefer easily managed ones with abundant soft pulp and small fruits/seeds such as figs. It has been calculated that fruits measuring less than 4 cm make up about 94.5% of the fruit-fall in a representative forest in Gabon (Dubost 1979), so small fruits represent the primary food source for most duikers. However, any animal that can process larger seeded fruits has fewer competitors (although the resource is more dispersed because there are fewer trees bearing such fruit). The Bay Duiker has specialized in stripping away pulps (that are often quite thin) from relatively large, hard (and sometimes poisonous) seeds. The majority of such seeds are high forest, closed-canopy species. Feer (1989b) and Wilson (2001) have documented at least 15 larger forest fruits that are preferred by Bay Duikers. These fruits range from 2 to 20 cm in size, but most are about 2–7 cm, dimensions that the Bay Duiker can easily cope with. The hard seeds within these fruits range from 1.5–5 cm and Bay Duikers swallow and regurgitate seeds that are up to 2.8 cm (Feer 1989b). Seeds over this size are not swallowed but are stripped within the

Bay Duiker *Cephalophus dorsalis* skull (above) compared with Blue Duiker *Philantomba monticola* (below) to show proportions in relation to tooththrow (not to same scale).

mouth and spat out. It is this ability to process relatively large seeds that distinguishes the Bay Duiker and explains its cranial anatomy.

These animals can combine mitigating competition and avoiding predators by consuming large numbers of fruits quite rapidly at the fruit-fall and the Bay Duiker has been recorded as being active for as short a period as 5–6 h per night (Wilson 2001). Once a duiker has fed it removes itself to a secure, sheltered place to rest and ruminate; here it regurgitates and spits out undamaged seeds, thus helping disperse them away from the parent tree (Feer 1995). It would be interesting to investigate the possibility of co-evolution between the Bay Duiker and some of its food trees. Many forest tree seedlings need some light during their early growth spurt and the Bay Duiker does sometimes deposit seeds in tree-fall gaps; however, these duikers also spit out large numbers of seeds from closed-canopy, high forest species in very densely shaded (but possibly less predated) sites. Under such circumstances only very shade-tolerant seedlings have any chance of growing to maturity. It is therefore likely that the duikers' regurgitation habits would only favour those seeds best able to survive under deep shade. If so, Bay Duikers might be actively selecting and propagating those food trees that contribute most to the maintenance of a closed canopy. Theoretically, and on an evolutionary time-scale, these habitat-specific duikers could be favouring precisely those tree species that combine food supply with the maintenance of habitat. If these duikers are exterminated it is possible that many major closed-canopy tree species could also decline and even die out.

Another peculiarity of the Bay Duiker skull is an enlarged olfactory region and this can be correlated with observed 'tracking' behaviour, and more generally with a nocturnal mode of life. The more dispersed a food supply the greater the demands on finding it and olfaction has to be a major sense guiding this task. Captives have been seen to sniff out and excavate well-buried fruits (Wilson 2001) by scraping soil with front hooves or incisors (Dubost 1983).

Head of Bay Duiker *Cephalophus dorsalis* female indicating vibrissae embedded in white 'signal' patches above eye and behind rhinarium.

Because the Bay Duiker is nocturnal, has large, prominent eyes and lives most of its life in dense vegetation, its facial vibrissae play an important role in avoiding potential snags. The positioning of such vibrissae above the eyes and around the nostrils is therefore appropriate, but it is interesting that in both instances the vibrissae are advertised by being embedded in small patches of vivid white fur. As with many other exclusively nocturnal mammals it would seem that unique combinations of white flashes on an otherwise dark facial 'mask' serve as intra-specific signal devices.

Foraging and Food The Bay Duiker has very precise preferences for fruit species and the characteristics of these fruits have been extensively studied by Feer (1988, 1989b, 1995) and by Wilson (2001). Of the larger, mango-like species, 'Gaboon chocolate' *Irvingia* spp. and the Tallow tree *Detarium macrocarpum* are favourites; another is the globular, latexy, fibrous fruit (7–10 cm) of Oboto *Mammea africana*. These large seeds are rasped for their pulp or 'flesh' and the seed spat out, not swallowed. The commonest seeds to be found in stomachs and at resting sites are from the yellow fruits of two *Antrocaryon* species, the indented, button-like seeds of which are appropriately known as 'antelope buttons'. Also eaten are the oval yellow fruits of climbers *Hugonia* spp. and the bilobed 6×3 cm fruits of *Ricinodendron heudelotii* (a forest relative of the Manketti tree *Schinziophyton rautanenii* that produces mugongo nuts) and oil-palm dates *Elaeis guineensis*, and the orange plums of milkwood *Chrysophyllum bequei* (4–6 cm), the olive-like, turpentine-scented fruit of *Pseudospondias longifolia* (3.5 cm), the green, strongly fibrous plums of *Panda oleosa* (5–7 cm) and the cocoa-pod-like *Cola rostrata*, which has a shell about 8×20 cm, but contains many small pulp-covered seeds.

Softer seeds without a hard shell or rind tend to be chewed up, and Feer (1989b) never found the seeds of such species at resting places but did record them being eaten. They included the sweet, yellow, apple-like *Drypetes gossweileri* (8–14 cm), the oil-seed *Staudtia gabonensis* (2–6 cm), blue ozigo olives *Dacryoides buettneri* (2–4 cm), Anguek *Ongokea gore* (2–4 cm), ebap, red beans of *Santiria trimera*, the African soursop *Annonidium mannii* (20–50 cm) and owala oil seeds (flat discs from the giant pods of *Pentaclethra macrophylla*).

There are occasional records of Bay Duikers stalking and killing birds (they discard legs and wings) and eating embryos from about-to-hatch eggs (Kurt 1963, Wilson 2001). They eat carrion, and the remains of African Porcupines *Atherurus africanus* (F. Feer pers. obs.) and cuscumanses (*Crossarchus* spp.) (Hart 1985) have been found in stomach contents. Termites, beetles and ants have also been recorded in their diet. Live prey are stalked and struck with a slash of the forefoot.

Social and Reproductive Behaviour Usually solitary, but occasionally observed in pairs. Two ♀♀ and their offspring have been found to occupy the home-range of a single ♂ (Feer 1989a), so as many as six or seven animals may live within a recognizable male territory or home-range of 79 ha. The existence of very pungent inguinal glands and exceptionally large pedal glands suggests that intra-specific contacts are probably regulated by scent. Males mark tree and shrubs with preorbital secretion (Dubost 1983). A lightly built skull and short, slender spike-like horns imply that fights do not involve head-clashing. Stabs into the haunches or sides of contestants are the most likely outcome of male competition. Nocturnal habits and intense wariness has hidden much of this duiker's social behaviour from view.

The ♂ pursues an oestrous ♀ with great persistence, meanwhile humming continuously and occasionally striking out with a foreleg (a rudimentary form of laufschiag) (Wilson 2001). On accepting to be mounted, the ♀ squats and holds her tail to the side.

Reproduction and Population Structure A wide spread of birth and pregnancy records implies that some breeding goes on throughout the year and no birth peak is currently known to occur. In Gabon, birth peaks were observed during and before maximum availability of fruit (Dubost & Feer 1992). About 57% of ♀♀ over 20 months old are pregnant. Oestrus only lasts about 18 hours (Wilson 2001). Females may conceive at about 18 months and always implant in the right horn of the uterus although both ovaries ovulate; gestation is cited as about 238 days (Wilson 2001). At birth the young weighs 1600–1690 g, and begins to take solid food within a few weeks; it is weaned by 3.5 months and is unusual in eating fruit almost exclusively from the beginning (Wilson 2001). In Gabon, a sample of 151 individuals from a moderately hunted population was composed of 20% adults. Males accounted for 58% of adults, a sex ratio most probably biased in favour of ♂♂ (Feer 1988). Longevity in captivity has been given as 17–18 years (Weigl 2005).

Predators, Parasites and Diseases Data from scats have confirmed that Leopards *Panthera pardus* are important predators (Hart, J. A. *et al.* 1996, Wilson 2001). Kudo & Mitani (1985) observed a Mandrill *Mandrillus sphinx* preying on a young Bay Duiker. Young animals are also known to be taken by Crowned Eagle *Stephanoaetus coronatus* (Wilson 2001), and African Golden Cats *Profelis aurata* are also likely to take young or subadults. The failure of an attempt to reintroduce Bay Duikers to Azagny N. P., Côte d'Ivoire, was blamed on large numbers of African Rock Pythons *Python sebae* in the park (Roth & Hoppe-Dominik 1990).

In a study investigating the health status of Bay Duikers, bacterial and viral serology tests returned positive for bluetongue disease, epizootic haemorrhagic disease, infectious bovine rhinotracheitis and *Leptospira* (which causes leptospirosis) (Karesh *et al.* 1995). Helminths recorded

include nematodes (genera *Cooperia*, *Strongylus*, *Cecropithifilaria*, *Filaria*, *Setaria*, *Skrjabinodera*, *Pygarginema*) and cestodes (*Moniezia*, *Avitinella*) (Round 1968). Infection with coccidia (Karesh *et al.* 1995) and trypanosomes (e.g. *Trypanosoma brucei*) (Njiokou *et al.* 2004b) has been recorded. Ntiemoa-Baidu *et al.* (2005) recorded the following ixodid tick species from Bay Duikers in Ghana: *Haemaphysalis parvata*, *H. leachi*, *Ixodes muniensis*, *I. moreli*, *I. cumulatipunctatus* and *Rhipicephalus ziemanni*. Beaucournu & Bain (1982) recorded a new species of flea (*Ctenocephalides chabaudi*) from the Bay Duiker in Gabon.

Conservation IUCN Category: Least Concern. CITES: Appendix II.

The combination of systematic habitat destruction and the commercialization of hunting and trapping likely will ensure the eventual elimination of this species outside protected areas. Even then they are unlikely to survive in smaller protected areas because of habitat degradation and poaching; in Ghana, for example, this species has been extirpated from seven parks and protected areas (Wilson 2001; although it does still occur in Kalakpa Resource Reserve; R. J. Dowsett pers. comm.), and Van Vliet *et al.* (2007) recorded its likely extirpation from Ipassa Natural Reserve in NE Gabon. Important populations survive in areas such as Sapo N. P. (Liberia), Taï N. P. (Côte d'Ivoire), Bia and Kakum National Parks (Ghana), Campo-Ma'an N. P., Lobéké N. P. and Dja Wildlife Reserve (Cameroon), Dzanga-Sangha Special Reserve and Bangassou F. R. (Central African Republic), Monte Alén N. P. (Equatorial Guinea), Lopé, Ivindo, Minkébé, Loango and Moukalaba-Doudou National Parks (Gabon), Odzala N. P., Nouabalé-Ndoki N. P. and Léfini Faunal Reserve (Congo) and Kahuzi-Biega, Maiko and Salonga National Parks (DR Congo).

This is a very popular quarry for hunters because it is compact, muscular and good-eating. It is hunted across its entire range, together with all other forest fauna, year-round and at increasingly intense, unregulated levels. In the Central African Republic, Bay Duikers accounted for 6.8% of all animals captured with nets (Noss 1998b). In Gabon, they accounted for 12% of duikers caught by village hunters and trappers (Lahm 1993). In the Dja area (Cameroon) they represent 17–25% of duikers killed (Fotso & Ngnegueu 1997, Muchaal & Ngandjui 1999). In Congo, Bay Duikers represent 15% of duikers for sale in Brazzaville bushmeat markets (F. Feer pers. obs.) and only 3.7% in Pointe Noire (Wilson & Wilson 1991). They rank between sixth and ninth among the game species on offer in Libreville (Gabon) markets (Ntsame Effa 2005), and were among the top five most hunted species in a bushmeat study in Nigeria (Fa *et al.* 2006). Studies in Equatorial Guinea, W Cameroon and Central African Republic have shown that current harvest rates are entirely unsustainable (Fa *et al.* 1995, Noss 1998b, Muchaal & Ngandjui 1999); in the Monte Mitra region of mainland Equatorial Guinea, Fa &

Garcia Yuste (2001) studied the offtake patterns of 42 hunters over a period of 16 months. The principal hunting method employed was cable snaring, and the Bay Duiker was by far the most heavily exploited species. As mentioned earlier, the extermination of this species could have much wider repercussions in the long-term ecology of those tree species (several of them highly desired commercial timbers) that are dispersed by Bay Duikers.

Measurements

Cephalophus dorsalis

TL (♂ ♂): 1040 (1030–1074) mm, n = 5

Cephalophus jentinki JENTINK'S DUIKER

Fr. Céphalophe de Jentink; Ger. Jentinkducker

Cephalophus jentinki Thomas, 1892. Proc. Zool. Soc. Lond. 1892: 417. 'Liberia'; since identified as Junk R. opposite Schieffelinville, Sharp-Hill (Kühn 1965).

LEFT: Jentink's Duiker *Cephalophus jentinki*.
ABOVE: Lateral view of skull of Jentink's Duiker *Cephalophus jentinki*.

Taxonomy Monotypic. Rode (1943) mistakenly suggested this species was conspecific with the Yellow-backed Duiker *C. silvicultor*. A multiple analysis of mtDNA sequences was consistent in always showing that *C. jentinki* was most closely allied to the Bay Duiker *C. dorsalis* and, more distantly, to Abbott's Duiker *C. spadix* and the Yellow-backed Duiker (Jansen van Vuuren & Robinson 2001). Synonyms: none. Chromosome number: $2n = 60$; the X chromosome is a submetacentric (Hard 1969, Robinson *et al.* 1996b).

Description A very robust, short-legged duiker with a bold pattern of black, white and grey. Very darkly coloured head and neck offset by a vivid white halter over the shoulders and lower chest and a white border surrounding lips, muzzle and nose. This colouring involves both skin and fur, the latter being extremely short and fine. In contrast to the fore-end, the hindquarters are grey agouti. There is an inconspicuous dark crest on the forehead. Young Jentink's Duikers are almost completely brown, similar to young Yellow-backed Duikers, and apparently have long lateral hooves. The tail is short. Preorbital glands are very large. Inguinal glands also are large, and often contain quantities of soft secretion (Wilson 2001). Pedal glands are present. The local inhabitants have many different names for them, and they are known as 'forest goat', 'white woman', 'white antelope' or as the duiker 'onto which the dew has fallen'.

Both sexes bear long (up to 21 cm) black horns, which are straight and smooth, oval in cross-section, extending backwards from the head in the plane of the face and curve very slightly downward towards the tips. The frontal outline of the skull is flat and the facial region above the toothrow and below the anteorbital fossa is markedly swollen out laterally, so that the teeth and their alveoli are quite hidden in an upper view of the skull. Grubb & Groves (2001) list a number of features that differentiate the skull of this species from the similar-sized Yellow-backed Duiker, including: the cranium

is longer and narrower; orbit larger; rostrum relatively longer but bowed anteriorly; forehead almost flat with grooves in which the supraorbital foramina are located; frontonasal suture more pointed; nasal and mandibular profiles more convex; mesopyterygoid fossa much narrower; bullae less angular; zygomatic arches more suddenly contracted in ear region; and no or rudimentary lateral nasal flanges.

Geographic Variation None recorded.

Similar Species

Cephalophus silvicultor. Sympatric and similar in size, but dark greyish-brown with a vivid cream-coloured patch on the back; horns less depressed.

Distribution Endemic to West Africa, being found only in the western part of the Upper Guinean forest block, from Sierra Leone through Liberia to W Côte d'Ivoire. In Sierra Leone, Jentink's Duikers were only positively reported from the country in 1989, from Western Area F. R. (southern part of the Freetown Peninsula). There is photographic evidence of their presence in the Gola F. R. complex (Ganas & Lindsell 2010), and their presence has been reported in areas such as the Mokañji Hills, Loma Mts and Tingi Hills (Davies & Birkenhäger 1990, Wilson & Wilson 1990, Grubb *et al.* 1998).

Kranz & Glumac (1983) indicated that the species occurred widely in E Liberia. It was found to be thinly distributed along the Sehnkwehn R., possibly present along the Sinoe R. and common at the Buto Oil Palm Plantation. Probably occurs locally throughout Liberia in areas of suitable habitat. The 1989/90 WWF/FAD survey confirmed its presence in the south-eastern forests including Grebo N. P. and surrounding forests. Also present in north-western forest blocks as well as in North Lorma National Forests. Presence in Sapo N. P. was confirmed in 1997 (East 1999). During a survey of hunters'

quarry in the area north of Sapo N. P. and along the logging road through the Krahn-Bassa Forest, Jentink's Duikers were readily recognized throughout the survey (R. Hoyt pers. comm.). A bushmeat study from Caspary *et al.* (1999) confirmed the presence of the species in the forests on Liberia's eastern border.

In Côte d'Ivoire, Jentink's Duiker, like the Zebra Duiker *Cephalophus zebra*, has apparently never occurred further east than the Niouniourou R., its historical distribution therefore having been limited to the south-western part of the Guinean forest zone (Roth & Hoppe-Dominik 1990). Widespread forest destruction and expansion of agriculture in this region during the last 25 years have confined the species to the remaining areas of primary forest: Haut Dodo, Rapid Grah, Hana, Cavally-Gouin and Scio Forest Reserves. Its main stronghold is Taï N. P., where it is found in primary forest and rarely in secondary forest. It is observed relatively frequently in the well-protected western part of Taï N. P., including the isolated Mt Nienokoué, and the IET scientific study area near the city of Taï (Hoppe-Dominik *et al.* 1998). It is seen less in the central part of the park and the heavily poached eastern part of the park.

Jentink's Duiker is sometimes reported as occurring in Ziama and Diécké forests in Guinea (e.g. Brugiére & Kormos 2009), based on a report by Butzler (1994). However, Jentink's Duiker is not recorded or mentioned at all by Sournia *et al.* (1990), Grubb *et al.* (1998), East (1999), or Wilson (2001), and was not reported by Barrie & Kanté (2006) in a rapid survey of Diécké in 2003. However, recent records from Mont Nimba Strict N. R. and the nearby Déré Classified Forest in 2009 (N. Granier pers. comm.) would lend support to their presence in SE Guinea.

Habitat Jentink's Duiker is only found in the high primary forest zone between Sierra Leone and the R. Niouniourou, a distribution that broadly coincides with many primate populations and also that of the Zebra Duiker. Within this zone, it does enter secondary growth, scrub, farms and plantations for brief periods (Davies & Birkenhäger 1990,

Wilson 2001), and is even known to visit the sea-shore, presumably for salt. It is a 'hider' choosing hollow trees, fallen trunks and the buttress bays of kapok (*Ceiba*), *Bombax* and mututu trees (*Klainedoxa*) for shelter. It is so secretive that it continued to survive less than 30 km from Free-town, a city of half a million people, hiding on steep, densely forested slopes in the city's water catchment area (Davies & Birkenhäger 1990). Its most basic requirements appear to be a diversity of fruiting trees and very dense shelter rather than a specific forest type (Kingdon 1997).

Abundance Jentink's Duiker appears to be uncommon to rare throughout its range. East (1999), assuming an average population density of 0.1/km², estimated the total population at about 3500, although Wilson (2001) doubted whether there were even more than 2000 animals left throughout the range. Peal & Kranz (1990) give densities of 1.0/km² in Liberia. Results from a survey in Taï N. P. in 2009 and 2010 covering 365 km recorded only a single sighting (N'Goran *et al.* 2009).

In 2000, most hunters described Jentink's Duikers as plentiful, but when pressed for information they reported only killing one or two individuals in their lifetime, even among hunters in their 60s. During a 10-month survey of hunters (representing 3% of the village populations) in three villages along the Juarzon–Pynes Town road near Sapo N. P., Jentink's Duikers were the ninth most commonly killed species ($n = 10$) (R. Hoyt pers. comm.). The population trend of the species is downwards except for a few remote areas where forest destruction and forest hunting pressures are lower, for example Sapo N. P., and the few areas where there is better protection, such as the western section of Taï N. P. (Hoppe-Dominik *et al.* 1998, 2011).

Adaptations As Jentink's Duiker is very shy and secretive, few direct observations exist. In Taï N. P., the species has been observed mostly during the day (Hoppe-Dominik *et al.* 2011), and animals held in captivity in Monrovia Zoo were active day and night (Newing 2001). It has been reported that Jentink's Duikers use their horns to uproot cassava plants so they can feed on the leaves, bark and tubers. Like Bay Duikers, they bolt from these daytime refuges with great speed if discovered, but have no stamina and do not go far. They are very residential and supposedly territorial, but make nocturnal forays out of thick forest, especially during periods when fruit is scarce (Davies & Birkenhäger 1990, Kingdon 1997).

Foraging and Food Fruits and foliage. Known to enter plantations to eat palm nuts, mangoes and cocoa pods. The growing stems of tree seedlings are eaten, including *Chlorophora* and *Hannoa klaineana* (Davies & Birkenhäger 1990). Hunters familiar with the animal's habits have identified many fruits with hard seeds or shells in its diet, notably kola nuts, erimado *Ricinodendron* sp., cherry mahogany *Tieghemella* sp., sand apples *Panaria* sp. and tallow tree *Pentadesma* sp. Jentink's Duiker has also been reported chewing roots after exposing them with its hooves (Kingdon 1997).

Social and Reproductive Behaviour Occasionally observed in pairs (Kranz & Glumac 1983), but most field observations are of lone animals, suggesting a primarily solitary social system.

Reproduction and Population Structure Observations in Liberia from Sapo N. P. (Kranz & Glumac 1983) indicate that young

are usually born between Mar and Jun, but young have been born in captivity in Monrovia between Nov and Jan. In captivity, young weigh 3–6 kg at birth (Pfefferkorn 2001). General recommendations of management and husbandry of captive duikers including the Jentink's Duiker are given by Barnes *et al.* (2002). A captive individual lived to 21 years (Weigl 2005).

Predators, Parasites and Diseases D. Jenny (pers. comm.) only once found hair from Jentink's Duiker amongst 200 examined scats of the Leopard *Panthera pardus* in Tāi N. P. It is possible that young animals are occasionally taken by the Crowned Eagle *Stephanoaetus coronatus*; however, they have not been found in prey remains examined in Tāi N. P. (S. Shultz pers. comm.). The extent to which African Golden Cats *Profelis aurata* and the African Rock Python *Python sebae* are to be regarded as predators is unknown. There is no information on diseases or parasites.

Conservation IUCN Category: Endangered C1. CITES: Appendix I.

Due to the continued demand for bushmeat and unsustainable hunting, the risk that species dependent upon primary rainforests such as Jentink's Duiker will die out is high. According to an examination by Caspary *et al.* (1999) in the region of Tāi N. P., the influence of hunting on these species is considerable. Subsistence hunting provides inhabitants of the park with an estimated 1500–3000 tonnes of wild animal meat per year. In this way the rural population consumes about 28–55 g of meat/inhabitant/day. Jentink's Duiker is poached both in the east and the west of Tāi N. P. For example, a market examination of a stand in the east of the park counted about 3.3% Jentink's Duiker (ten of a total of 2171 animals killed here). The share of Jentink's Duiker killed in the forests to the west of the Cavally R. in Liberia and smuggled into Côte d'Ivoire was 2.5%. Of a total of 11,215 dead animals, 55 Jentink's Duikers were counted. During a survey conducted in Liberia in 2002 by the Philadelphia Zoo, Jentink's Duikers were not common in the Monrovia bushmeat markets and no preference for Jentink's Duiker meat was identified, but carcasses were observed during the survey (R. Hoyt pers. comm.).

Although poaching still has a highly negative influence on the population, the long-term survival of Jentink's Duiker is closely linked to the future of the remaining blocks of primary forest of the Guinean forest zone. At present only the western part of Tāi N. P. receives effective protection. Rehabilitation of Sapo N. P. and development and implementation of protection and management programmes for the forests and wildlife as key areas are important. Better protection of areas such as Cestos–Sehnkwen, Sapo–Putu–Range, Grebo, Upper Krahn–Bassa in Liberia, Haute Dodo and Cavally Goin Forest Reserves in Côte d'Ivoire, and Western Area F. R. and Gola Complex Forest Reserves in Sierra Leone could result in a dramatic improvement of this species' current conservation status (East 1999).

Measurements

Cephalophus jentinki

HB: 1300–1500 mm

T: 120–160 mm

WT: 55–80 kg

Throughout geographic range (Kingdon 1997)

There are no reliable body measurements available, but weights reported by Wilson (2001) for animals from captivity (♂♂: 56.5–79.4 kg, n = 3 and ♀♀: 60.3–76.7 kg, n = 4) compare favourably with those measures given above. Haltenorth & Diller (1980) give a shoulder height of 750–850 mm

Wilson & Wilson (1990) recorded horn lengths ranging from 14.4 to 21.2 cm, and Davies & Birkenhäger (1990) recorded a pair 21.5 cm in length, which is slightly longer than the maximum horn length recorded by Rowland Ward of 21.3 cm from NE Liberia

Jentink's Duiker *Cephalophus jentinki*.

Tribe RAPHICERINI

Grysboks, Steenbok, Beira

Raphicerini Knottnerus-Meyer, 1907. Arch. Naturgesch. 73: 49.

Many of the small antelopes formerly allocated to the taxon Neotragini have long been thought to be basal to the antelope radiation, but so long as genealogical trees were not attempted the issue scarcely arose that these antelopes might not be monophyletic. Contemporary efforts to construct phylogenetic trees on the basis of relatedness (Hennig 1966) and newly available genetic information have challenged the monophyly of Neotragini as traditionally defined (Georgiadis *et al.* 1990, Gatesy *et al.* 1997, Hassanin & Douzery 1999, Matthee & Robinson 1999a, Rebholz & Harley 1999) and that taxon is now redundant for all of its former members barring *Neotragus* and *Nesotragus*. This dissolution of a convenient 'waste-paper basket' has raised, once again, the position of grysboks *Raphicerus* (and the Beira *Dorcatragus megalotis*) in relation to other antelopes and revived, in an entirely new context, the validity of assigning *Raphicerus* an exclusive tribe (including, very tentatively, *Dorcatragus* as a species that may have more complex affinities than are currently supposed). Haldenorth (1963), who used the tribe Raphicerini to accommodate *Raphicerus* as well as the Oribi *Ourebia ourebi*, included *Dorcatragus* in the tribe Dorcatragini.

The nomenclatural history of this taxon has been summarized by Grubb (2001a): 'Knottnerus-Meyer (1907) used the form Raphicerotinae; this was based on "*Raphicerus* Hamilton Smith, 1827", a misquotation of *Raphicerus* Hamilton Smith, 1827. The correct form, Raphicerinae, was used by Frechkop (1955) ("justifiable emendation of Raphicerotinae"); Haldenorth (1963) used Raphicerini, which of course is just the tribal form of Raphicerinae and so counts as the same name under the Principal of Coordination. The Code, Art. 35.4.1, says "A family-group name based on an unjustified emendation ... or an incorrect spelling of the name of the type genus must be corrected".'

In a composite tree of ruminant phylogeny, calibrated against a molecular clock, Hernández Fernández & Vrba (2005) estimated a 20 mya divergence for the *Raphicerus* lineage (they included the Beira as a sister species; see also Price *et al.* 2005). The dik-diks *Madoqua* spp. and the Oribi lineages were estimated to be equally old. Although these authors lumped the three lineages within Antilopini, 20 mya is between 5 and 10 millions years earlier, according to the same methods and authors, than the emergence of reduncines, hippotragines, alcelaphines and caprines, all well-defined and long accepted taxa. Aside from the issue of divergence times (according to Goodman *et al.* 1998, a 20–14 mya divergence is the acceptable time-rank for a tribe), there are also many unsolved puzzles about details of the antelopes' earliest radiations.

The excessive lumping or glossing over of differences implicit in the neotragine 'waste-paper basket' has deterred recognition of polyphyly. Uncritical transfer of basal or near-basal taxa from a 'Neotragini' that is now known to have been polyphyletic (and see Gentry 1992) to similarly polyphyletic groupings under an enlarged 'Antilopini' merely perpetuates the problem. We have, therefore, resuscitated Raphicerini, hoping it will help underline the complexity and subtlety of the antelopes' evolutionary radiation and provoke further research into the earliest radiations of antelopes.

Lateral view of skull of Steenbok *Raphicerus campestris* female.

Lateral view of skull of Cape Grysbok *Raphicerus melanotis* male.

Upper-right tooththrow of Cape Grysbok *Raphicerus melanotis*.

The cranial morphologies, ecology and distribution of contemporary *Raphicerus* and *Dorcatragus* manifest two divergent trends in temperature regulation: the former species are adapted to relatively moderate temperatures, whereas the Beira tolerates much higher levels of heat. The ecological and geographic distributions of the two genera help provide a proximate explanation for such differences but any (very ancient) common ancestor was probably closer to living at the hotter end of the spectrum (although it is unlikely that any such primitive ancestor was as highly adapted to heat as the living Beira). The principal indication of divergent heat-tolerances lies in the sizes and proportions of the nasals and premaxilla, well developed in *Raphicerus*, much reduced in *Dorcatragus*. An opened-up nasal area allows for a flexible 'nasal bellows' mechanism to develop a cooling system that is illustrated in its most extreme form in the dik-diks.

Sorting out the precise genetic relationships between the provisional tribes that are presented here (formerly all included in Neotragini), including Raphicerini, Madoquini, Ourebiini (and perhaps other lineages), is a task for the future. Details of behaviour and ecology in the four very different species that have been allocated to Raphicerini appear in the generic and species profiles.

Jonathan Kingdon

GENUS *Raphicerus*

Grysboks, Steenbok

Raphicerus C. H. Smith, 1827. In: Griffith et al., Anim. Kingd. 5: 342.

Living *Raphicerus* species are the Cape Grysbok *R. melanotis* and Sharpe's Grysbok *R. sharpei*, constituting what Ansell considered a superspecies (Ansell 1972), and the Steenbok *R. campestris*. The Cape Grysbok is endemic to South Africa, being restricted almost entirely to the Cape Floristic Region; Sharpe's Grysbok occurs in the savanna woodland from Tanzania to Swaziland, with a particular association with *Brachystegia* woodland; and the Steenbok has a disjunct distribution in East Africa (S Kenya, N and C Tanzania) and southern Africa. Earliest fossil records are of *R. paralius*, from 5.0 to 2.6 mya in South Africa (Gentry 1980, Vrba 1995); Steenboks and Cape Grysboks are known from Pleistocene deposits in South Africa.

The three species are generally small, but absolutely larger than species of the genus *Neotragus* or *Nesotragus*. The pelage is uniform or streaked, with white underparts. The rhinarium is naked. Ears are large or very large; the tail is short and not tufted. Preorbital glands open through single small orifices, and pedal glands are present (the Cape Grysbok ♂ also has a preputial gland); however, there is no subauricular gland, and no inguinal glands. Females have two pairs of inguinal nipples. Horns are present in ♂♂ only, rising nearly vertical, slender, cylindrical and smooth with almost no indication of annuli. The skull is stout with the rostrum much shortened and tapered compared with *Ourebia*. Other characteristics of the skull include: small but deep lachrymal depressions with upper and lower margins not forming sharp ridges; secondary deposition of bone on frontals and parietals; well-marked, widely spaced temporal ridges; ethmoid vacuity present; and the dentary with rounded angle. The first incisors are less broadened than in *Ourebia*; other incisiform teeth are narrow, but the second incisors are broader than the rest. The cheekteeth are small (though the premolars are relatively large) and low-crowned; the occlusal pattern is simple with styles not well marked.

Cape Grysboks were formerly assigned to their own genus *Nototragus* (Thomas & Schwann 1906), based on their retention of small lateral or false hooves and substantial differences in limb proportions and stance. Subsequently, both Shortridge (1934) and Roberts (1951) included both the Cape and the closely related Sharpe's Grysbok in *Nototragus* to distinguish the two shorter-legged, broader-mouthed grysboks from the longer-legged, smaller-mouthed and nominate Steenbok. Kingdon (1982) pointed out the differing lips and mouth structure between *R. melanotis/sharpei* and *R. campestris* and correlated these differences with diet and habitat. Haltenorth (1963) even considered the two grysbok species conspecific. However, Ellerman *et al.* (1953) and Ansell (1972) thought there were no grounds for recognizing *Nototragus*, considering both *R. sharpei* and *R. melanotis* as distinct enough to warrant species status; subsequent authors have followed this treatment (e.g. Meester *et al.* 1986, Grubb 1993c, 2005, Bronner *et al.* 2003). Species are distinguished by colour of pelage, size of ears, length of horns, relative length of limbs, and presence or absence of lateral hooves.

ABOVE: Steenbok *Raphicerus campestris* skeleton.

BELOW: Facial myology of *Raphicerus* spp. compared, showing mouths predominantly adapted to browsing, Sharpe's Grysbok *R. sharpei* (above) and to grazing, Steenbok *R. campestris* (below).

Peter Grubb

Raphicerus melanotis CAPE GRYSBOK

Fr. Grysbok du Cap; Ger. Kaapgreisbock

Raphicerus melanotis (Thunberg, 1811). Mem. Acad. Imp. Sci. St. Petersburg 3: 312. No locality cited, but selected as the Cape Peninsula, Western Cape Province, by Grubb (1999c) based on the records of Levaillant who encountered the species on the peninsula. Rookmaker (1988) noted that the Cape Grysbok was first named by J. R. Forster as both *Antelope melanotis* and *A. grisea*, both considered as *nomina nuda*.

LEFT: Cape Grysbok *Raphicerus melanotis*.
ABOVE: Lateral and palatal views of skull of Cape Grysbok *Raphicerus melanotis*.

Taxonomy Monotypic. Several authors (Haltenorth 1963, Haltenorth & Diller 1980) have considered the Cape Grysbok and Sharpe's Grysbok *Raphicerus sharpei* to be conspecific (separating the species into two subspecies), but Ellerman *et al.* (1953), Ansell (1972) and many other authors have treated them as distinct (and see Genus profile). Synonyms: *grisea*, *rubroalbescens*, *rufescens*. Chromosome number: not known.

Description A small reddish-brown antelope, standing only about 0.5 m at the shoulder, with a hunched or curved back, and short inconspicuous tail. The muzzle is short and with a black bridge to the nose. The common name is derived from the conspicuous white hairs visible in the overall rufous pelage on the sides and the back, which creates a greyish appearance ('grys' is grey in Afrikaans); the undersides are a lighter uniform brown. Ears relatively large with prominent whitish hairs on the inside whereas the outside is greyish. Supplementary or 'false' hooves are present above the fetlocks on all four legs (commonly absent in other *Raphicerus* species). Active preorbital glands are present, and pedal glands are present on all four feet; ♂♂ also have preputial glands (Manson 1974). Horns present in ♂ only, smooth and rising vertically from the head with a slight forward curve.

Geographic Variation None recorded.

Similar Species

Raphicerus sharpei. Allopatric in savanna woodland from Tanzania to Swaziland. Slightly smaller (mass of ± 7.5 kg), and a slightly paler reddish-brown pelage, also interspersed with white hairs, whilst

the underparts are also comparatively lighter having been described as buffy-white; false (lateral) hooves absent, being reduced to areas of thickened skin (Ansell 1972).

R. campestris. Broadly sympatric. Slightly heavier (± 11 kg), with a relatively straight back (as opposed to the hunched or arched appearance of Cape Grysbok), and tends to live in more open areas than the scrub-loving Cape Grysbok; more uniform red-brown without interspersed white hairs, the underparts are white or nearly so; horns longer (up to 190 mm); false (lateral) hooves absent.

Distribution The Cape Grysbok is endemic to South Africa. Boshoff & Kerley (2001) referred to the Cape Grysbok as nearly endemic to the Cape Floristic Region, occurring in montane and lowland habitats (with the exception of dense forest) to the south and west of the Cape Fold Mts. Skinner & Chimimba (2005) stated it occurs 'from the Cedarberg Mts in the Western Cape to the Vredenburg area and southwards and eastwards coastally to the Albany (= Cacadu) and Bathurst (= Cacadu) districts in the Eastern Cape, with records from the Komga (= Amatole) district'. Shortridge (1934) gave the extreme north-eastern limits as Port St Johns although there appears to have been some contention as to the precise limits for the Cape Grysbok along the E South African coastline (Skead 1987). Skead (1980) cited the reports of Barrow (1804) who stated that 'steenbok, oribi and grysbok were still plentiful in 1799 in the "Onder Bokkeveld"' but went on to warn that doubts should be cast on the records of both Cape Grysboks and Oribis (*Ourebia ourebi*) for that region.

Distribution extends into the mountain renosterveld of the Nieuwoudtville region and Cape Grysboks have been observed in

Oorlogskloof N. R. (C. T. Stuart & T. Stuart pers. comm.). The distribution of the species within this vegetation transition zone between the Fynbos and Succulent Karoo biomes of southern Africa is likely to be restricted to valleys and gorges with dense vegetation. Their northern limits would appear to have been the southern parts of the Great Karoo, probably south of the Escarpment. An apparently isolated population in the Eastern Cape has been indicated by two questionnaire surveys (Bigalke & Bateman 1962, Lloyd & Millar 1983) supported by personal interviews (Lynch 1989). Records from landowners have been substantiated by additional observations from the Barkly East district (Stuart 1984) and skins obtained in the vicinity of Maclear (Feely 1992). Archaeological records from this region also point to the presence of Cape Grysbocks in the area dating back some 2000–8000 years ago (Feely 1992). The species has also been recorded in the southern Drakensberg (Vincent 1962, Bourquin 1966, cited in Rowe-Rowe 1994) (for earlier records see Du Plessis 1969). There is a substantial gap between the southern limits of Sharpe's Grysbock and the north-eastern limits of the Cape Grysbock.

Habitat Bigalke (1979) stated that although it occurs in other vegetation types, the Cape Grysbock is 'essentially an animal of the Cape fynbos', in both winter and non-seasonal rainfall areas. Cape Grysbocks prefer dense cover and closed-canopy habitats. The propensity of the species to select dense vegetation is particularly true in the western portion of its distribution, where dense fynbos (scrub) communities dominate. Towards the east of their range Cape Grysbocks also utilize the dense thicket habitats associated with many of the river valleys and coastal regions. Presence in the high-altitude grasslands of the north-eastern Cape is conditional on the proximity of forest fragments and bush clumps, but, in some areas, Cape Grysbocks may also use long grass for cover. Although much of the Cape Floristic Region is now cultivated, the Cape Grysbock is one of the few antelope that can survive in relatively small patches of natural vegetation surrounded by cultivated lands (Manson 1974), and Skinner & Chimimba (2005) suggest that such cultivation may sometimes actually improve habitat for Cape Grysbocks provided that some dense cover is nearby. As commercial rooibos tea plantations have become established in the Cedarberg Region, the Cape Grysbock has been blamed, along with the Common Duiker *Sylvicapra grimmia*, for extensive damage to new shoots (C. T. Stuart & T. Stuart pers. comm.).

Abundance Cape Grysbocks are normally solitary and cryptic in their behaviour and therefore seldom seen. Visibility is further reduced in dense vegetation and this is exacerbated in fire-prone areas such as the fynbos of the Western Cape. Fires, bush clearing, grazing and agriculture all affect the visibility of Cape Grysbocks in the field and can influence counts. Boshoff *et al.* (2002) estimated the spatial habitat requirements of medium- to large-sized mammals in the Cape Floristic Region and compared some of their predictions with empirical data. Predictions from the model, based on intact habitat, suggested that Cape Grysbocks required between 6 and 456 ha per animal depending on the nature of the vegetation type. Based on the available habitats this would suggest that Cape Grysbock numbers could lie between 231,448 (post-habitat transformation) and 322,977 (pre-habitat transformation) in the Cape Floristic Region (Kerley *et al.* 2003). This is almost an order of magnitude higher than earlier estimates of their abundance in an area covering 61,000 km² (East 1999).

Cape Grysbock numbers in the Eastern Cape appear subject to local cyclical fluctuations in population numbers (Skead 1980, 1987), but this may also apply more widely to the Western Cape (P. H. Lloyd pers. obs.). Gamkaberg N. R. in the late 1990s had a notably conspicuous population of Cape Grysbocks on top of the mountain (as illustrated by the fact that Norton [1986] listed Cape Grysbocks, Klipspringers *Oreotragus oreotragus* and Grey Rhebocks *Pelea capreolus* as the most abundant antelopes). In the early 2000s, animals were rarely seen because a large fire had intervened and it is possible that the animals were destroyed, as well as much of their cover being destroyed, necessitating movement to less accessible areas. Skead (1987) also stated that outbreaks of ophthalmia (with increased vulnerability to predation) might have been implicated in some of these declines.

Scott (1991) studied the distribution of small antelopes in De Hoop (Provincial) N. R. between 1985 and 1987 and recorded density indices (number of animals per 100 km travelled) of 0.21 for Cape Grysbocks compared with 2.64 for Steenbocks. This might suggest that Steenbocks are at least ten times more abundant than Cape Grysbocks but, when habitat preferences and relative visibility are taken into account, it is likely that Cape Grysbocks have been substantially underestimated. In some protected areas the abundance of Cape Grysbocks appears to be linked to the density of other herbivores, particularly where such herbivores alter the structure of the vegetation. Grysbock ranges have seen local declines in numbers from areas such as Addo Elephant N. P., where escalating numbers of elephants have opened up or transformed thicket habitats (J. G. Castley pers. obs.).

Adaptations As described elsewhere, the Cape Grysbock is the only member of the genus *Raphicerus* that consistently has false hooves, a peculiarity that implies a more primitive evolutionary state within the Bovidae. Likewise, skull structure conforms with that of early, relatively unspecialized antilopine bovids (Kingdon 1982). In general, therefore,

the Cape Grysbok appears to represent the relatively unmodified descendant of an early line of antelope, rather than a more recently adapted form.

Only the ♂ is horned in this species and Novellie *et al.* (1984) have gone into some detail on the nature of conflict encounters between ♂♂ and suggested that damaging encounters rather than ritualized ones might be the more appropriate evolutionary strategy for the Cape Grysbok. Their arguments were based on the assertion that for small species, occupying small territories, retreats from conflict encounters put the retreating individual at a disadvantage. They argued that losing meant loss of access to forage as well as mating opportunities. Hence the unelaborated horn shape, a lack of observed rituals and retention of short, smooth, stabbing weapons in ♂♂.

The need to hold and demarcate small territories has probably influenced the intensity of other activities such as scent-marking using the preorbital glands. To date a total of 85 chemical compounds have been isolated from the black aqueous secretion of the preorbital gland (Burger *et al.* 1981b, 1996), implying a highly complex olfactory signalling system.

Cape Grysbocks are small antelopes that appear to be dependent on dense, bushy or scrubby vegetation. The archaeological record suggests that their abundance has been directly related to the bushiness of the vegetation (Klein 1983). In the archaeological sites evaluated (which were southern and south-western areas of the Cape Floristic Region, as opposed to grassland areas further east), its abundance was thought to have fluctuated over the last two interglacials according to the availability of bushy vegetation.

Foraging and Food Cape Grysbocks are predominantly browsers, although earlier accounts reported Cape Grysbocks as predominantly grazers (Dorst & Dandelot 1970, Smithers 1983). Manson (1974) recorded Cape Grysbocks grazing, but he only made one such observation out of 30 in total (although he conceded that grass might play a more important dietary role in other areas of their distribution). Kigozi *et al.* (2008), by investigation of faecal samples, also concluded that Cape Grysbocks were selective browsers and had a restricted diet of only nine species in the *Acacia*-dominated coastal dune fynbos of the Port Elizabeth region. Interestingly, these invasive species, notably *Acacia cyclops*, formed a significant part of the diet; no monocotyledonous plants were identified in the grysbok faecal samples. A wider variety of species is eaten in the western portions of their range where Cape Grysbocks have become a problem to farmers as more and more of the habitat has been taken over for vineyards, orchards (Manson 1974) and rooibos tea plantations (C. T. Stuart & T. Stuart pers. comm.). More recent evidence suggests that Cape Grysbocks are able to broaden their diet in response to changing forage availability. Such dietary flexibility also influences the amount of grass in the diet, which at times can be substantial (Kerley *et al.* 2010, Faith 2011).

Because they tend to eat fresh-growing shoots, Cape Grysbocks' water requirements are limited, but they have even been observed to utilize water with a high salt content (Manson 1974). During the period of his study Manson (1974) found that the greater part of the animals' feeding time was at night. He found feeding periods of 2–3 hours interspersed with periods of rest during which they ruminated. Browse is mostly cut by the premolars, but the bite selection process also occasionally involves the lower incisors.

Social and Reproductive Behaviour Cape Grysbocks are primarily solitary animals. Out of approximately 40 sightings in the wild, only two were of pairs: in one case a ♀ with her offspring, and in the other a ♂ with a ♀, during Sep (Manson 1974). Cape Grysbocks are territorial, particularly the ♂♂, but even the more tolerant ♀♀ exhibit strong territorial characteristics (Manson 1974). Novellie *et al.* (1984) noted that Cape Grysbocks, particularly ♂♂, had well-defined home-ranges averaging 2.5 ha (range 1.26–4.84 ha) and suggested that pairs did not share territories.

Males mark their territories by using their preorbital glands to mark twigs and grass stalks, leaving a conspicuous black sticky deposit. Females also have prominent preorbital glands with secretions clearly visible, but they appear to mark infrequently (only two observations being recorded, and those in captive animals) while juveniles of both sexes have never been observed using their preorbital glands (Novellie *et al.* 1984). On several occasions ♂♂ have been noted biting off twigs prior to marking the stems with their preorbital glands. Marking tends to take place at night and dominant animals mark more frequently than subordinates (Novellie *et al.* 1984). The effect of pedal, or interdigital, gland marking is less obvious, but animals were noted scratching the ground whenever establishing a new dung midden. Number of middens used in the wild has yet to be established, but both adults and juveniles use the same midden in captivity (Novellie *et al.* 1984).

In captivity, adult ♂♂ appear, without exception, to exhibit aggression to other adult ♂♂, with the dominant animal deposing subordinates regardless of supposed territorial boundaries (Novellie *et al.* 1984). Unrelated ♀♀ also exhibit relatively little tolerance of other ♀♀. Subordinate animals generally exhibit submissive behaviour by lying down, upon which the dominant animal approaches and makes naso-nasal contact. Occasionally, subordinate animals creep closer on their knees. At no stage can more than one adult ♂ be kept together in an enclosure. All attempts at keeping two rams have ended in major aggression, necessitating separation.

When a ♂ discovers a midden with female excretions, he first smells it, frequently following this with flehmen behaviour (typically lip and tongue movements and outstretched horizontal neck). Once oestrus has been detected and contact is made the ♂ marks the ♀ with preorbital gland secretions, thereby (according to Manson 1974) making her a part of his known environment. Once visual contact has been made the ♂ approaches and rubs against the female's head and neck, sometimes the rest of her body, occasionally licking her face, neck and shoulders. This sequence of behaviour is often repeated during the early courtship phase, but abates later. Manson (1974) also cited Ewen (1956) as having observed 'butting matches' during courtship, but did not observe it himself.

Males pay particular attention to the female's urogenital region during later stages of courtship, continually licking and following as the ♀ moves forward: the intensity increases and following becomes incessant. This appears to stimulate urination by the ♀, notably on established middens, and each time the ♂ again exhibits typical flehmen behaviour. Unsuccessful mating attempts often follow and these are caused by sudden forward movements by the ♀, with the ♂ standing on his hind legs, front legs folded to the chest, and very little, if any, actual body contact. Males often make bleating sounds while licking the ♀, or just prior to mounting. Females also bleat during encounters but less frequently than ♂♂. Novellie *et al.* (1984) also reported a greater frequency of licking and bleating behaviour by the ♂ during

periods of successful mating and he suggested that there are seasonal peaks (Mar–Jun) in this reproductive behaviour. Successful copulation only lasts for a few seconds and laufschiag (foreleg mating kick) was never observed in Cape Grysbooks (Novellie *et al.* 1984).

The young of territorial species are typically concealed, or conceal themselves, until sufficiently mature to emerge. Manson's (1974) sole observation of such an event was of a Cape Grysbook young that hid itself after being suckled. Suckling apparently takes place with the mother either standing or lying down.

Reproduction and Population Structure A single young is born at any time of the year, although a captive group showed a birth peak between Sep and Dec (Novellie *et al.* 1984); Spence (2003) notes birth peaks in captivity in Mar/Apr and Oct/Nov. Skinner & Chimimba (2005) noted that under favourable conditions ♀♀ can have up to two young in one year.

Skinner & Chimimba (2005) indicated that ♀♀ have their first young at 17–26 months while ♂♂ become sexually mature at 17–18 months. Manson (1974) observed a ♀ give birth at the age of approximately 18½ months, suggesting that sexual maturity in ♀♀ can occur at least as early as 12 months (which agrees with Spence [2003]). Based on subsequent observations, the gestation period appears to be approximately 192 days, or six months (Manson 1974). In captive animals at Tygerburg Zoo, Spence (2003) estimated gestation at 171–180 days, and recorded inter-birth intervals of 177–215 days. One captive specimen lived to more than seven years (Weigl 2005).

Predators, Parasites and Diseases Stuart (1981) identified Cape Grysbook remains in the stomach contents of both Caracals *Caracal caracal* and Leopards *Panthera pardus*. Skead (1980) reported that a considerable number of farmers were convinced that Cape Grysbook numbers had declined due to an alleged increase in Caracal numbers, but he noted that, at least in the Eastern Cape, these appeared to be cyclical events for both Caracals and Cape Grysbooks. In West Coast N. P., Cape Grysbooks are likely to have contributed to the diet of Caracals even though they are a low-density species compared with other ungulates. Even so, Avenant & Nel (1997, 1998) found that ungulates only made up about 7% of the Caracal diet (the bulk being rodents). Another probable carnivore predator is the Black-backed Jackal *Canis mesomelas*, whilst Ratels *Mellivora capensis* could potentially prey on young. Langley (1986) reported a number of attacks on Cape Grysbook young by Cape Grey Mongooses *Herpestes pulverulentus*, suggesting that newborns may be under predation risk, even from small carnivores. Other predators known to prey on Cape Grysbooks include some of the larger raptors, such as Crowned Eagles *Stephanoaetus coronatus* (Boshoff *et al.* 1994), Verreaux's Eagles *Aquila verreauxii* (Boshoff *et al.* 1991), and probably Martial Eagles *Polemaetus bellicosus* (Boshoff & Palmer 1980, Boshoff *et al.* 1990).

A number of studies have investigated the parasite loads on Cape Grysbooks and compared them with other susceptible species (Boomker *et al.* 1989a, MacIvor & Horak 2003, Watermeyer *et al.* 2003). Boomker *et al.* (1989a) reported that nematodes of nine species as well as a further two genera and cestodes of one species

and a further genus were recovered. Highest loads were of the nematodes *Skrjabinema* spp., *Trichostrongylus pieterse* and *T. rugatus*. High numbers of the nematode *Skrjabinema* spp. (parasites that are commonly reported to occur in high numbers in grazing antelopes) has lent indirect support for some grazing activity taking place in Cape Grysbook (Boomker *et al.* 1989a). The nematodes *Haemonchus contortus* and *Impalaia tuberculata* were not recorded in this survey and Boomker *et al.* (1989a) felt that earlier records (Mönnig 1931, 1933) should be treated with caution as the hosts may actually have been Steenboks. Watermeyer *et al.* (2003) identified a new parasite record for the Cape Grysbook (*Setaria saegeri*).

One of the most frequent disease issues reported to conservation authorities in the Western Cape (P. H. Lloyd pers. obs.) and Eastern Cape (Skead 1987) is that of infectious ophthalmia in Cape Grysbooks. By contrast, relatively few reports have been received of incidents of this infection in Steenboks. Since the organism causing the disease, *Rickettsia conjunctivae*, is frequently found in, and dispersed by, a variety of flies and other arthropods, it would appear that the Cape Grysbook's selection of dense vegetation could be a contributory factor, since many flies use shaded areas under vegetation.

Conservation IUCN Category: Least Concern. CITES: Not listed.

The Cape Grysbook is officially conserved in the majority of formal conservation areas in the Western Cape, as well as in many others in the Eastern Cape. It is known from seven National Parks, including Table Mountain N. P., West Coast N. P., Agulhas N. P. and Wilderness N. P., and at least 27 Provincial Nature Reserves. The long-term viability of state parks and reserves as well as the increasing number of privately owned reserves will be contributory factors to the future persistence of the species. For many of the private reserves and even some of the state-protected areas the continued presence of undesirable species (extralimital, exotic or domestic) that out-compete or negatively impact on the Cape Grysbook should be a major concern.

Measurements

Raphicerus melanotis

TL (♂♂): 771 (450–810) mm, n = 4

TL (♀♀): 793 (720–815) mm, n = 5

T (♂♂): 58 (40–72) mm, n = 4

T (♀♀): 54 (44–60) mm, n = 5

HF c.u. (♂♂): 245 (240–250) mm, n = 4

HF c.u. (♀♀): 248 (235–265) mm, n = 5

E (♂♂): 113 (105–115) mm, n = 4

E (♀♀): 115 (110–120) mm, n = 5

WT (♂♂): 10.0 (10.0) kg, n = 4

WT (♀♀): 10.5 (8.8–11.4) kg, n = 5

Western Cape (C. T. Stuart, in Skinner & Chimimba 2005)

Maximum recorded horn length is 13.3 cm for a pair of horns from the Western Cape, South Africa (Rowland Ward)

***Raphicerus sharpei* SHARPE'S GRYSBOK**

Fr. Grysbok de Sharpe; Ger. Sharpegreisbock

Raphicerus sharpei (Thomas, 1897). Proc. Zool. Soc. Lond. 1896: 796, pl. 34 [1867]. S Angoniland, Malawi.Sharpe's Grysbok *Raphicerus sharpei*.Lateral and dorsal views of skull of Sharpe's Grysbok *Raphicerus sharpei*.

Taxonomy Sharpe's Grysbok has been considered synonymous with the Cape Grysbok *Raphicerus melanotis* (Haltenorth 1963, Haltenorth & Diller 1980), but Ellerman *et al.* (1953) and Ansell (1972) regarded both as distinct species (and see Genus profile). Ansell (1972) recognized two subspecies: *R. r. sharpei*, a supposedly smaller, paler form from the northern parts of the species' range, and *R. r. colonicus*, a larger, marginally darker form from the southern parts of the range. However, the precise limits of distribution between the two have never been very clear, and the validity of these subspecies is doubtful. Synonyms: *colonicus*. Chromosome number: not known.

Description Small antelope with a rich, reddish-fawn body colouration and a liberal sprinkling of white hairs on the dorsal parts, shoulders and flanks. Eyes surrounded by an ill-defined whitish ring. Ears with buffy-white hair inside; dark on the outside. A short, dark band on top of the muzzle extends from the rhinarium to the front of the eyes. Sides of the face, outer parts of the limbs, forehead and upperparts of the muzzle yellowish-brown, lacking the white grizzling seen on the dorsal parts. Underparts, throat and insides of the legs paler than upperparts, almost white. Body hairs fairly long (30 mm). Lateral (false) hooves are absent (present on hindlegs of Cape Grysbok). Preorbital glands are present as small patches of black naked skin, about 2 mm in diameter and 3 mm deep (Ansell 1964). Preputial gland present, the opening lying anterior to that of the urethral canal. Pedal glands on both fore- and hindfeet, opening into the interdigital cleft that is well covered with hair (in contrast to the Cape Grysbok in which it is very sparsely haired [Ansell 1964]). No obvious sexual dimorphism, although meagre data from animals taken in Zimbabwe and E Zambia suggest that ♀ is slightly larger. Horns present in ♂ only, short and sloping slightly backward, tapering to sharp points.

Geographic Variation See Taxonomy.

Similar Species

Raphicerus campestris. Marginally sympatric in the northern and southern parts of the range of Sharpe's Grysbok, but absent from the miombo *Brachystegia* woodlands of N Mozambique, Malawi and much of Zambia. Slightly larger (± 11 kg), with smoother coat, more uniformly coloured, and lacking white speckling; black-rimmed eyes very conspicuous against pure white margin; horns longer (max. 190 mm); back profile more horizontal and less hunched.

R. melanotis. Allopatric, with distribution nearly confined to the Cape Floristic Region. Slightly larger (mass of ± 10 kg), with conspicuous white hairs visible in an overall rufous pelage; false (lateral) hooves present.

Distribution Endemic to Africa, occurring in savanna woodland from Tanzania to Swaziland. They are recorded from the western and southern parts of Tanzania (close to L. Victoria at their northern limits). Distribution then extends southwards through SE DR Congo, most of Zambia (though not west of the Zambezi R.), Malawi and Mozambique (not including the coastal forested regions), to extreme NE Botswana and the eastern Caprivi Strip in Namibia, much of Zimbabwe (including the dry western parts, such as Hwange) and NE South Africa (Limpopo Province, E Mpumalanga), and E Swaziland (Ansell 1978, Kingdon 1982, Ansell & Dowsett 1988, Monadjem 1998, East 1999, Skinner & Chimimba 2005). Not yet recorded from SE Angola or N KwaZulu-Natal Province.

Habitat Across much of their range (Zimbabwe, Zambia and Tanzania) they appear to be associated with *Brachystegia* woodland where there is good undercover in the form of low-growing scrub or medium-length grass (Smithers & Wilson 1979, Kingdon 1982). In some parts of Zimbabwe and Tanzania they live in rocky terrain with low bush and grass cover, often around kopjes and stony ridges. In

Raphicerus sharpei

Hwange N. P., Zimbabwe, they are common in riverine vegetation, but also occur in broken country where there are thickets at the base of kopjes (Wilson 1975).

Although they appear to be associated with areas of good ground cover, Wilson (1975) recorded that, in Hwange N. P., they were also found in pure stands of mopane *Colophospermum mopane* with very little good cover and in Chobe N. P., Botswana, they were seen on a sandy plateau in open woodland with light grass and scrub cover.

Wilson (1975), referring to his 1969/71 survey of Hwange N. P., indicated that Sharpe's Grysbok was confined to the northern part of the Park, and was replaced in the southern sections by the Steenbok. At that time the species was common along the Lukosi R. where there were considerable riverine thickets. Over a distance of 10 miles, 19 Grysbocks were seen on the evening of 9 October 1969. In 1996, another detailed survey of the Park was undertaken and Wilson (1997) noted: 'the Lukosi River Marked Transect was covered on no less than 18 occasions by several different teams and at different times of the day throughout the year and not one Sharpe's Grysbok was seen'. Wilson (1997) goes on to say: 'I have mentioned previously ... that 25 years ago the riverine vegetation along the Lukosi River was very dense and that was when grysbocks were found there. Today [1996] the vegetation has thinned out considerably as a result of elephant destruction and grysbocks no longer occur along the Lukosi River Drive where 25 years ago they were common. However, their distribution may well have shifted southwards into the broken country south of Lukosi and east to Shumba where they are now found.' The species also still occurs in other areas in the northern parts of Hwange N. P.

Abundance East (1999) summarized recorded population density estimates for this species (0.3–0.7 ind/km²), and estimated a total population size of about 95,000 animals. Sharpe's Grysbocks are predominantly nocturnal, exceptionally shy and secretive, and can be overlooked in areas where in reality they are reasonably common, so they may be more abundant than supposed.

Sharpe's Grysbok *Raphicerus sharpei* detail of head.

Adaptations This species has remarkably robust teeth correspondingly deeply embedded in skull and mandible. The mouth has a substantially wider maw than in the Steenbok. These dental and oral peculiarities correspond to a more demanding diet, probably including more lignified and mature growth than is taken by Steenbocks, which prefer newer younger shoots. The extreme caution and mainly nocturnal activity of this species also contrast strongly with the commonly diurnal and often conspicuous behaviour and appearance of the larger Steenbok. The shorter legs and cryptic colouration of Sharpe's Grysbocks imply greater vulnerability to predators, which probably include both coursers and large raptors. Flight behaviour includes a brief, stamping pronk and a fast dash for dense cover. The longer-legged Steenbok instead may race away in the open, jinking from side to side before hiding. During the game rescue operations that took place during the formation of L. Kariba, Sharpe's Grysbocks were recorded as readily taking to water, and were said to swim well for their size (Child 1968).

Foraging and Food Predominantly a browser, but they also will graze, and as such are classified as browser–grazer intermediates by Gagnon & Chew (2000) in their review of the dietary preferences of African bovids. In SE Zimbabwe, stomach contents consisted of 70% browse and 30% grass, with important browse items including: *Acacia* spp., sand olive *Dodonaea viscosa*, buffalo thorn *Ziziphus mucronata*, false marula *Lannea edulis*, horn-pod tree *Diploerhynchus condylocarpon*, beechwood *Faurea saligna* and bitter albizia *Albizia amara* (Smithers & Wilson 1979). Wilson (1975), in Hwange N. P., recorded *Diospyros lycioides* fruits, *Grewia flavescens* fruits and leaves, the leaves and soft stems of *Commelina* sp., the leaves and fruits of *Cyphostemma burchanani*, and a number of unidentified grasses.

Although they feed mainly at night, Sharpe's Grysbocks may be seen foraging in the early morning or late afternoon, lying up during the heat of the day in dense cover (Smithers 1971).

Social and Reproductive Behaviour Very little is known about the behaviour of this species. They usually occur solitarily, in pairs, or a ♀ with her single offspring. A loosely connected pair may share a territory throughout the year (Kingdon 1982). Droppings are apparently placed in small middens, which are used over long periods (Smithers 1971). The latter suggests that Sharpe's Grysbocks do not undertake extensive seasonal movements.

They are notoriously secretive and reclusive, inclined to lie up very tightly hidden in the undergrowth. When they do run off they often

crouch low to the ground as they run through the thick underbush, in contrast to the Common Duiker *Sylvicapra grimmia*, which bounds through the undergrowth, or the Steenbok (described above). They have been recorded hiding in Aardvark *Orycteropus afer* burrows (Shortridge 1934, V. J. Wilson pers. obs.).

Reproduction and Population Structure Pregnant ♀♀ have been recorded throughout the year (Shortridge 1934, Ansell 1960a, Kerr & Wilson 1967, Smithers 1971, Smithers & Wilson 1979, V. J. Wilson pers. obs.), suggesting that they are aseasonal breeders. A single young is born following a gestation of about seven months. Birth-weight in captivity is around 830 g (range 790–863 g, $n = 5$; V. J. Wilson pers. obs.). There is limited information available on population structure, although during the game rescue operations on L. Kariba, of 222 sexed individuals recorded in reports, there were 113 ♂♂ and 109 ♀♀ (V. J. Wilson pers. obs.).

Predators, Parasites and Diseases Predators include Lions *Panthera leo*, jackals *Canis* spp., Caracals *Caracal caracal*, African Rock Pythons *Python sebae* and large raptors. On one occasion a 10-foot python, captured on the Lukosi R. in Hwange N. P., was being stretched out in order to measure it and it regurgitated a partly digested adult Sharpe's Grysbok ♀ (V. J. Wilson pers. obs.). A single animal examined in the Central Province of Zambia was infected with *Amblyomma variegatum*, *Rhipicephalus appendiculatus*, *R. kochi* and *R. punctatus*; *R. appendiculatus* constituted 94% of all ticks present (Zieger *et al.* 1998b).

Conservation IUCN Category: Least Concern. CITES: not listed.

Although they have been extirpated from parts of their range by expanding human settlement and localized hunting for bushmeat, Sharpe's Grysbok remain relatively widespread with about one-third of the total population occurring in protected areas, including: Selous G. R. (Tanzania), Upemba N. P. (DR Congo), Kafue N. P. and North and South Luangwa National Parks (Zambia), Lengwe N. P. (Malawi),

Banhine N. P. (Mozambique), Hwange N. P. and Gonarezhou N. P. (Zimbabwe) and Kruger N. P. (South Africa) (East 1999).

Measurements

Raphicerus sharpei

TL (♂♂): 751 (710–800) mm, $n = 12$

TL (♀♀): 757 (725–800) mm, $n = 11$

T (♂♂): 58 (50–70) mm, $n = 12$

T (♀♀): 59 (45–70) mm, $n = 11$

E (♂♂): 90 (83–98) mm, $n = 12$

E (♀♀): 91 (85–98) mm, $n = 11$

WT (♂♂): 7.3 (6.8–8.9) kg, $n = 12$

WT (♀♀): 7.7 (6.4–8.9) kg, $n = 11$

SE Zimbabwe (Smithers & Wilson 1979)

TL (♂♂): 760, 880 mm, $n = 2$

TL (♀♀): 763 (550–820) mm, $n = 8$

T (♂♂): 60, 70 mm, $n = 2$

T (♀♀): 78 (50–90) mm, $n = 8$

WT (♂♂): 8.9 (6.3–11.8) kg, $n = 4$

WT (♀♀): 9.0 (7.2–10.8) kg, $n = 19$

E Zambia (V. J. Wilson pers. obs.).

In E Zambia, an additional seven adult ♂♂ had a mean mass of 8.9 kg (range 7.1–10.7 kg), and eight adult ♀♀ 9.9 kg (range 8.5–11.9 kg). The mean masses of animals caught at Kariba during game rescue operations was: ♀♀ 10.1 kg (range 8.6–11.1 kg, $n = 9$); ♂♂ 9.6 kg (range 9.0–10.1 kg, $n = 6$) (V. J. Wilson pers. obs.).

Maximum recorded horn length is 10.4 cm for a pair of horns from Massingir, Mozambique (Rowland Ward)

***Raphicerus campestris* STEENBOK (STEINBUCK, STEINBOK)**

Fr. Steenbok; Ger. Steinbockchen

Raphicerus campestris (Thunberg, 1811). Mem. Acad. Imp. Sci. St. Petersburg 3: 313. No locality cited; since selected as Western Cape Prov., Malmesbury Div., Swartland (Grubb 1999: 23).

Steenbok *Raphicerus campestris*.

Taxonomy The colouration of Steenboks varies widely throughout their range, and has partly contributed to the recognition of so many subspecies. Ansell (1972), in his revision of the taxonomy of the species, listed eight subspecies, noting that their acceptance was provisional and that study of a more complete series of specimens would lead to a reduction in the number of recognized subspecies. Of the eight listed by Ansell (1972), only one was listed for East Africa, namely *R. c. neumanni*, one (*R. c. kelleni*) for Angola and Zambia, and the remaining six for southern Africa; Meester *et al.* (1986) reduced this list to five. Pending a much-needed taxonomic revision, the most reasonable approach appears that of Kingdon (1997), who lists only two subspecies: the nominate form from the southern part of the range, and *R. c. neumanni* for East Africa. Synonyms: *acuticornis*, *bourquii*, *capensis*, *capricornis*, *cunenensis*, *fulvorubescens*, *grayi*, *hoamibensis*, *horstockii*, *ibex*, *kelleni*, *natalensis*, *neumanni*, *pallida*, *pediotragus*, *rufescens*, *rupestris*, *steinhardtii*, *stenbock*, *stigmatus*, *subulata*, *tragulus*, *ugabensis*, *zukowskyi*, *zuluensis*. Chromosome number: $2n = 30$ (Wallace & Fairall 1967a). All autosomes are metacentric; the X-chromosome is a large acrocentric and the Y is a small metacentric.

Description A small, gracile antelope (about 0.5 m at the shoulder), with long, slender legs, a glossy light brown to reddish-brown pelage on the flanks and back and white underparts. Ear pinnae large with white inside, light grey on the back and a thin black line around the pinnae rims. Throat and chin white, nose and dorsal ridge of rostrum black, and there is a distinctly pale or white eyebrow line, giving the animal a neatly groomed appearance. The brown eyes are rimmed by black skin that enlarges their visual impact. Hooves narrow and sharp; false

Lateral, palatal and dorsal views of skull of Steenbok *Raphicerus campestris*.

hooves absent. Tail short, brown above and white underneath. Hairs on the tail and the posterior margins of the hindquarters are longer than on the rest of the body. Steenbok have preorbital glands, pedal glands in all feet, but no inguinal glands. Build and colouration similar in ♂ and ♀, except that ♂ has short, sharp, straight, smooth and upward-pointing horns (usually 100–150 mm long) that are relatively widely spaced on the head; as in some other bovids, horned ♀♀ are known. Juveniles are darker than adults, especially on the rump where there is a greyish tinge, and have longer hair all over the body. Juveniles also have two distinctive black spots on the crown of the head where horns would be expected, and these fade with maturity.

Geographic Variation

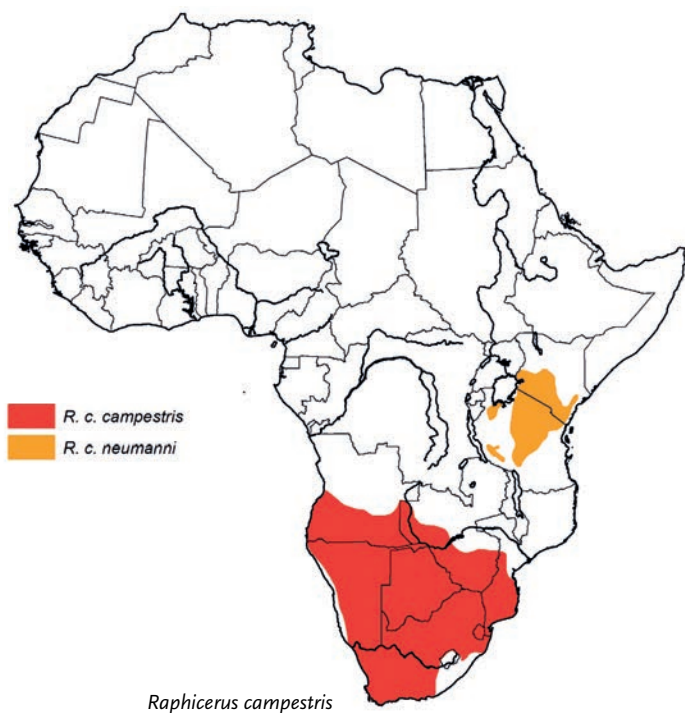

R. c. campestris: southern Africa, including Angola and Zambia.

R. c. neumanni: East Africa.

Similar Species

Raphicerus melanotis. Sympatric in SW Africa. Slightly smaller (ca. 10 kg), with slightly hunched or arched appearance; grizzled hairs on back, sides and neck; lateral hooves present; ♂ has a preputial gland.

R. sharpei. Marginally sympatric especially in Zimbabwe and S Mozambique. Slightly smaller (ca. 10 kg), with shorter legs and more hunched profile; horns shorter (max. 104 mm); pelage grizzled with white flecks.

Sylvicapra grimmia. Broadly sympatric. Larger, with sagittal hair tuft.
Ourebia ourebi. Sympatric in parts of range. Larger, with longer neck, and black patch above the tail; inguinal glands present; bare glandular patch below the ear.

Distribution Endemic to Africa. Steenboks have a disjunct distribution, with one population in East Africa (S Kenya, N and C Tanzania) and a larger one in southern Africa, the isolating barrier being the tall miombo *Brachystegia* woodlands of C Zambia, Malawi (from which there are no records) and N Mozambique.

Historical Distribution In East Africa, their distribution covers most of S Kenya and N and C Tanzania. They formerly occurred in E Uganda but are now believed extinct. Not recorded from Somalia (Funaioli & Simonetta 1966, Simonetta 1988).

In southern Africa, their range extends southwards from S Angola and W and SW Zambia, into most of Namibia (except the arid coastal parts), throughout Botswana and W, C and S Zimbabwe (though naturally absent from the Zambezi Valley below Victoria Falls), S Mozambique (being very common south of the Save R.), to South Africa. In South Africa, they occur almost throughout, being absent from S and SE KwaZulu–Natal and much of the neighbouring Eastern Cape (Ansell 1978, Kingdon 1982, East 1999, Skinner & Chimimba 2005). They are not recorded from Lesotho (Lynch 1994).

Current Distribution Their distribution is largely unchanged in southern Africa, but in East Africa Steenboks no longer occur in Uganda, where most of the suitable habitat is now cultivated (East 1999).

Habitat Steenboks are found in a variety of habitat types, from Kalahari semi-desert to alpine moorland zones up to 3500 m on Mt Kenya (Young & Evans 1993). However, within any particular ecosystem, Steenboks use a relatively narrow range of habitats with a common factor being the presence of pioneer plants and encroaching

thorn bushes in areas where vegetation is disturbed. For example, they are often seen feeding along road verges. In southern Africa, they show a particular preference for heavily grazed areas, where the herb layer has a high forb : grass ratio and the woody layer is dominated by encroaching thorn scrub, typically comprising *Acacia tortilis* and *Dichrostachys cinerea*. Such conditions often occur around watering points although the availability of drinking water is not a habitat requirement for Steenboks. The key habitat requirement is the availability of high-quality food items (green browse, geophytes, berries, flowers or pods) throughout the year. In the lower Kuiseb River Canyon, Namibia, there was a strong relationship between the distribution of Steenboks and the occurrence of *Acacia albida* (staple food) and *Salvadora persica* (shelter) (Cloete & Kok 1986b).

Abundance Steenboks are common throughout their range. Aerial surveys underestimate population numbers, but ground surveys, in areas where the species is common, give density estimates of 0.3–1.0/km² (East 1999). Based on these estimates, East (1999) estimated a total population size in excess of 600,000, but this clearly is an underestimate. In general, there are no reliable estimates of Steenbok population density, as census methods are too unreliable for this cryptic species.

Adaptations The ability to survive without access to drinking water in arid regions might suggest that Steenbok physiology is specifically adapted for advanced water economy, but in fact this is not the case. Steenboks in the Namib Desert were found to have a water turnover rate of 135 ml/day and their rate of faecal water loss was 145 ml/day, while their dietary water intake rate was 343 ml/day (Cloete & Kok 1986a). The surplus of 63 ml/day would be lost in breathing and evaporative cooling. From kidney structure and function there is no evidence that Steenbok renal efficiency is any higher than average for ruminants, indicating that water balance is maintained largely by behavioural means. These include feeding very selectively on food items of high water content, avoiding heat stress by lying in shade in the heat of the day, restricting diurnal activity mostly to morning and late afternoon, and being active nocturnally. Being small-bodied, Steenboks gain and lose body temperature relatively quickly. They have a low metabolic rate and a high overall thermal conductance (Haim & Skinner 1991). When ambient temperatures exceed about 38 °C, typical heat-shedding behaviour is to stand panting in the shade, with legs spread to dissipate heat from thermal ‘windows’ in the armpits, groin and belly.

Their requirement for highly nutritious food items precludes sociality, since such food items are rare and widely dispersed in the environment. If Steenboks foraged in groups there would never be enough food to share at each feeding stop. An implication is that living alone, or sometimes in mixed-sex pairs, precludes the sharing of vigilance costs among herd members. Steenboks do not, in fact, invest more in vigilance, but rely almost entirely on crypsis for predation avoidance (du Toit & Yetman 2005). Steenbok are adapted for vigilance by having relatively large ears and apparently good eyesight. When an approaching predator is detected, the Steenbok will lie motionless in the grass with its ears laid flat and usually the predator will pass by. It is only when a predator approaches within a few metres that the Steenbok will bolt suddenly and at high speed, employing a bouncing hare-like gait and jinking in sharp zig-zags,

then stopping suddenly to stand stock-still or dropping into cover to lie motionless again. Besides Sharpe's Grysbok, Steenboks are the only antelope species known to take refuge in burrows, especially those of Aardvarks *Orycteropus afer*, for predation avoidance and possibly thermoregulation (Smithers 1971, J. T. du Toit pers. obs.).

Foraging and Food Although they are frequently referred to in the scientific literature as mixed feeders, largely because of Hofmann & Stewart's (1972) classification based on stomach structure, Steenboks are predominantly browsers throughout the year. In Kruger N. P., South Africa, both Cohen (1987) and du Toit (1993) found that grass leaves are ingested when they are green and tender after rains but, overall, grass contributes an insignificant amount to the mean monthly diet. These field studies are supported by a review of dietary preferences in African bovids (Gagnon & Chew 2000) and dietary studies involving analysis of stable carbon isotopes that show that Steenboks eat far less grass than is believed (Cerling *et al.* 2003, Sponheimer *et al.* 2003b). However, in Zimbabwe, a sample of 91 stomachs from shot animals comprised 30% grass on average (Smithers 1971), and the same author notes that in a sample of 25 stomachs from Botswana, there was an average of 50% browse and 50% grass. This is surprising but indicates that grazing can be important at times. Indeed, in Kenya, Hofmann (1973) noted from stomachs that grass predominated in the diet after rain had stimulated new growth.

Steenboks in Kruger N. P. allocate most of their feeding time to forbs during the wet season (>80% feeding time) with the balance being made up mainly of leaves of woody plants, of which *Flueggea*, *Acacia* and *Ziziphus* species are staples (du Toit 1993). The monthly proportional allocation of feeding time to forbs varies closely with the three-month running mean of rainfall, which is an indicator of soil moisture content. During the late dry season in Kruger N. P. (Jul–Oct) forbs make up only about 30% of the diet, with the rest being mainly leaves of woody plants, although the fallen pods of *Acacia tortilis* are avidly sought out. It appears that the availability of these highly nutritious pods is a key factor enabling Steenboks to remain resident within their territories during the dry season and not to move down-slope to feed along river lines, as most of the other ungulates do during this 'lean' period. Also, Steenboks benefit from the micro-climate created within the recumbent canopies of trees felled by elephants, where forbs remain green well into the dry season. Bigger browsers are excluded from this resource by the cage of branches, through which Steenboks are able to creep.

Steenbok *Raphicerus campestris*.

The mean height above ground at which Steenboks feed varies from 140 mm in the wet season when forbs are the staple, to 390 mm in the late dry season when woody browse predominates in the diet. At full neck stretch, Steenboks cannot browse any higher than about 1 m above ground (du Toit 1990a) and they do not rise up on their hindlegs to gain additional height.

Being one of the smallest ruminant species, Steenboks have a narrow dietary tolerance range and thus have to be efficient at maximizing net energetic gains from foraging. Steenboks spend about one-third of their day foraging (feeding and walking in search of food items) in both wet and dry seasons, and the same proportion of the night in the wet season, but in the dry season they spend almost 60% of their night foraging. When not foraging, Steenboks generally lie ruminating or resting to conserve energy (and heat, in winter), and throughout the year they spend about half of their time lying down. Rumination is important for processing ingested food as quickly and thoroughly as possible, and in the wet season this accounts for an additional 26 min for every hour spent foraging, rising to 33 min per foraging hour in the dry season. Steenboks seek out flowers and fruits when they are available, although frugivory appears to be regulated by plant toxins. For example, a radio-collared Steenbok in Kruger N. P. would eat only one *Solanum panduraeforme* fruit per day, even when they were abundantly available.

Geophagia is common. When a Steenbok is seen standing head down near the water's edge of a pan it may mistakenly be assumed to be drinking, but on close inspection it will invariably be licking the salt crust off dried mud. Steenboks in Kruger N. P. are sometimes seen digging with their front hooves and apparently consuming bulbs or tubers. The only documented observation of this behaviour is by Smithers (1983) in Botswana.

Social and Reproductive Behaviour Steenboks are solitary, unless a ♂ is consorting with a ♀, or a ♀ has a juvenile with her. Both sexes maintain territories and a defender will drive a conspecific intruder of the same sex out of its territory in an energetic chase, although physical combat is rare. It is unclear what cues are used among ♀♀ to assess dominance and submission, since without horns the options for physical combat seem limited. However, in ♂♂, opponents kneel on their forelegs and present their horns to one another, with the loser breaking away and running after only a few seconds. This behaviour is most frequently seen when a ♂ is consorting with an oestrous ♀ and other ♂♂ attempt to gain access to her.

Scent-marking entails depositing secretions from the preorbital glands on the browsed stumps of forbs and shrubs. Burger *et al.* (1999a) examined the organic constituents of the preorbital secretion of the Steenbok, and identified 109 different compounds. However, these authors noted that although the secretion is similar to that of the Cape Grysbok *Raphicerus melanotis*, it is far more complex, with more than 260 different compounds present in the secretion. Steenboks also scent-mark by means of urinating and defecating in latrines. A shallow scrape is prepared with the front hooves, the animal then squats to deposit urine and/or faeces in the scrape and then fresh soil is kicked over the latrine with the front hooves. This behaviour presumably is to keep the deposit moist and maintain the odour for longer than if it was uncovered. The home-range (and presumably also territory) of adult ♀♀ in Kruger N. P.

Side and frontal views of male Steenbok *Raphicerus campestris* head.

covered about 0.6 km² (du Toit 1993), although it is unknown if ♂♂ use more or less space than this.

When a ♀ is in oestrus the attending ♂ will kick and stroke her hindquarters with his forelegs and lick her genital region until she squats to provide a sample of urine, which he tests in typical flehmen posture. During this interaction the ♀ may be uncooperative and the ♂ may make a loud cat-like growl. Mounting occurs suddenly, with the ♂'s body held almost vertical, forelegs folded back not clasping the ♀, and involving a few quick pelvic thrusts before dismounting. Mounting and penetration may be repeated two or three times in quick succession, after which the ♂ and ♀ typically lie down together resting. The young lies hidden for its first three or four months of life while the mother moves around foraging, but she visits it regularly for suckling (Cohen 1987). When an oestrous ♀ has offspring with her the consorting ♂ sometimes attacks the juvenile with his horns, which suggests that infanticide could occur, presumably when the attacking ♂ has recently attained dominance, at which time the juvenile cannot be his offspring. If infanticide is a real risk, this probably explains the adaptive value of juveniles having black spots on the head where horns would be expected. An approaching adult ♂ could see these 'pseudo-horns' and mistake the juvenile for an attending adult ♂, at least for long enough to allow the juvenile to move away.

Reproduction and Population Structure Females attain reproductive age at about seven months. Steenboks are aseasonal breeders, although examination of 188 female specimens in Zimbabwe suggested a possible birth peak shortly after the onset of the rains (Nov/Dec) (Wilson & Kerr 1969). A single young is born with a birth-weight of <1 kg; twins are rare. Gestation lasts about 170 days (Hofmeyr & Skinner 1969). Steenboks can live for about nine years in captivity (Weigl 2005), although life expectancy in the wild is considerably shorter due to predation.

There has been debate about Steenbok sex ratios, with some small data-sets having given rise to the suggestion that ♂♂ outnumber ♀♀ in all age classes (e.g. Van Bruggen 1964, Wilson & Kerr 1969). In fact, the sex ratio does not differ from parity. Males are more easily sighted and positively sexed than the shyer ♀♀: when horns are seen the sighting is immediately labelled 'male'; when no horns are seen the sighting is unconfirmed and labelled 'sex unknown' if the head cannot be scrutinized to establish that indeed the animal has no horns and is thus female. In Kruger N. P., Cohen (1987) found

a ♂ : ♀ sex ratio of 1 : 1.04 in a sample of 4600 adults, and results from Namibia (Stuart 1975) and KwaZulu–Natal (Mentis 1972) based on large sample sizes yielded an even adult sex ratio.

Predators, Parasites and Diseases The biggest impact of predation on Steenbok populations probably occurs in the juvenile age class (0–3 months) when jackals *Canis* spp. and avian raptors such as Martial Eagle *Polemaetus bellicosus* encounter the undefended young lying in the grass. In the South African lowveld, adult Steenboks are important prey in the dry season for Cheetahs *Acinonyx jubatus* and African Wild Dogs *Lycaon pictus* in particular (Radloff & du Toit 2004); other known predators include Caracals *Caracal caracal* and Cape Foxes *Vulpes chama* (Kok & Nel 2004, Melville *et al.* 2004).

Not much is known about parasites. Boomker *et al.* (1986) recorded that an animal from the Kalahari harboured the helminths *Trichostrongylus* sp. (subsequently identified as *T. auriculatus* by Boomker [1986]), *Paracooperia serrata* and *Skrjabinema* spp.; elsewhere, Steenboks were recorded infested with helminths of the genera *Trichostrongylus*, *Skrjabinema*, *Haemonchus*, *Longistrongylus*, *Impalaia* and *Moniezia* (Boomker *et al.* 1986), and, in a separate study, *Setaria scalprum* and *S. saegeri* (Watermeyer *et al.* 2003). There is no single disease to which Steenboks are known to be particularly susceptible.

Conservation IUCN Category: Least Concern. CITES: Not listed.

The conservation status of the Steenbok is satisfactory and no specific conservation action is required at present. However, Steenboks are locally vulnerable to predation by domestic dogs and subsistence herdsman who frequently capture and kill juveniles in particular (when they are found lying alone in cover). Important protected populations include those in Serengeti–Mara (Tanzania, Kenya), Tsavo N. P. (Kenya), Etosha N. P. (Namibia), Hwange N. P. (Zimbabwe), Kgalagadi Transfrontier Park (Botswana/South Africa) and Kruger N. P. (South Africa).

GENUS *Dorcatragus*

Beira

Dorcatragus Noack, 1894. Zool. Anz. 17: 202.

Dorcatragus includes only the Beira *D. megalotis*, a small and slender gazelle-like antelope with very large ears, confined to N Somalia and adjacent parts of Ethiopia and Djibouti in rocky upland habitats, but not on steep slopes. The Beira was first described as a kind of Klipspringer (genus *Oreotragus*). Pocock (1918), noting that the footglands of Beiras are similar to those found in the genera *Madoqua* and *Rhynchotragus*, allied them with the dik-diks (as did Allen 1939). While traditional classifications consider them as forming a

clade with the other dwarf antelopes traditionally included in the paraphyletic Neotragini (including *Madoqua*, *Ourebia*, *Oreotragus*, *Neotragus*/*Nesotragus* and *Raphicerus*), *Dorcatragus* is here tentatively included along with the genus *Raphicerus* in the tribe Raphicerini. It is just possible that Haltenorth (1963), who resurrected the tribe Dorcatragini for the species, might eventually prove correct.

Peter Grubb

Dorcatragus megalotis BEIRA

Fr. Beira; Ger. Beira

Dorcatragus megalotis (Menges, 1894). Zool. Anz. 17: 130. Somalia, 'in den Schluchten des Hekebo' (ravine in the Hekebo region); 35 mi (56 km) south-west of Berbera (Moreau *et al.* 1946: 437).

RIGHT: Lateral, palatal and dorsal views of skull of Beira *Dorcatragus megalotis*.

Taxonomy Monotypic. Synonyms: none. Chromosome number: not known.

Description Small and slender gazelle-like antelope with very big and oval ears and somewhat overbuilt rump, about the same size as a Klipspringer *Oreotragus oreotragus*, but with longer legs and neck. Head is short and broad with a small muzzle. Russet-coloured front and bridge of nose, yellow-brown cheeks, and conspicuous white rings around dark eyes. Ears from front show darkish lines in

dense white hair tracts, and are light brown with blackish margins from behind. Neck, back and rump are dove-grey to bluish-grey. Back separated from cream underparts by a dark grey oblique strip along the flank extending from forelegs to the groin. Inner limbs are cream, like the underparts; outer limbs yellow-brown. Rather long, bushy tail of the same grey colour as the rump. Preorbital glands are absent, but they have pedal glands, and cushion-like pads on the short hooves; small lateral hooves present. There is a single pair of inguinal nipples. Female is larger than ♂. There are no obvious differences in

*Dorcatragus megalotis*

colouration between the sexes, but slight inter-individual variations are noticeable.

Only ♂ has horns, which are thin, cylindrical and relatively short (9–13 cm) and straight, with tips slightly curving forwards. The skull is characterized by short nasals, and elongated premaxillae that taper to a narrow tip. An ethmoid vacuity is present. Lateral incisiform teeth are mostly narrow, but the first incisors are broader than the rest; the premolars are relatively large, as in other small antelopes.

Geographic Variation None recorded.

Similar Species

Oreotragus oreotragus. Sympatric in many parts of the range. More sturdily built than Beira, with shorter legs. Ears smaller and darker, head with the same grey-brown colour as the rest of the body, and visible preorbital glands.

Madoqua saltiana. Co-exists on the lower slopes occupied by Beira. Similar coat colour, but much smaller in size, with very short horns and a short erectile crest; preorbital glands present; ♀♀ with two pairs of inguinal nipples.

Redunca fulvorufula. Allopatric. Larger, with short, heavily ridged, forward-curving horns; black subauricular patches present; upperparts predominantly grey, with underparts pure white; ♀♀ with two pairs of inguinal nipples.

Pelzeln's Gazelle *Gazella dorcas pelzelni*, Dibatag *Ammodorcas clarkei* and Gerenuk *Litocranius walleri* overlap in range, but are not found in mountainous regions. Pelzeln's Gazelle is a bit taller than the Beira, with horns present in both sexes; the female's horns are about the same size as those of the Beira ♂, and male Pelzeln's Gazelles have bigger and longer horns, inclined backward. Two lateral white stripes are visible on the head and the coat is brown with white underparts and a black tail. The Dibatag has a similar colour to the Beira, with a grey body and ochre legs, but the head has white lateral stripes. It is

taller, has a rather long tail, and ♂♂ have horns that are annulated at the base with tips sharply angled forward. The Gerenuk is much taller, with a very long neck, a long tail and ♂♂ have S-shaped and heavily ridged horns.

Distribution Endemic to the Horn of Africa, in S Djibouti, NE Ethiopia and N Somalia.

Historical Distribution In Djibouti, recent investigation shows that Beiras were found in four distinct areas in the mid-1940s: Arta region, Yaguer massif, Mt Garbi and Arrey–Assamo massif (Chédeville, in Laurent *et al.* 2001). In Ethiopia, there is at least one historical record of an individual killed close to Hadjin (Poncins 1899) about 10 km south to Assamo, on the Ethiopian–Djiboutian boundary (Laurent *et al.* 2001). In Somalia, it is doubtful whether they ever occurred south of the Nogal Valley. There is no evidence of their historical occurrence in Eritrea (Laurent *et al.* 2001).

Current Distribution The species' existence in Djibouti was only confirmed in 1993, when Beiras were observed on hillsides at two sites in the south-east, close to the borders with Somalia and Ethiopia (Künzel & Künzel 1998). Subsequent surveys have shown that the area of distribution in Djibouti is about 250 km² and located in the mountainous Ali Sabieh–Ali-Addé–Assamo region (Künzel *et al.* 2000, Laurent *et al.* 2001, Giotto *et al.* 2009).

The exact range in Somalia is unknown but seems to be restricted to the northern part of the country, mainly Somaliland, north of the Nogal (Nugaleed) Valley, from southern hills above Kandala, ca. 11° 20' N, 49° 50' E (Chazée 1987), to Garoowe in the south (reliable location approximately 30 km south of the town; P. Moehlman pers. comm.) and to Guban–Bodaleh region in the east. From historical and recent information (Moustapha Elmi 1992), the remaining core areas of the population are: Asse hills–Lahan Sheik, Garoowe area (Bur Cobohille), Wagar, Buuraha and Golis mountains, Araweina, Ali Haidh and Guban region. Between these locations, occasional sightings have been reported. Mallon (2011) recorded Beira in the stony hills east and west of Hargeisa and on rocky ridges in the coastal hills east of Berbera.

In Ethiopia, the species is known from the Marmar mountains along the border with NW Somalia (Bolton 1973, Hillman 1988a); there is no evidence of their occurrence in the Ogaden region (Wilhelmi 1997).

Habitat Beiras inhabit rocky hills and edges of plateaux at medium altitudes up to 1800 m (Ansell 1972). In Djibouti, the present altitudinal range is between 600 m (Go'ondâle Addé) and about 1300 m (Arrey; Giotto *et al.* 2009) and Mallon & Jama (2012) reported seeing Beira at sites ranging in elevation from 600 m to 1450 m in Somaliland.

Beiras frequent rocky or stony hillsides, rarely steep slopes, where the dominant vegetation is a woody steppe of mixed *Acacia* scrub. In Djibouti, they have been reported in association with ligneous steppes supporting *Acacia etbaica uncinata* (sometimes *A. horrida*, *A. asak*, *A. oerfota*, *A. tortilis* and rarely *A. sarcophylla*), patches of *Commiphora* spp. and *Maerua* spp., low spiny shrub *Rhigozum somalense* on slope bottoms (less than 5% soil cover), and grasses such as *Cenchrus*, *Eragrostis* and *Cymbopogon* (Laurent *et al.* 2001). This vegetation is heavily exploited by domestic livestock resulting in a prevalence of grass species such

as *Zygophyllum simplex*, *Aerva javanica*, *Aizoon canariense*, *Iphionopsis rotundifolia* and *Arnebia hispidissima* (Collenette & Mallet 1993, N. Giotto pers. obs.).

In Somaliland, Mallon & Jama (2012) noted that most sites where Beira were observed consisted of dry, flat-topped hills with steep stony slopes and scattered trees (*Acacia etbaica*, *A. tortilis* and *Commiphora* spp.), a habitat described as typical for the species by Drake-Brockman (1911). Kingdon (1997) reported that dominant plants in some supposed habitats are *Acokanthera*, *Buxus*, *Cadaba*, *Cadia*, *Carissa*, *Dodonea* and various succulents, such as aloes, euphorbias and *Sanseveria*, as well as hemps (*Crotalaria*), and that this might indicate some plasticity in their diet. His list referred to the high plateau's succulent steppes (e.g. Yaguer, Gamaré and Siyyarou plateaux in Djibouti) that show differences in abundance and variety from the vegetation cover in Ali Sabieh–Assamo region.

Abundance In Djibouti, the total population has been estimated at between 50 and 150 individuals (Künzel & Künzel 1998, Laurent *et al.* 2001, Giotto *et al.* 2009). Nevertheless, a recent study in the south of Djibouti revealed a local density of ca. 7 ind/km² (Giotto 2004), suggesting that Beiras could be concentrated in some areas within their range. There is no recent information from Ethiopia, where the population is considered small and localized (Hillman 1988a). In Somalia, information on numbers is meagre, but they are probably rare (Simonetta 1988). Population trends are unknown, although probably stable in areas with few settlements. However, in some parts of their range where settlements are expanding and livestock densities are high, numbers are likely decreasing. East (1999) estimated a total population of perhaps 7000 individuals.

Adaptations The Beira is not adapted to mountainous regions like the Klipspringer, but is essentially an animal of high hills and low-elevation mountains. The rounded, cushion-like pads on the lower face of the hooves maintain balance by ensuring a firm grip on slippery and unsteady ground. Stealth and colouration make direct observations of the species very difficult and chance sightings very unlikely, especially when animals are motionless (Poncins 1899, Bolton 1976).

The areas where the species lives have no permanent water source. This suggests a high level of adaptation to dry and hot conditions, accompanied by morning condensation (dew) during some parts of the year (at least in Djibouti; A. Laurent pers. obs.).

Morning feeding is followed by a period of rest and rumination in the middle of the day (Laurent *et al.* 2001), the duration of which increases with temperature (Giotto 2004, Giotto *et al.* 2008). Resting sites are generally under the shade of trees, mostly *Acacia etbaica*, but when mid-day temperature exceed 38°C, Beira often rest in the shade of rock shelters (N. Giotto pers. obs.). According to Prévot (1993) and Laurent *et al.* (2001), those sites are often located at the top of the slopes close to the summits, above fallen rocky areas with views over the valleys (Prévot 1993, Laurent *et al.* 2001). As with the Klipspringer, the choice of these upper zones is likely linked to vigilance. On the other hand, during the study conducted by Giotto *et al.* (2008), the observed daytime resting sites were very rarely located on the top of slopes, but rather in rocky areas on the middle or even on the bottom of hillsides. Thus, the many resting sites observed on the top of hillsides might be used during night-time when temperatures are cooler (J.-F. Gerard pers. comm.). A

second feeding period takes place in the afternoon, and lasts until sunset (Giotto 2004, Giotto *et al.* 2008). Whether Beiras also feed at night is unknown, but it seems likely in the hot season at least, as the mid-day resting period can last for more than seven consecutive hours, leaving limited time for daytime foraging (Giotto 2004). As a non-negligible part of the incoming water seems to come from the food plants, length of time spent foraging might correlate with the hydration level of food plants (A. Laurent pers. obs.).

Foraging and Food Based on direct observations and enquiries among herders in Djibouti, the plants eaten by Beiras are rather similar to those eaten by goats (Laurent *et al.* 2001, Giotto *et al.* 2008). Indeed, the diets of both species include the leaves of *Acacia etbaica* as a major component (N. Giotto pers. obs.). Nevertheless, analysis of faeces reveals that species like *Aizoon canariense* and *Croton somalense*, which are largely consumed by goats, are not as preferred as other less abundant species such as *Solanum adoens*, *Cordia* spp. and *Hibiscus* spp. (N. Giotto pers. obs.). Accordingly, Beira seem to be strict browsers, eating almost exclusively the leaves of woody plants and forbs.

Social and Reproductive Behaviour The most common grouping includes a single ♂ and one to several adult ♀♀ with or without young (Kingdon 1997, Laurent *et al.* 2001, Giotto *et al.* 2008, Giotto & Gerard 2010). Solitary ♂♂ and ♀♀ are also observed, as well as unisex groups of 2–4 ♀♀ (Giotto 2004). Single-sex groups of ♂♂ have never been recorded. A group of six individuals including two ♂♂ has been observed in one instance, but as one of them was smaller and had shorter horns than the other (about half the size), he was probably the young of one of the adult ♀♀ of the group (N. Giotto pers. obs.). Mixed-sex groups of 12 individuals including two ♂♂ have been reported (Walther 1990), although these are likely to be temporal associations. In a study conducted in S Djibouti, group size never exceeded five individuals, and mean group size was 2.7 (n = 56 sightings). Solitary animals comprised 26.7% of sightings, of which 50% were ♀♀, 43.8% were ♂♂ and 6.2% were young. Among groups observed, 25% were female groups and 72.7% were mixed-sex groups of 2–5 individuals, none including more than one adult ♂ (Giotto 2004, Giotto *et al.* 2008, Giotto & Gerard 2010). A pair with three apparent offspring has been observed, although this interesting social grouping has not been explained (Prévot 1993). This particular group composition could be indicative of some group instability, as on one occasion a ♀ was seen to leave the group for an entire day despite having dependent young (Giotto 2004). Within a group, individuals remain in close proximity, the distance between them rarely exceeding 10 m (N. Giotto pers. obs.).

Beiras are sedentary (Prévot 1993, Laurent *et al.* 2001, Giotto & Gerard 2010, J. Roche pers. comm.), with groups regularly seen in the same areas for several months and at different periods of the year (Prévot 1993, Künzel *et al.* 2000, Giotto 2004, Moustapha Elmi pers. comm.). The presence of domestic cattle has been identified as a primary cause of daily movements (Prévot 1993, A. Laurent pers. obs.), although even when domestic livestock were present in the same areas as Beiras the area of movement covered during a period of about 9 hours (n = 8) never exceeded 15 ha, and mean size was

4.0 ha (Giotto 2004). The small distance covered when fleeing is probably due to the topography of the area, as the animals only have to pass a high point to be out of sight of the source of disturbance.

Dunging ceremonies have been recorded in the Beira (Laurent *et al.* 2001, Giotto 2004, Giotto *et al.* 2008, Mallon & Jama 2012), and comprise scratching the soil and urinating and/or defecating, and displaying in turn by members of a group at the same place. Either ♂♂ or ♀♀ may initiate this activity, which lasts from 5 to 20 min. Laurent *et al.* (2001) observed a group of five animals involved in a dunging ceremony that was initiated and carried out vigorously by the ♂, followed by a ♀, then a mother and her offspring, and finally by the last ♀ of the group. In a study conducted on the same site in spring 2004, N. Giotto (pers. obs.) observed ♀♀ initiating these dunging ceremonies, with ♂♂ then following them and urinating and/or defecating in the same places.

An observation of one ♂ chasing another before rejoining the group of ♀♀ he was attending suggests that adult ♂♂ do not tolerate the presence of other ♂♂ (Giotto *et al.* 2008, Giotto & Gerard 2010). Such behaviour reinforces the proposals of Prévot (1993) and Laurent *et al.* (2001) that ♂♂ are territorial. Indeed, in a 10-month study in Djibouti, Beira were found to live in relatively stable socio-spatial units whose ranges were almost non-overlapping (mean home-range was about 0.7 km²) (Giotto & Gerard 2010). However, there is no evidence that the dunging behaviour described above has a territorial marking function (Giotto & Gerard 2010).

When alarmed, Beiras utter a whistling alarm call and adopt an alert posture, remaining motionless with head up and ears oriented toward the source of potential danger, sometimes maintaining this posture for more than an hour (A. Laurent pers. obs.) until they flee trotting, galloping or jumping, or until the source of disturbance disappears. Laurent *et al.* (2001) suggest that the ♂ occupies a special (dominant?) position in the group, as he guides the group's escape, takes up guard and leads movements. However, Giotto (2004) observed that ♂♂ were not always the leaders of fleeing groups, and that ♀♀ were also (and seemed to be even more often) involved in vigilance activity, and often initiated movements of groups engaged in foraging.

There are limited data on reproductive behaviour. During courtship the ♂ sniffs the vulva of the ♀, performs flehmen and taps the female's hindlegs or the ground with his forelegs (laufschiag). The ♂ may approach bipedally and mounts with head up, without resting upon the ♀, while the ♀ carries head and neck raised when mounted (N. Giotto pers. obs.). For the first few weeks of life young remain motionless in hiding places where they are difficult to see (Laurent *et al.* 2001).

Reproduction and Population Structure Births are known to occur in spring (Mar and Apr). However, spring is also the mating season, as copulations have been recorded at the end of Mar and in May (Giotto *et al.* 2008), suggesting a second birth season in autumn. A single young is born, following a gestation period estimated at about six months (Hammer & Hammer 2005, Hammer 2011). During the study conducted in SDjibouti, the observed sex ratio was biased toward ♀♀ and was found to be 1 : 2.5 (N. Giotto pers. obs.).

Predators, Parasites and Diseases Carnivores known to be present in S Djibouti include the Caracal *Caracal caracal* and the Leopard *Panthera pardus*, both of which are potential predators of Beiras. Spotted Hyaenas *Crocuta crocuta* and Striped Hyaenas *Hyaena hyaena* are also present, but seem less likely predators (Laurent & Laurent 2002, Giotto 2004). Hamadryas Baboons *Papio hamadryas*, as well as Verreaux's Eagle *Aquila verreauxii* and Bonelli's Eagle *Hieraaetus fasciatus* may take young animals (Giotto 2004, Giotto *et al.* 2008). There is no information available about parasites and diseases.

Conservation IUCN Category: Vulnerable C1. CITES: Not listed.

In Djibouti, Beiras are restricted to a limited area and likely decreasing in number due to desertification by overgrazing and disturbance from an incoming population of refugees (Giotto *et al.* 2009). In Somalia, animals underwent a marked decline in number during the 1975 drought (Simonetta 1988), and may have suffered due to uncontrolled hunting and habitat deterioration caused by overpopulation of livestock (Moustapha Elmi 1992, East 1999), but there is limited recent information.

There have been several proposals to help ensure the future prospects for Beira in Djibouti (Laurent 1993, Künzel *et al.* 2000). The classification of a limited area (the Assamo region) as a Community Protection Area has been proposed by local people and a pilot *in situ* conservation project, based on income from tourism and familial socio-economic activities, such as handicraft and agro-alimentary production, is in preparation with local NGOs (Association de Développement Durable Local Aser-Jog and DECouvrire et Aider la Nature). Due to a long-lasting partnership with the international network T2D2 (Tourismes, Territoires et Développement Durable), the patrimonial value of Beiras, a species whose presence was unconfirmed a little more than two decades ago, is now increasingly being recognized and offers much potential for future conservation efforts in the region.

There is a captive self-sustaining population of about 40 Beira at Al Wabra Wildlife Preservation/Sheikh Saoud Mohammed Bin Ali Al-Thani in Qatar (Heckel & Rayaleh 2008, Hammer 2011).

Measurements

Dorcatragus megalotis

HB: 760–870 mm

T: 50–80 mm

WT: 9.0–12.0 kg

Throughout geographic range (Kingdon 1997)

Maximum recorded horn length is 13.9 cm for a pair of horns from Somalia (Rowland Ward)

Tribe MADOQUINI

Dik-diks

Madoquini Pocock, 1910. Proc. Zool. Soc. Lond. 1910: 876.

ABOVE: Günther's Dik-dik *Madoqua guentheri* myology.

RIGHT: Salt's Dik-dik *Madoqua saltiana* skeleton.

The arid-adapted dik-diks are very small, long-legged antelopes with fine, grizzled (sometimes colourful) pelages. They have relatively large eyes and ears, a prominent crest and a fur-covered nose that is enlarged into a very flexible proboscis that is especially long in Günther's Dik-dik *Madoqua guentheri* and the dik-diks of the *M. (kirkii)* complex. The dik-diks have traditionally been included along with other dwarf antelopes in the tribe Neotragini (e.g. Grubb 2005), but with increasing evidence of paraphyly of this taxon (Georgiadis *et al.* 1990, Gentry 1992, Matthee & Robinson 1999a), it has been necessary to disaggregate its members and to resurrect the tribe Madoquini for the dik-diks.

In most arid habitats there is so little food in the dry season that it is only possible for a very small ruminant to live within a limited area all year round. Permanent residence in sub-desert means having to do without water yet needing to keep cool. This is problematic because the large surface area of a small animal relative to its weight heats up fast. Dik-diks minimize heat production and reduce water-loss by means of inconspicuous adaptations in the water economy of their kidneys and digestive tracts and in subtle adjustments of their activity cycles, but the specialized nose is probably their major cooling device.

Proboscides are visible signs of a technique of temperature control that is more highly developed in dik-diks than in any other African antelope. The proboscis is lined with numerous blood vessels in the mucous membrane where the blood can be cooled by evaporation off the inner lining of the nose, a method of cooling that is very economical with water, a precious commodity in arid areas. These surface blood vessels are cooled by increasing the normal breathing rate from one to nearly eight breaths per second (Schoen 1972, Hoppe 1977a, Frey & Hofmann 1996). The cooled blood returns to the heart via a sinus below the brain, where hot blood going to the brain is cooled in a heat exchanger (rete mirabile) (Baker & Hayward 1968). This very selective cooling allows general body temperatures to rise without risking brain function. The nose of each species shows a different degree of elaboration, implying different levels of efficiency in

Tentative phylogenetic tree for *Madoqua* radiation (adapted from Hernández Fernández & Vrba 2005).

temperature control and, perhaps, in water economy. This adaption seems to be the outcome of prolonged and progressive specialization in a faculty that is of great utility in the arid Horn of Africa.

It is significant that north-east Africa has been home to the greatest variety of heat-tolerant antelopes and that some of them, most notably the dik-diks, belong to basal groups. The concentration of antelopes in this region further implies that it is, or is very close to, the geographic centre of origin for Antilopinae as a whole. In this perspective, Madoquini can be seen as one of the earliest lineages of conservative antelopes to refine and benefit from the heat tolerance and water economy that first defined and separated the Antilopinae from the Bovinae (which have remained predominantly Asian).

Dik-dik fossils are only known from some 7–4 mya, but the lineage has been estimated (by molecular clock techniques) to have emerged some 20–18 mya (Hernández Fernández & Vrba 2005), almost certainly in the Horn of Africa. The distribution and physio-morphology of living forms is some guide to the progress of evolution. Thus, the most conservative, least specialized forms, namely Salt's Dik-dik *M. saltiana* and Silver Dik-dik *M. piacentinii*, remain confined to evergreen thickets that fringe the Ethiopian plateaux and the Somali coast. The most advanced and most heat-tolerant species, Günther's Dik-dik, lives in the driest deserts and sub-deserts of the region while intermediate types, of the *Madoqua* (*kirkii*) complex, occupy a much broader range of habitats. Essentially, these antelopes are endemic to the Horn of Africa, with a single outlying and isolated population in south-west Africa. An arid corridor has clearly connected the two regions many times in the past, as is clear from other species (e.g. *Oryx*) with similar patterns of distribution.

The more primitive species minimize the effects of high temperatures by being largely nocturnal (Simonetta 1966). The long-nosed Günther's Dik-dik, with the greatest tolerance of heat, is more diurnal. All species depend on low-level thickets and succulents growing on well-drained soils where there is little grass growth. Dung, urine and face-gland deposits are the boundaries, landmarks and focal centres of social life: the preorbital glands, especially in males, can be so large that they rival the eyes and lie in comparably sized 'sockets'. Males are the principal markers and defenders of territories but their movements are entirely subordinate to those of the ♀♀ – in a real sense *he* marks *her* territory. Both sexes make breathy shrieks through a specially modified nasal whistle. Whistle-like calls are characteristic of many antelopes and distinguish them from Bovinae. Dik-diks have refined the acoustic properties of their calls, an aspect of social communication that awaits further research. The name dik-dik is an onomatopoeic rendering of one of their calls.

Jonathan Kingdon

GENUS *Madoqua*

Dik-diks

Madoqua Ogilby, 1837. Proc. Zool. Soc. Lond. 1836: 137 [1837].

LEFT: Salt's Dik-dik *Madoqua saltiana* (top). Kirk's Dik-dik *M. (kirkii)* complex (centre). Günther's Dik-dik *M. guentheri* (below).
 CENTRE: Diagram of nasals and premaxilla in Salt's Dik-dik *Madoqua saltiana* (top). Kirk's Dik-dik *M. (kirkii)* complex (centre).
 Günther's Dik-dik *M. guentheri* (below).
 RIGHT: Naivasha Dik-dik *M. (kirkii) cavendishi* female.

This genus was formerly subdivided between two genera, *Rhynchotragus* for the 'Long-snouted Dik-diks', namely Günther's Dik-dik *M. guentheri* and the dik-diks of the *M. (kirkii)* complex, and *Madoqua* for the 'Short-snouted Dik-diks', Salt's Dik-dik *M. saltiana* and Silver Dik-

dik *M. piacentinii*. *Madoqua* have longer premaxillae, longer nasal bones and a less prominent nasal notch than *Rhynchotragus*. Given the homogeneity of this group, a single genus comprising two subgenera seems appropriate, but should it be shown that separation between

Cross-section of Günther's Dik-dik *M. guentheri* head. Shows vestibule of nose served by blood vessels in the mucous membranes. Venous blood returns via cavernous sinus below brain. Whistle-like maxilla turbinal shown *in situ* and above, left. Glottal region shown in breathing position.

the two groups is of very long standing, the resuscitation of two genera might be justified.

Likewise, regional populations of Salt's Dik-diks have differentiated into ten forms, which were formerly grouped under five species (Allen 1939). The nomenclature of this group was revised and simplified by Yalden (1978) and this work provisionally follows his inclusion of all these forms as subspecies of Salt's Dik-dik (and see Grubb 2005). None the less, further molecular analysis of this complex of dik-diks could justify the resurrection of some species within Salt's Dik-dik as well as the two genera.

The dik-diks represent a distinctive gradient in the adaptation of a very small antelope to heat and desiccation. The most obvious external sign of this adaptation is modification of the nose into a flexible, bellows-like mechanism for cooling the blood. The workings of this adaptation have been summarized in the tribe profile above and in more detail in the profiles of Günther's Dik-dik and the Kirk's Dik-dik complex (and see Frey & Hofmann 1996). Paradoxically, the less specialized Salt's Dik-dik occupies some very arid parts of the dik-diks' overall range. This species avoids excessive overheating by lying up in the shade during the day and restricting most of its activity to the night-time (Simonetta 1966). This escape from diurnal heat is facilitated by preference for evergreen *Salvadora* scrub, which is characteristic of the eastern foothills of the Ethiopian massif. Thus, restriction to the Horn of Africa may have much to do with a long-standing dependence on evergreen growth for food and shelter.

While the Long-snouted Dik-diks have much in common with Salt's Dik-diks and Silver Dik-diks, and clearly derive from a similar shorter-snouted ancestral stock, they live in more exposed situations. The beginnings of their adaptation to such exposure merit speculation. An early dik-dik population living south of the Ethiopian dome (or, perhaps in Somalia) during periods of aridification would have faced the twin challenges of scarcer food and less shelter. This could have forced these animals into longer activity periods and further development of the nasal cooling chamber to enhance their capacity to withstand heat. Once emancipated in this way, a southern population could have responded to every dry phase of every past climatic fluctuation, each of which would have opened up

very extensive areas of suitable habitat to dik-diks in eastern Africa (and sometimes beyond). Parts of the L. Turkana basin and areas to the south-east have probably remained relatively arid since the mid-Miocene and this arid focus, decisively separate from the Ethiopian dome, must have become the most consistent home of the long-snouted lineage.

The most highly specialized of them all is Günther's Dik-dik and, appropriately, this species inhabits the driest and most exposed of all dik-dik habitats. It is obvious that Günther's Dik-dik derives from a form that was more advanced than Salt's Dik-dik, so it has to be significant that the dik-diks belonging to the *M. (kirkii)* complex are, indeed, intermediate between Salt's and Günther's (though much closer to the latter).

The likely sequence of evolutionary events that followed has been outlined in Kingdon (1982). During a period in which arid habitats were very extensive (possibly during the Messinian, 6.5–5.3 mya), 'Long-snouted Dik-diks' spread as far as south-western Africa along the Somali–Namib corridor. The modern survivor of this expansion is the Damara Dik-dik *M. (k.) damarensis*, which has genetic similarities with Günther's Dik-dik. A warmer, moister period (perhaps the mid-Pliocene?) then separated the 'Long-snouted Dik-diks' into two populations: ancestral *guentheri* in the east, ancestral *damarensis* in the south-west. A subsequent re-opening of the Somali–Namib corridor (possibly during the first Glacial, 3–2.5 mya) allowed proto-*damarensis* to expand northwards and colonize a band of less extreme habitats surrounding the arid core around L. Turkana. The arrival, from the far south-west, of a competitor presumably exerted strong selection on Günther's Dik-dik to become even more arid-adapted and probably led to some contraction of range back towards the arid core. Because the invading population tolerated a broader range of habitats it spread widely but soon became subject to the climatic vicissitudes of the late Pliocene and Pleistocene. These oscillations probably led to the genetic isolation that has culminated in the three East African species of the *Madoqua (kirkii)* complex.

While there is insignificant overlap between the dik-diks of the *Madoqua (kirkii)* complex and Salt's Dik-dik, the interaction with Günther's Dik-dik is more complex, interesting and still very poorly

understood. There is a narrow belt over 1000 km long where the margins of the L. Turkana basin and the Somali interior meet the moister habitats fringing the Kenya highlands and the coastal strip. North of the Tana R., *M. (kirkii) kirkii* does not extend beyond the isohyet for 50 cm mean annual rainfall (or the boundary between savanna and dry bushland). Along this interface, the two species meet and in places co-exist side-by-side without any interbreeding (Hollister 1924, Hofmann 1973). However, skins and skulls from localities as far apart as the Shebelle R. (Somalia), south Turkana and the Kenya–Uganda border display intermediate or mixed characteristics, suggesting that hybridization may be persistent and widespread. More problematically, strongly reduced premaxillae in some *M. (k.) kirkii* specimens (notably from Tsavo and Manda I.) imply either convergence or past mixing between the two species. For observers inspecting individual dik-diks in these areas of overlap the possible presence of hybrids (albeit presumably infertile ones) needs to be considered.

In spite of such local ambiguities, the primary effect of the radiation of dik-dik species has been to increase the overall ecological range and diversify the responses of a very small ruminant to exceptionally difficult conditions. The main mechanism in achieving this has been the separation of subpopulations in geographically and ecologically distinct areas, demarcated by moist forested rivers valleys and mountain slopes, and subsequent expansions and contractions under the influence of many oscillations in climate.

Dik-diks are widespread throughout arid north-eastern Africa and they are particularly common in some localities. Their success is due to a variety of physiological specializations, which are discussed in further detail in the sections on Adaptations in both the *M. guentheri* and *M. (kirkii)* complex species profiles. Among the many

morphological changes that have taken place in the nasal area of dik-diks is a remarkable modification of the ethmoid turbinal, which seems to have been turned over to function as a whistle. Drawings (above, from Kingdon 1982) illustrate the position and shape of this whistle within the nasal area and these cross-sections also illustrate how the aforementioned ‘nasal bellows’ cooling mechanism works.

The colouring of dik-diks is interesting, exemplifying complex interplays between crypsis (directed at predators) and conspicuousness (directed at conspecifics). The eye margins, ears, belly and buttocks have white or very pale fur in all species and the last is an important signalling device. The long hair of the buttocks is capable of being opened out into two circular flares, a display that seems to advertise oestrus but may also signify subordination. In most species the overall colouration is subdued and subservient to the overall cryptic effect. Legs and crest are plainer and warmer in colour while rump and neck tend to have a cooler, greyish, grizzle. This distribution of warmer and cooler tints is common to all dik-diks but finds its most exaggerated contrasts in *M. saltiana lawrancei*. It correlates with crouching or head-down creeping by an appeasing subordinate and a head-up, fluffed-crest, high-stepping strut by dominant individuals, notably territorial ♂♂. The latter shows off warm orange tints while the subordinate postures flatten the orange crest and present predominantly grey areas to view. The pelage therefore represents a sort of intra-specific, status-linked colour-code, half concealed under a coat of camouflage.

The long-term future of dik-dik species will largely depend on what sort of policies emerge from the present era of conflict in the Horn of Africa.

Madoqua saltiana SALT'S DIK-DIK

Fr. Dik-dik de Salt; Ger. Eritrea-Dikdik

Madoqua saltiana (de Blainville, 1816). Bull. Sci. Soc. Philom. Paris 1816: 79. 'Abyssinie' (Ethiopia). The author of the name is usually cited as Desmarest, 1816 (Nouv. Dict. Nat., Nouv. ed., 2: 192), who acknowledged de Blainville's paper and cited the page number where *saltiana* was named, confirming that de Blainville is, in fact, the author (Grubb 2005).

LEFT: Salt's Dik-dik *Madoqua saltiana phillipsi*.
ABOVE: Lateral and palatal views of skull of Salt's Dik-dik *Madoqua saltiana*.

The species is named for Sir Henry Salt, who in 1809 was tasked with establishing contact with the King of Abyssinia on behalf of the British Government.

Taxonomy Although Yalden (1978) included the forms *phillipsi* and *swaynei* as subspecies of *saltiana* (the arrangement followed here), the relationships of these two forms to *saltiana* are uncertain, and they have been treated as distinct species (e.g. Ansell 1972). Yalden (1978) argued that there was a series of geographically allopatric subspecies, with some clinal variation in size and colour. Synonyms: *citernii*, *cordeauxi*, *erlangeri*, *gubanensis*, *hararensis*, *hemprichiana*, *hemprichii*, *lawrancei*, *madoka*, *madoqua*, *phillipsi*, *swaynei*. Chromosome number: not known.

Description A small, dainty antelope showing modest sexual dimorphism, with ♀ slightly larger than ♂. The nominate *saltiana* has dorsal pelage grizzled greyish-brown, shading into pale sandy-orange, plain (ungrizzled) legs. Ventral pelage is white, with a sharp demarcation line from the dorsal colour. The top of the head has a short, reddish-brown erectile crest. Snout enlarged into a slight proboscis, though not so much as in, for example, Günther's Dik-dik *M. guentheri*. Face and neck paler and greyer than trunk. Conspicuous, black preorbital gland, set off by a white ring around the eye. Ears large, white internally, but a greyish grizzled colour posteriorly. Tail short and inconspicuous, white, in a white peri-anal region. Females have two pairs of inguinal nipples.

Horns are present in ♂ only; black, essentially straight, short and barely project above the ears or crest (when erected). Like the Silver Dik-dik *M. piacentinii*, the M₃ lacks the third (posterior) lobe, and the upper line of the premaxillae is slanting and not strongly curved.

Geographic Variation

M. s. saltiana: Sudan, Eritrea, Djibouti, Afar triangle. As above, larger than forms further south.

M. s. phillipsi: N Somalia. Dorsal surface paler, greyer (brown tinges absent); pale orange of forelegs extending into flares over shoulders.

M. s. hararensis: N Somalia, south from mountains through Ogaden region of Ethiopia, to the Shebelle R. Both grizzled dorsal colour and flares reddish-brown, giving overall chestnut appearance.

M. s. lawrancei: coastal Somalia. Silver-grey grizzled dorsal colour, contrasting sharply with the deep reddish-brown legs, flanks and shoulders.

M. s. swaynei (includes *citernii*): S Ethiopia, S Somalia, from the Shebelle R. to Juba/Dawa Rivers. Colour as for nominate form.

Similar Species

Madoqua piacentinii. Sympatric with *M. s. lawrancei* in coastal Somalia, and with *M. s. hararensis* in well-vegetated lowland areas of the Shebelle R. in the Ogaden. Smaller, both in body mass and mean length of maxillary tooththrow (P²–M³, 25.7–31.5 mm cf. 28.2–36.8 mm in *saltiana*); uniformly speckled silver-grey dorsally (lacks the red-brown shoulder flares of *lawrancei*).

M. guentheri. Sympatric in Somalia and Ethiopia. Characterized by enlarged and elongated proboscis.

Distribution Endemic to the Horn of Africa. Marginal occurrence in NE Sudan, along the Eritrean border, southwards along the coastal plain of Eritrea into the northern and eastern lowlands of Ethiopia, Djibouti and Somalia, extending southwards round the Ethiopian

mountains possibly just into the border region of Kenya (Mandera district) and southwards to the Juba valley, Somalia (Yalden 1978, Kingdon 1982, Yalden *et al.* 1984, East 1999, Künzel *et al.* 2000).

Habitat Typically found in semi-desert scrub, and usually associated with *Aloe* and *Sanseveria*; probably avoids true desert, and limited in range by the mountains of Ethiopia. Ingersol (1968) remarks that they are usually found in valley bottoms and hillsides, whereas sympatric Günther's Dik-diks are only found on drier, scrub-covered hillsides. Common from sea level to 1500 m, but perhaps as high as 2000 m (Yalden *et al.* 1984, Künzel *et al.* 2000). A. Simonetta (pers. comm.) remarks that in Somalia there are distinct differences in habitat usage, with Günther's Dik-diks confined to thick bush, whereas *M. s. lawrancei* is found in open conditions, even sub-desert, wherever there are scattered thickets.

Abundance A common antelope where it occurs, although there are few detailed studies. Künzel *et al.* (2000) counted only 73 during recent survey work in Djibouti, far fewer than the 600 Pelzel's Gazelles *Gazella dorcas pelzeni* or 190 Soemmerring's Gazelles *Nanger soemmerringi* seen, and estimate a density of only 0.04/km². Laurent & Laurent (2002) confirm that although Salt's Dik-diks are still widespread throughout Djibouti, they have declined over the last 20 years. On the Haud plateau in N Somalia, P. Moehlman (pers. comm.) saw 41 individuals while driving 72 km in April 1997, compared with only three grey dik-diks (presumably Günther's), yielding a density of 11.6/km² in N Somalia, perhaps an overestimate (East 1999). Road counts also gave an estimate of 1.8/km² in the Ogaden of Ethiopia, perhaps an underestimate (Wilhelmi 1997). A three-year study in Awash N. P., Ethiopia, using monthly road surveys, gave a density of 14.1/km² (ranging from 13.3 to 15.3/km² across three different routes) (M. Jacobs & C. Schloeder pers. comm.). Using a modest density of 2/km² across a putative range of 242,800 km², East (1999) estimated the total population as at least 485,600 individuals.

Adaptations Colouration serves as good camouflage, emphasized by the animal lying prostrate in shade when not active. It is probable that variation in colour between subspecies is at least in part matched to soil colour locally. The proboscis/nasal cavity is believed to serve a thermoregulatory function and to assist in water conservation. Salt's Dik-diks are thought not to drink, relying entirely on water in dew and food; indeed, a captive animal deprived of food took only small amounts of water (Simonetta 1966). Their kidneys are extremely efficient in retaining water, and their faeces are very dry and urine highly concentrated. Salt's Dik-diks are mainly nocturnal and crepuscular, lying up in shade during the day, and during the mid-day heat they pant with their mouth partly open and tongue slightly protruding (Simonetta 1966, Kingdon 1997).

Foraging and Food There are no detailed studies on feeding, but Salt's Dik-diks are selective browsers. In Awash N. P., they have been reported browsing on *Acacia* shrubs (leaves), fruits of *Grewia tenax* and *Cordia gharaf*, *Lantana viburnoides*, *Seddera bagshewai* and *S. arabica*, shrubby herbs *Abutilon*, *Hibiscus micranthus*, *Melhanian ovata*, *Sida ovata*, *Plecanthus*, *Vernonia cinerescens* and *Pavonia propinqua*, the herbs *Corchorus*, *Blepharis edulis*, *Achyranthus aspera*, *Justicia* and various Labiatae, and monocots such as *Cyperus*, *Tetropogon* and *Sporobolus* (M. Jacobs & C. Schloeder pers. comm.). It is not known how their diet differs from the sympatric Günther's Dik-dik in the south of their range, or from the Silver Dik-dik *M. piacentinii* in coastal Somalia.

Social and Reproductive Behaviour Salt's Dik-diks are territorial, and usually seen in pairs or family groups of a pair with 1–2 young. Künzel *et al.* (2000) recorded 34 groups, ranging from 1 to 6 (mean = 2). Simonetta (1966) described the formation of territories in captivity, with young ♂♂ displacing their fathers; in the wild, it is assumed that young would be displaced from the parental territory. Territories are marked by means of urine over-marking and dung piles, including over-marking the dung of other species. Females and subordinate ♂♂ place the deposit from their preorbital gland on the tip of the dominant male's horns, presumably as a form of submission. Males erect their crest as a threat display to subordinates. In courtship and threat, ♂♂ may use a high-strutting gait that emphasizes the paler colours of the legs and shoulder flares. The white rump is flared by the ♀ in oestrus, and may also be used as a warning 'flag', but the usual warning is a double 'whistle' that is responsible for the onomatopoeic name dik-dik.

Reproduction and Population Structure The very limited observations available suggest that there is usually only one young per litter, despite the presence of four teats in the ♀. M. Jacobs & C. Schloeder (pers. comm.) report only 0.2% juveniles and 3.5% subadults during surveys in Awash N. P.; the sex ratio of adults was equal.

Predators, Parasites and Diseases Salt's Dik-diks are probably vulnerable to predation from most large predators, including jackals *Canis* spp., Caracals *Caracal caracal*, Servals *Leptailurus serval*, Leopards *Panthera pardus* and larger eagles. Predation by adult male Olive Baboons *Papio anubis* and Olive-Sacred baboon hybrids *P. anubis* × *P. hamadryas* on young was witnessed in Awash N. P. (M. Jacobs & C. Schloeder pers. comm.). There is no information available on parasites or diseases.

Conservation IUCN Category: Least Concern. CITES: Not listed.

Salt's Dik-diks are vulnerable to overhunting and to habitat loss/degradation, especially through overgrazing or irrigation and agriculture. For example, Laurent & Laurent (2002) remark on declines evident in Djibouti due to overgrazing in some areas and overhunting in others (although the latter is now banned). Simonetta (1988) remarks that in Somalia dik-diks are rarely shot, are usually hunted in nets and that they have become scarce near human habitation. Although there are only a few protected areas within their range (such as Awash N. P. and Yangudi Rassa N. P. and several wildlife reserves), they remain widespread throughout, and are considered to be in a satisfactory conservation status (East 1999).

Measurements

Madoqua saltiana hararensis

HB (♂ ♂): 510 (495–517) mm, n = 9

HB (♀ ♀): 509 (479–550) mm, n = 9

T (♂ ♂): 34 (30–38) mm, n = 9

T (♀ ♀): 31 (21–40) mm, n = 9

HF c.u. (♂ ♂): 174 (170–183) mm, n = 9

HF c.u. (♀ ♀): 175 (160–188) mm, n = 9

E (♂ ♂): 65 (61–70) mm, n = 9

E (♀ ♀): 64 (60–70) mm, n = 9

WT: 2.7–4.0 kg

Ethiopia (Ingersol 1968)

Maximum recorded horn length is 11.8 cm for a pair of horns from Sudan (Rowland Ward)

Derek W. Yalden

Madoqua piacentinii SILVER DIK-DIK (PIACENTINI'S DIK-DIK)

Fr. Dik-dik argente; Ger. Piacentini Dik-dik

Madoqua piacentinii Drake-Brockman, 1911. Proc. Zool. Soc. Lond. 1911: 981. E Somalia, 'Gharabwein, within a day's march of Obbia [5° 25' N, 48° 25' E], in the Mijertain country, Italian Somaliland'.

LEFT: Silver Dik-dik *Madoqua piacentinii*.

ABOVE: Lateral and palatal views of skull of Silver Dik-dik *Madoqua piacentinii*.

Taxonomy Ansell (1972) considered this species a subspecies of *M. swaynei*. However, Yalden (1978) in his revision of the genus included *swaynei* as a subspecies of Salt's Dik-dik *M. saltiana*, and treated the Silver Dik-dik *M. piacentinii* as a distinct species (and see Funaioli & Simonetta 1966), which is the classification followed by Grubb (2005) and here. Synonyms: none. Chromosome number: not known.

Description A small antelope, statistically the smallest of the genus, although its measurements overlap with those of the other Somali dik-diks (*M. saltiana lawrancei* and *M. s. swaynei*). Uniformly silvery-grey due to fine speckling of the individual hairs, except for a

bright, rust-red, erectile crest and part of the dorsal side of the nose and the equally reddish legs; there is a narrow white ventral stripe. Pelage is fine and soft. Sexual dimorphism is modest, with ♀ slightly larger than ♂. Females have two pairs inguinal nipples. The skull of the Silver Dik-dik is immediately distinguishable from that of the sympatric *M. s. lawrancei* from coastal Somalia in several respects: it is distinctly narrower, especially in the orbital region; the zygomatic arch in the suborbital region is distinctly narrower than in all other dik-diks; and the profile of the suborbital fossa is comparatively narrower and elongated in its antero-posterior axis. Like Salt's Dik-dik, the Silver Dik-dik has the lower M₃ without a third (posterior) lobe.

Geographic Variation None recorded.

Similar Species

Madoqua saltiana. Although possibly ecologically separated, the Silver Dik-dik is sympatric with *M. s. lawrancei* in coastal Somalia, and with *M. s. hararensis* in the Ogaden region of Ethiopia. Larger, both in body size and mean length of maxillary tooththrow (P^2-M^3 , 28.2–36.8 mm cf. 25.7–31.5 mm in *piacentinii*); the reddish colour always extends considerably both on the shoulders and on the sides of the body.

M. guentheri. Sympatric at the limit of the inland distribution of Silver Dik-dik, and also in the lowland areas of the Shebelle R. in the Ogaden where reported in sympatry (Wilhelmi *et al.* 2006). Duller overall colouring, and the proboscis is noticeably enlarged and elongated.

Distribution The Silver Dik-dik is an enigmatic species. It is recorded as occupying the central, coastal plain region of Somalia, where its range apparently does not extend more than 10 km inland (Ansell 1972, Simonetta 1988, East 1999). The species is represented in museums by two series of specimens: one in the British Museum (Natural History Museum) in London, collected by Drake-Brockman at Eil Hur, near Hobyo, and one in the Natural History Museum of Florence (Italy). However, it is not recorded whether the specimens in London were personally collected by Drake-Brockman or whether he obtained them from local hunters. Hobyo itself is a big village in the middle of a low coastal steppe and, at least when visited by the current author in 1982, no dik-diks of any kind were seen, although Speke's Gazelles *Gazella spekei* were quite common in the vicinity. Most of the specimens in Florence were obtained either from local hunters from the vicinity of Mogadishu or from skin dealers in the town. Specimens were obtained from local hunters of Balad, a large village on the Shebelle R. just north of Mogadishu, which reported the animals to be found within a few miles of this locality. Some were

personally collected about 10 miles west of Mahaddei Wein, a village on the Shebelle R. about 90 miles north of Mogadishu. However, having repeatedly visited the area inland and north of Mogadishu between 1969 and 1982, apart from this single occasion the only dik-diks found were Salt's Dik-diks (*M. s. lawrancei*).

Recently, this species has been reliably reported (and photographed) further up the Shebelle R. valley and in the valley bottoms of its seasonal tributaries in the Ogaden of Ethiopia (Wilhelmi *et al.* 2006). It therefore seems likely that this species might occur in other well-vegetated lowland areas of the Shebelle R. valley up to about 500 m above sea level. South of Mogadishu, in the strip between the coast and the Shebelle R., only Kirk's Dik-diks *Madoqua (kirkii) kirkii* have ever been reported. In the more open areas on the right bank of the Shebelle R. only *M. s. swaynei* is to be found, and in areas of denser scrub one finds Günther's Dik-diks, with rare specimens of intermediate characters with Kirk's, which may be either hybrids or representative of the transition between the two taxa.

Habitat Very little is known of the habitat of Silver Dik-diks. The specimens obtained from west of Mahaddei were found in low bush with large open spaces, a habitat commonly used also by Salt's Dik-dik (*M. s. lawrancei*) and, occasionally, by Günther's Dik-dik, both species having been observed within a few miles from the locality where Silver Dik-diks were collected. In the south-eastern part of the Ogaden, *M. piacentinii* have been observed in dense to semi-dense *Acacia-Commiphora* bushland and in one area of less than 2000 m² three species of *Madoqua* (*M. guentheri*, *M. saltiana* and *M. piacentinii*) were found together (Wilhelmi *et al.* 2006). The latter authors listed *Acacia bussei*, *A. mellifera*, *A. ziziphospina*, *Commiphora hoday*, *C. ogadensis* and *Boswellia neglecta* as prominent members of this 'Acacia-resin bush', with sparse *Chrysopogon* and *Dactyloctenium* grasses below a mostly closed canopy.

Abundance In the Ogaden, where this species is probably on the very edge of its range, a density of 1–2 individuals was estimated in an area of less than 2000 m² where the habitat was shared with *M. guentheri* and *M. saltiana* (Wilhelmi *et al.* 2006). East (1999), assuming a population density of 2.0/km², estimated the total population at about 30,000, but remarked that this might be an overestimate.

Adaptations As the morphology of these dik-diks is extremely similar, apart from the colour pattern, to that of the other dik-diks of the subgenus *Madoqua* it may be expected that their adaptations are also very similar. Kingdon (1997) suggested that this was possibly the least arid-adapted of the dik-diks. Although most dik-diks are usually active both during the day and night, since Silver Dik-diks appear to be especially elusive, it may be suspected that it is somewhat more nocturnal than other species. In any event, studies of partitioning of the habitat in those areas where three *Madoqua* species occur would be very interesting and valuable.

Foraging and Food Silver Dik-diks generally are browsers, yet, as with most aspects of this species' ecology, no reliable information is available. The captive specimens observed in Florence used the same food as captive *M. s. lawrancei*: pellet food, with an addition of a variety of fresh green food, and the animals did not appear to be

Madoqua piacentinii

very selective. During their brief period of captivity in Somalia, the animals were fed with the fronds of various *Acacia* species.

Social and Reproductive Behaviour As all other species of dik-diks are strictly territorial, and their territories stretch at most across a few hundred metres, this almost certainly applies to Silver Dik-diks. Some animals kept in captivity in Florence did not show any behavioural differences compared with other dik-diks.

Reproduction and Population Structure No observations have been made in the wild. Observations from captive specimens in Florence revealed behavioural similarities to Salt's Dik-dik. Two hybrids with *M. s. lawrancei* survived to adulthood; however, no hybrids have ever been reported from the wild.

Predators, Parasites and Diseases There are no reliable records, but Silver Dik-diks are probably vulnerable to the same predators and diseases as the other species in the genus.

Conservation IUCN Category: Data Deficient. CITES: Not listed.

Up to about 1965–70, when Somalia was still officially exporting trophies, an average of 200,000 dik-dik skins were exported annually and skins of the Silver Dik-dik were commonly obtainable from the tanning firm in Mogadishu. As a moderate increase in most species of game was observed after the ban of legal hunting in 1971, it is possible that the Silver Dik-dik enjoyed a brief period of recovery. However, the complete turmoil that has especially affected C and S Somalia over the last decades suggests that the species probably is in decline.

Prior to the civil war in Somalia a reserve had been declared covering a considerable stretch of the presumed range of the Silver Dik-dik. This reserve was to be transformed into a National Park bounded to the south by a line joining from the Shebelle R. about 15 km north of Balad to the village of Warsheik on the coast and extending north to Adale. Unfortunately, the National Park has never been formally gazetted and, at present, there is no information available concerning the status of the species or on the condition of its habitat. The only conservation measures available are the establishment of secure protected areas within its range (which seems unlikely in the foreseeable future) or the establishment of secure, self-sustaining populations in captivity (East 1999).

Alberto M. Simonetta

Madoqua (kirkii) KIRK'S DIK-DIK SPECIES GROUP

Sir John Kirk was a Scottish naturalist who served as David Livingstone's chief assistant from 1858 to 1863.

Taxonomy For the purposes of this handbook, *Madoqua kirkii sensu lato* is treated as a species complex or superspecies that provisionally includes four species. Molecular research has confirmed there are at least four cytotypes that are genetically well demarcated (Ryder *et al.* 1989, Kumamoto *et al.* 1994, Zhang & Ryder 1995, Kingswood & Kumamoto 1997).

That *Madoqua kirkii sensu lato* may represent a complex of more than one species first became evident when crosses involving specimens of Kirk's Dik-dik (captured at two different localities in Kenya) resulted in sterile male hybrids (Ryder *et al.* 1989). Subsequent studies of chromosome number and morphology revealed that these were the result of cross-breeding between two distinct cytotypes ($2n = 46$, $FN = 48$ and $2n = 46-47$, $FN = 56-59$), which, given their advanced state of reproductive isolation (male hybrid sterility), had to be considered separate species, respectively *M. (k.) cavendishi* and *M. (k.) kirkii* (Ryder *et al.* 1989). A third cytotype from Tanzania was also identified, *M. (k.) thomasi*, with $2n = 48$ and $FN = 52$ (Kingswood & Kumamoto 1997). Karyotyping of the south-western population, the Damara Dik-dik *M. (k.) damarensis*, also revealed this to have a distinct cytotype within the *M. kirkii* complex ($2n = 48$, $FN = 50$; Kumamoto

et al. 1994). According to Kingswood & Kumamoto (1997) the four cytotypes can be identified by six chromosomal rearrangements: two heterochromatic additions/deletions, two pericentric inversions, one tandem fusion and an autosome-to-X translocation.

A re-assessment of the status of subpopulations within *M. kirkii* has, therefore, been warranted, with the need to distinguish four genetically distinct forms. Molecular evidence strongly suggests that these are effectively full species, but it needs to be recognized that the details of taxonomy as well as the biogeography of the species remains uncertain and the nomenclature proposed here is provisional. For example, while Cotterill (2003a) recognized four evolutionary species (*M. kirkii*, *M. cavendishi*, *M. thomasi* and *M. damarensis*), Grubb (2005) was of the opinion that *thomasi* grades into *cavendishi* and is not a separate taxon. For this reason we place all members of this complex under a single profile. Differentiating the biology of these species and elucidating their evolution will be a task for future scientists. Long before molecular techniques became available, seven geographically and morphologically defined subspecies had been recognized (Ansell 1972). We present a synthesis that provisionally distributes Ansell's seven subspecies within the four molecular cytotypes.

Synonyms: *M. (k.) kirkii*: *minor*, *nyikae*; *M. (k.) cavendishi*: *hindei*, *langi*; *M. (k.) damarensis*: *hemprichianus*, *variani*; *M. (k.) thomasi*: none.

Chromosome number: *M. (k.) cavendishi* is characterized by cytotype A ($2n = 46$, $FN = 48$); *M. (k.) kirkii* is characterized by cytotype B ($2n = 46-47$, $FN = 56-59$); *M. (k.) thomasi* is characterized by cytotype C ($2n = 48$, $FN = 52$); *M. (k.) damarensis* is characterized by cytotype D ($2n = 48$, $FN = 50$). In captivity, dik-diks of the *M. (kirkii)* complex have hybridized with Günther's Dik-dik *M. guentheri* (Kumamoto 1995) and hybridization in the wild is believed to occur at low frequencies across the range (Kingdon 1982).

Description A grouping of very small, elegant antelopes with distinctive elongated and flexible noses. There is an erectile tuft of hair on the crown of the head between the large ears, these hairs reaching 45 mm in length. Large eyes surrounded by white eye-rings and with black preorbital scent glands in front of the eyes, especially prominent in ♂♂; the latter are enclosed by connective tissue and consist of a black core of sebaceous glands surrounded by a white layer of apocrine glands (Skinner & Chimimba 2005). External rhinarium is absent. Colouration is cryptic and paler in more arid regions (Estes 1991a). Dorsal pelage is grizzled with grey to brown hairs and white flecks, face and legs are tan-coloured and chin and belly are whitish. Long hindlegs give a hunched, almost hare-like appearance. Hooves are black and pointed and have pedal glands opening through narrow

cylindrical tubes between the hooves; however, these are absent in the Damara Dik-dik, having in their place invaginated folds of skin, with tufts of hair about 15 mm in length, and underlying sweat and sebaceous glands (Skinner & Chimimba 2005). Very small tail, white underneath. Females are about 10% heavier than ♂♂, and have two pairs of inguinal nipples.

Typical features of the skull include: posterior cranial roof strongly angled downward; anterior sides of the braincase widen anteriorly; temporal ridges very wide; lachrymal pits large and shallow to accommodate preorbital glands; maxillary tuberosities prominent; infraorbital foramina high and more posterior; auditory bullae large; and horn cores keeled and strongly inclined (Gentry 1992). Horns in ♂♂ only, short and spike-like, with strong annular rings towards the base. Molars and premolars are high crowned and the lingual walls of the lower molars are flattened. A small pair of upper canines is sometimes found in juvenile skulls and, rarely, in adults (Poggesi *et al.* 1982).

Geographic Variation As discussed above, the well-established *Madoqua kirkii* taxon is here considered to embrace four genetically distinct species that encompass the seven subspecies recognized by Ansell (1972).

Madoqua (kirkii) kirkii KIRK'S DIK-DIK

Fr. Le Dik-dik de Kirk; Ger. Kirkdikdik

Madoqua kirkii (Günther, 1880). Proc. Zool. Soc. Lond. 1880: 17. Somalia, 'near Brava, in the South Somali country'.

Kirk's Dik-dik *Madoqua (kirkii) kirkii*.

M. (kirkii) kirkii species ($2n = 47$): north-east African coastal and lowland regions south to Pare, Usambara.

M. (k.) k. kirkii: S Somalia and along the Kenyan east coast, south to the Tana R. One of the smallest subspecies; dorsal pelage darker ochre-tawny, flanks pale buff graduating into white underparts.

M. (k.) k. minor: Kenya, from just south of N Ewaso Nyiro R., north to Merelle Water and east towards Lorian Swamp. One of the smallest subspecies; pale desert subspecies, dorsal pelage bleached buff, flanks showing little contrast to white underparts.

M. (k.) k. nyikae: SE Kenya from Taveta eastwards, and into NE Tanzania. Dorsal pelage darker ochre-tawny, flanks pale buff showing little contrast to white underparts; sometimes with white spots on legs.

(Dik-dik images not to scale)

***Madoqua (kirkii) cavendishi* NAIVASHA DIK-DIK (CAVENDISH'S DIK-DIK)**

Madoqua cavendishi Thomas, 1898. Proc. Zool. Soc. Lond. 1898: 278. Probably from region of L. Baringo, British East Africa.

The vernacular name Naivasha Dik-dik follows Roosevelt & Heller (1915).

M. (kirkii) cavendishi species ($2n = 46$): uplands from E Uganda to Eastern Rift Valley and into N Tanzania.

M. (k.) c. cavendishi: E Uganda south through Rift Valley and into N Tanzania between Mt Kilimanjaro and L. Victoria; exact southern limits unknown. One of the largest subspecies; darker dorsal pelage, flanks rufous and in strong contrast to white underparts.

M. (k.) c. hindei: C Kenya, from Nairobi area, east to Kitui and south to Mtito-Andei; exact limits unknown. Darker dorsal pelage, flanks rufous and in strong contrast to white underparts.

Naivasha Dik-dik
Madoqua (kirkii) cavendishi.

***Madoqua (kirkii) thomasi* UGOGO DIK-DIK (THOMAS'S DIK-DIK)**

Madoqua thomasi (Neumann, 1905). Sitzber. Ges. Nat. Freunde Berlin 1905: 89. Itiso, Northern Ugogo, central Tanganyika Territory.

The vernacular name Ugogo Dik-dik (in reference to the type locality) follows Swynnerton & Hayman (1951).

M. (k.) thomasi species ($2n = 48$): Tanzania. Thicket and *Acacia* bushlands from C Tanzania south to L. Rukwa and the Udzungwa Mts, west to south-eastern shores of L. Tanganyika and northwards to the southern and western shores of L. Victoria as far as the Kagera R. More rufous on the flanks, which are in strong contrast to white underparts. This population inhabits a unique vegetation zone within a discrete geographic area.

Ugogo Dik-dik
Madoqua (kirkii) thomasi.

***Madoqua (kirkii) damarensis* DAMARA DIK-DIK**

Madoqua damarensis (Günther, 1880). Description of two new species of dwarf antelope. Proc. Zool. Soc. Lond. 1880: 17–22. Damaraland.

M. (kirkii) damarensis species ($2n = 48$): south-western Africa. C and NW Namibia and SW Angola. One of the largest species in the group; anterior of the back slightly lighter, and hair tuft between the ears darker; hooves have no pedal glands, but have a rubbery pad, which may be an adaptation to rocky ground.

Damara Dik-dik
Madoqua (kirkii) damarensis.

Lateral and dorsal views of skull of Damara Dik-dik *Madoqua (kirkii) damarensis*.

Similar Species

Madoqua guentheri. Sympatric in Kenya and Somalia; very similar but has longer nose, with the length of the nasal chamber exceeding the interorbital width of the skull, unlike that of dik-diks in the Kirk's complex.

M. saltiana and *M. piacentinii*. Sympatric in Somalia, but both are smaller and have shorter noses.

Oreotragus oreotragus. Broadly sympatric. Yellow-grey pelage; larger (12 kg), and with a more upright stance; invariably close to rocky terrain.

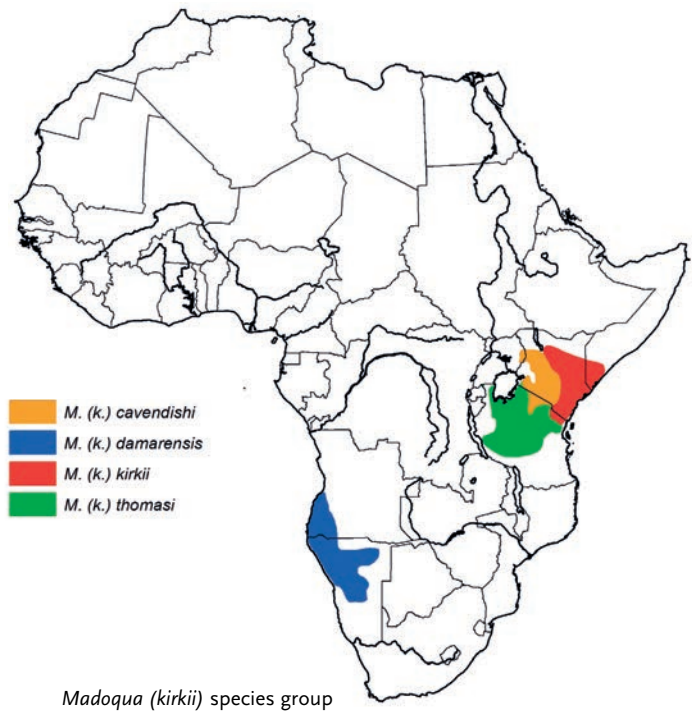

Distribution Endemic to Africa. Over 2000 km separates the East African populations (*cavendishi*, *thomasi* and *kirkii*) from *damarensis* in south-west Africa. Several authors (e.g. Kingdon 1971, Coe & Skinner 1993) have suggested that this division was brought about by climatic changes that took place during the Pleistocene, and that this has resulted in the intervening terrain experiencing wetter climates during interglacials with consequent changes in the vegetation structure.

Kirk's Dik-dik, the nominate species, has a lowland semi-littoral range that extends from S Somalia (formerly as far north as the Shebelle R.), through N and E Kenya and just into N Tanzania.

Naivasha Dik-diks inhabit uplands in the interior of eastern Africa. Mount Elgon, the Karamoja/Acholi border, and the southern tip of L. Turkana mark the western and northern boundaries. To the east, their range ends with the lowland Chalbi, Kaisut and Isiolo deserts. Their southernmost extension is the Mbulu highlands.

Ugogo Dik-diks inhabit the C Tanzanian bushlands. They extend to the southern and western shores of L. Victoria as far north as the Kagera R. and westwards to parts of the eastern shores of L. Tanganyika, south to L. Rukwa and the Udzungwa Mts and eastwards to the coastal lowlands.

In south-western Africa, Damara Dik-diks occur at least as far north as Lobito in SW Angola, and extend into NW and C Namibia, with isolated pockets further south along the Fish R. and around Mt Brukkaros (Crawford-Cabral & Veríssimo 2005, Skinner & Chimimba 2005).

Madoqua (kirkii) species group

Habitat Restricted to arid areas where they inhabit dense thorn scrub or open woodland in which the ground layer is mostly free of grass, but has a well-developed shrub layer (Tinley 1969). This provides good browse and shade, cover from predation, and an open understorey at eye-level. May also be found on isolated rocky hills or outcrops in savanna habitats, such as Serengeti N. P. in Tanzania (Hendrichs 1975a), and in riverine woodland and thickets. In W Kenya and Tanzania, dik-diks occur in areas receiving up to 1000 mm of rainfall per annum (Hendrichs & Hendrichs 1971). Reliably recorded up to about 2000 m (Hendrichs & Hendrichs 1971); records from upper Kilimanjaro (to 4270 m) are the result of a misidentification with a duiker (Grimshaw *et al.* 1995).

In Namibia, Damara Dik-diks are largely restricted to areas of hard, usually stony, ground, and are typically confined to areas with a mean annual rainfall of between 75 and 500 mm (Skinner & Chimimba 2005). In East Africa, Kirk's Dik-diks inhabit hot lowlands dominated by *Acacia* spp., *Boswellia*, *Indigofera* and *Duosperma* spp., Naivasha Dik-diks occupy dry uplands dominated by species of the genera *Acacia*, *Olea*, *Turrea*, *Tinnea*, *Aspileia*, *Psiadia*, *Aloe* and *Sansevieria*, and Ugogo Dik-diks inhabit dry bushlands characterized by very irregular rainfall and *Grewia*, *Baphia*, *Acacia* and *Pseudopropsis* thickets.

Abundance Widespread and locally abundant in areas of high shrub density. Based on average population densities, East (1999) estimated a total population size of 971,000 for the species group. Ground surveys have revealed density estimates for Kirk's Dik-dik of 109 ind/km² in Tsavo East N. P., Kenya (Komers 1996). Coe *et al.* (1999) made a gross overall estimate of about 33/km² for Mkomazi G. R., N Tanzania, but local densities in prime habitat were clearly much higher. Densities have been estimated at 55/km² in Arusha N. P., Tanzania (Amubode & Boshe 1990) and 24/km² in Serengeti N. P. (Hendrichs 1975a). In Etosha N. P., Namibia, Brotherton (1994) estimated the density of the Damara Dik-dik at 90/km².

Adaptations These animals are superbly adapted to life in an arid, hot climate. In these habitats water is at a premium, so dik-diks are faced with the problem of staying cool while conserving water (Schoen 1972, Maloiy 1973, Hoppe 1977a). They overcome this by a combination of physiological and behavioural adaptations. Water economy is high due to slow water turnover, the kidneys' ability to form highly concentrated urine and voiding very dry faecal pellets (Maloiy 1973, Hoppe 1977a, Maloiy *et al.* 1988). Indeed, dik-diks have the lowest daily water use and excrete the driest faeces and most concentrated urine of any ungulate so far studied; this ability is probably due to the kidney's relatively high volume (47%) of renal medullae and its long loops of Henle (Schoen 1969, Maloiy *et al.* 1988). During dehydration, the faecal water content reduces to 68 g/100 g dry faecal material, compared with 76/100 g in camels (Maloiy *et al.* 1988). This enables them to live entirely independently of water, even during long dry seasons (though dik-diks with standing water in their territories have been observed to drink, P. Brotherton pers. obs.). In captivity, voluntary water intake is just 278 ml/day (Hoppe 1977b) while in the field, dry season water intake has been estimated at a mere 134 ml/day (Manser & Brotherton 1995). In captive trials, dik-diks were observed to consume forage at a rate of 40.4 g per kg body weight per day, while daily water intake was about 68 ml per kg body weight (Maloiy & Clemens 1999).

Dik-diks conserve water further by licking condensation droplets that form on the nose, and panting instead of sweating (Hoppe 1977a); a histological examination of dik-dik skin revealed a sweat gland density of 120 glands per cm², far less than that of actively sweating ungulates such as cattle (1500 glands per cm²) (Maloiy *et al.* 1988). One of the most striking features of dik-diks is the elongated nose and this, too, is an adaptation to reduce water loss. The nasal chamber is enlarged to accommodate the proboscis and the roof of the nasal cavity is supported by cartilage for greater flexibility (see Kingdon 1982, Frey & Hofmann 1996). The elongated nose is richly vascularized, allowing cooling of the blood by nasal panting; the wide, flexible trunk functions like a bellows to increase air flow while the hairy muffle and tiny nostrils reduce water loss. This serves to cool the blood going directly to the brain, keeping this most sensitive organ at the correct temperature, while the body core temperature may rise up to 43°C (Maloiy *et al.* 1988). This excess body heat is apparently stored or lost to the environment without using water for evaporation.

Dik-dik activity patterns are also adapted to their hot, arid habitat. They are mainly crepuscular in their activity (and intermittently throughout the night) and rest in the shade of dense bushes during the hottest times of the day. This also means that they feed on plants at the times when the water content of their leaves is highest (Bowker 1978).

Like Günther's Dik-dik, these dik-diks have a relatively small stomach, and a digestive tract designed for rapid passage and absorption of high-quality food (Hofmann 1973, Hoppe 1977b). The rumen is simple, with dense papillation that increases the absorptive mucosal surface as much as 18-fold. Volatile fatty acid production in the rumen is about three-fold the rate found in roughage-eating grazing antelopes. The short residence time of rumen contents precludes fibre digestion and survival of intra-ruminal protozoa except, in a few individuals, *Entodinium* (Hoppe *et al.* 1983) that are tolerant to or degrade tannins (Odenyo *et al.* 1999) (see also Günther's Dik-dik profile).

Being independent of water enables dik-diks to remain in their territories and reduces the risk of predation. Cryptic colouration and

small size also help dik-diks to hide from their numerous predators. Their long hindlegs are powerful and enable dik-diks to make explosive bursts of speed when they encounter predators (see also Günther's Dik-dik profile). The Damara Dik-dik has a rubbery pad behind the hooves, which may be an adaptation to rocky ground (Tinley 1969).

Foraging and Food Like their congeners, dik-diks of the *M. (kirkii)* complex are selective browsers, consuming the leaves, flowers, shoots and fruit of shrubs, bushes and trees, selecting the freshest parts of the plant available and only rarely eating grass (when sprouting). In Kenya, Bowker (1978) found that they browsed almost every available species of tree and bush. In Tarangire G. R., Tanzania, their diet comprised 56% shrubs, 23% trees, 17% grasses, 3% forbs and 1% sedges (Lamprey 1963).

In Namibia, Damara Dik-diks were found to eat from over 85% of the species of woody plants occurring in their territories during the course of the year (Manser & Brotherton 1995), although species with less palatable fibrous leaves were only utilized in the dry season, a time when leaf litter also became an important part of the diet. Availability of the latter is increased by other browsing species, such as Greater Kudu *Tragelaphus strepsiceros*, Giraffe *Giraffa camelopardalis* and Savanna Elephants *Loxodonta africana*, which break down the browse plants. Tinley (1969) recorded 28 species of browse and four grass species eaten during the wet season in Etosha N. P. (including *Securinega virosa*, *Rhus marlothii* and *Ziziphus mucronata*), to which he added a further 22 browse species consumed in the dry season (including *Boscia albitrunca*, *Grewia* spp. and *Terminalia prunioides*). Other species, such as thorn trees and sickle bushes *Dichrostachys cinerea*, were eaten all year round. In CTanzania, Harrison (1936) noted Ugogo Dik-diks switching from *Acacia pennata* and various other woody plants in the dry season to *Acacia senegal* in the wet season, at which time ephemeral herbs such as *Ipomoea* spp. and *Leonotis* spp. were also eaten.

In Namibia, the period of lowest food availability at the end of the long dry season coincides with the flowering of certain tree species, notably *Lonchocarpus nelsii* and *Boscia albitrunca*, and dik-diks may temporarily leave their territories to feed on fallen flowers; up to nine dik-diks at a time have been observed feeding under large flowering trees. Dik-diks make use of their long proboscis-like snout to search for preferred foods. Like the Gerenuk *Litocranius walleri*, dik-diks may feed bipedally, standing on their hindlegs to reach browse otherwise out of reach.

Simonetta (1966) found that regular access to mineral salts was important for maintaining captive dik-diks, and in the wild they are known to eat sand, visit salt-licks and chew on bones to gain minerals (Harrison 1936, Bowker 1978, P. Brotherton pers. obs.).

Social and Reproductive Behaviour The typical social unit is a monogamous pair (Hendrichs 1975a) accompanied by a single juvenile from the most recent breeding event, though sometimes an older offspring is also present. The pair-bond apparently lasts until one member dies, and genetic studies have confirmed fidelity within the pair bond (Brotherton *et al.* 1997). Occasional polygynous groups occur, comprising a ♂ and two unrelated ♀♀ (10% of groups in Etosha N. P.); these groups apparently form in response to a lack of territorial vacancies for ♀♀ (Brotherton & Manser 1997). Temporary aggregations may form during the dry season at sites of food abundance (see Foraging and Food above).

Ugogo Dik-dik *Madoqua (kirkii) thomasi*.

Both sexes defend the pair's territory (female territoriality is rare in antelopes), mainly against same-sexed intruders, and the territory boundaries can be stable for several years (Amubode & Boshe 1990). Depending on local resource availability, territories may vary in size from under 1 ha to over 10 ha. Territories are marked with dung piles and scent from the preorbital gland. Dung piles are most commonly situated on the territory boundaries and can be several metres in diameter. Dung piles are typically located next to animal trails, presumably to increase the likelihood of intruders encountering them. The behaviour of the pair at dung piles follows a distinct pattern: the ♀ enters the dung pile and urinates before defecating (urination and defecation is linked, as in many antelopes). Sometimes, especially as the ♀ approaches oestrus, the ♂ puts his nose in her urine flow and displays flehmen. After the ♀ has defecated, the ♂ smells her deposit and then scrapes dirt over it with his front hooves before urinating and defecating on top (Hendrichs 1975a). In a similar fashion, ♂♂ over-mark the deposits of any other group members. Dik-diks may also defecate on top of the dung of other species and the faeces of unfamiliar dik-diks (Hendrichs & Hendrichs 1971). Preorbital secretions are dabbed onto protruding twigs throughout the territory, and accumulate into black, tar-like deposits. Between 200 and 500 mg of this substance is deposited per day (Hoppe 1977a). In Namibia, ♂♂ were observed to preorbital mark at a rate of about 19 marks/h, compared with a female rate of about 6 marks/h (Brotherton 1994), and ♂♂ over-mark any female scent marks that they encounter. Male over-marking of female dung deposits and preorbital secretions appears to have two functions: concealing the oestrous status of the ♀ from neighbouring and intruding ♂♂; and advertising that the ♀ has a pair-mate who will defend her.

Fights may occur when neighbours, especially ♂♂, encounter each other at territory boundaries, although physical contact during fights is uncommon. When dik-diks fight in captivity, where one cannot escape, the results can be fatal (Kingdon 1982). In the wild, combatants typically engage in highly ritualized 'air-cushion' fights, in which they make frequent short charges at each other, but stop about 50 cm apart (Estes 1991a). During these fights dik-diks erect the tuft of hair between their ears and display by thrashing vegetation with their heads. Males also erect their hair tuft and thrash vegetation during periodic displays of dominance over their ♀♀. It is typically the ♀ that initiates changes of activity for the group, and determines where the group moves within the territory, although if she attempts to leave the territory the ♂ may chase her back (Komers 1996).

Oestrus lasts less than 24 hours (Dittrich & Böer 1980) and copulation behaviour follows a distinctive pattern: the ♀ adopts an upright stance with her back curved downwards and her tail erect, and the ♂ mounts without touching her with his forelegs (Brotherton 1994). Intromission occurs in approximately 10% of mounts and copulation lasts about two seconds. Occasionally, the ♂ licks or nuzzles the female's anogenital region before mating. Dik-dik young are precocious: they can stand 5–15 min after being born and suckle within 1–2 hours. For the first few weeks of life, the young remain hidden in dense vegetation and mothers return to feed them. At 10–14 days of age, young begin browsing and thereafter they increasingly accompany their mothers until they are constantly with their parents from 5–6 weeks of age. Males have no role in parental care (Brotherton & Rhodes 1996). Reciprocal grooming is sometimes observed between mothers and offspring.

Brotherton (1994) recorded six vocalizations in Damara Dik-diks, most notably a high-pitched nasal whistle given as an alarm call. Explosive utterances of this whistle while stotting sound like 'zik-zik' and this may be the source of the dik-dik's name. This loud whistle may also be used to threaten intruders. The five other vocalizations are a trill (a soft whispering call, apparently used to warn other group members of danger and also used during submissive display by ♀♀, juveniles and intruders); bleat (occasionally made by fleeing intruders); chatter (almost horse-like grunt, used by ♂♂ during intra-group dominance displays); 'phee-oo' (a mother–infant contact call), and a scream (when captured by predators).

Reproduction and Population Structure Birth peaks coincide with wet seasons. In East Africa, where two wet seasons occur, ♀♀ typically give birth twice a year, with most young being born in Apr–Jun and Nov–Dec (Hendrichs & Hendrichs 1971, Bowker 1978). In Namibia, where one wet season occurs, most ♀♀ of the Damara Dik-dik give birth only once a year, usually between Dec and Apr (Shortridge 1934, Brotherton 1994).

Females give birth to a single young after a gestation period lasting 166–174 days (Dittrich & Böer 1980). Male young weigh about 650 g (range 585–795 g, $n = 5$) at birth (which, at over 10% of maternal body weight, is relatively large for an ungulate) while female young average 607 g (range 560–680 g, $n = 5$). Captive young reach half adult mass by four months, and adult mass at about a year (Dittrich & Böer 1980). Sexual maturity is reached at about 6–8 months of age (Kellas 1955), and ♀♀ may have their first calf at one year.

Female offspring disperse prior to their first oestrous period at about six months of age. Female dispersal typically is associated with little or no aggression from either parent, and a ♀ whose mother had died still dispersed even though she was the only ♀ left in the territory, suggesting that ♀♀ leave to avoid mating incestuously with their fathers (P. Brotherton pers. obs.). Sons disperse later than daughters, at about one year, and this may be the result of aggression from their father (Hendrichs 1975a). However, if no territorial vacancies are available sons may remain with their parents until they are up to two years old (Brotherton 1994). Males are more philopatric than ♀♀: in one study in Namibia, four out of eight ♂♂ dispersed to territories within 250 m of their parents while all daughters moved further away (Brotherton 1994).

Mortality rates vary according to predation pressure. About 50% of dik-diks die before the age of four months (Bowker 1978,

Brotherton 1994). In a Serengeti N. P. population, adult annual turnover rates were 7% for ♀♀ and 16% for ♂♂ (Hendrichs 1975a); at one site in Kenya, 16% of adults (of both sexes) died in a 10-month period (Bowker 1978); and in Namibia, average adult mortality was about 20% for both sexes (Brotherton 1994). Records from captivity show a slight, but significant, male bias in the sex ratio at birth (of 372 captive births of known sex, 166 were ♀, 206 were ♂; Kingswood & Kumamoto 1997). Since dik-diks are monogamous, adult sex ratio among territorial individuals is necessarily close to 1 : 1. However, following the death of a resident animal, ♂♂ are typically replaced much quicker than ♀♀: in Namibia, ♂♂ were replaced within three days while ♀♀ were replaced on average after 32 days (Brotherton 1994). In Serengeti N. P., a male dik-dik remained unpaired for over five months after his mate died (Hendrichs & Hendrichs 1971). This suggests that there is likely to be a male bias in the non-territorial population. In captivity, ♂♂ and ♀♀ have been known to live for 16–17 years (Kumamoto 1995, Weigl 2005); the oldest dik-dik recorded in a wild population was about ten years (Hendrichs 1975a).

Predators, Parasites and Diseases Dik-diks are taken by a broad spectrum of terrestrial and aerial predators. Known predators of adults include Leopards *Panthera pardus*, Cheetahs *Acinonyx jubatus*, jackals *Canis* spp., African Wild Dogs *Lycaon pictus*, Caracals *Caracal caracal*, Lions *Panthera leo*, Martial Eagles *Polemaetus bellicosus* and Tawny Eagles *Aquila rapax*; while predators known to take juveniles include Olive Baboons *Papio anubis*, African Rock Pythons *Python sebae* and African Hawk-Eagles *Hieraetus fasciatus* (Tinley 1969, Bowker 1978, Kingdon 1982, Spinage 1986).

Virtually nothing is known about diseases suffered by dik-diks in the wild, although they apparently have low susceptibility to rinderpest (Plowright 1982). Bowker (1978) noted two young ♂♂ heavily infected by unidentified external parasites on their necks and heads, but both recovered. In C Namibia, some individuals have been observed with stump-like ears (P. Hoppe pers. comm.), which may have been due to frost-bite damage. Also in Namibia three individuals were observed to suffer from a severe eye infection, which in each case led to the loss of the infected eye, and was usually followed by death (P. Brotherton pers. obs.). Ectoparasites include a range of fleas (*Ctenocephalus* spp.), lice (*Linognathus* spp.), muscid flies (*Stomoxys* sp.) and ticks; numerous endoparasites are recorded, including nematodes, cestodes, pentastomids and protozoans (see Kingswood & Kumamoto 1997, and references therein).

Conservation IUCN Category: Least Concern. CITES: Not listed.

Dik-diks are trapped for food by local people throughout their range, and are also taken by trophy hunters. Their ability to exist in scrub and overgrazed areas has made their populations resilient to the vegetation changes that have accompanied human population growth,

and may have even favoured them in the short term. Populations in protected areas include those in Samburu, Tsavo, Amboseli and Lake Nakuru National Parks (Kenya), Serengeti, Arusha and Mkomazi National Parks (Tanzania) and Etosha N. P. (Namibia) (East 1999).

Measurements

Madoqua (kirkii) species group

TL (♂♂): 676 (570–780) mm, n = 31

TL (♀♀): 690 (640–750) mm, n = 35

T (♂♂): 45 (30–77) mm, n = 22

T (♀♀): 51 (32–70) mm, n = 20

HF c.u. (♂♂): 198 (159–218) mm, n = 41

HF c.u. (♀♀): 203 (191–216) mm, n = 34

E (♂♂): 78 (57–86) mm, n = 39

E (♀♀): 79 (57–85) mm, n = 35

Sh. ht (♂♂): 383 (300–445) mm, n = 189

Sh. ht (♀♀): 397 (240–444) mm, n = 157

WT (♂♂): 4.59 (2.6–6.0) kg, n = 181

WT (♀♀): 5.17 (3.5–6.4) kg, n = 151

Throughout geographic range (Kingswood & Kumamoto 1997). Note that local species or subspecies may differ in dimensions, *M. (kirkii) kirkii* in particular having smaller dimensions than the other species. This can be appreciated by comparing total length of skull measurements:

Madoqua (k.) kirkii (including *minor*)

GLS (♂♂): 105 (101–108) mm, n = 10

GLS (♀♀): 110.5 (105–114) mm, n = 4

Madoqua (k.) cavendishi

GLS (♂♂): 120.8 (116–124) mm, n = 8

GLS (♀♀): 119.5 (116–127) mm, n = 6

Madoqua (k.) thomasi

GLS (♂♂): 115 mm, n = 126

GLS (♀♀): 117 mm, n = 85

Madoqua (k.) damarensis

GLS (♂♂): 109.7 (105–113) mm, n = 3

GLS (♀♀): 118 (116–120) mm, n = 3

Kellas (1955) gave mean head and body length (\pm S.D.) for ♂♂ as 595 (\pm 26) mm (n = 126) and for ♀♀ 615 (\pm 26) mm (n = 83)

Maximum recorded horn length is 11.4 cm for a pair of horns from Selous, Tanzania (Rowland Ward)

Madoqua guentheri GÜNTHER'S DIK-DIK

Fr. Dik-dik de Günther; Ger. Zwerg-rüsselantilope

Madoqua guentheri Thomas, 1894. Proc. Zool. Soc. Lond. 1894: 323–329. Ethiopia, 'Central Ogaden, 3000 feet [914 m]'; identified as 'District immediately north of Imi and Karanle on the Webi Shebeli, Ogaden, Ethiopia, about 6° 30' N, 42° 30' E by Moreau *et al.* (1946: 437).

Günther's Dik-dik *Madoqua guentheri*.

Taxonomy Four subspecies were recognized by Ansell (1972), although one of these (*M. g. hodsoni*) is based on a single specimen whose skull is indistinguishable from *M. g. guentheri* (Drake-Brockman 1930), and there is some debate as to the validity of another of the four possible subspecies, *M. g. wroughtoni*, which is probably also allied with *M. g. guentheri* (Yalden *et al.* 1984). If these two subspecies are indeed synonymous with the nominate subspecies, then the total number of subspecies is two. However, for the purpose of this handbook, all four subspecies are provisionally retained (and see Kingswood & Kumamoto 1996).

Synonyms: *gussuleh*, *hodsoni*, *nasoguttatus*, *smithii*, *wroughtoni*. Chromosome number: $2n = 48-50$; there are 8–10 submetacentrics and 36–40 acrocentrics, with acrocentric sex chromosomes (Ryder *et al.* 1989). Variation in diploid number results from putative centric fusion occurring in homozygous ($2n = 48$) and heterozygous ($2n = 49$) forms; $2n = 50$ forms lack the fusion. $2n = 49$ heterozygotes of both sexes are fertile (Kumamoto 1995). In the wild, skins and skulls displaying intermediate characteristics of *M. guentheri* and dik-diks of the *M. (kirkii)* complex have been found from parts of Somalia, Ethiopia, Kenya and the Kenya–Uganda border, suggesting that hybridization may occur over a wide area (Kingdon 1982). Crosses between these species in captivity have produced sterile male hybrids (with $2n = 48$) and backcrossing a F1 hybrid ♀ with a *M. guentheri* ♂ produced stillborn offspring (Kumamoto 1995). This high level of reproductive isolation confirms that the two are indeed distinct (albeit sometimes difficult to distinguish).

Lateral view of skull of Günther's Dik-dik *Madoqua guentheri*.

Description A small, delicately built antelope, with a trunk-like nose, a tuft of hair on the crown and cryptic colouration with inconspicuous markings. Head small, with an elongated, mobile nose resembling that of a tapir (*Tapirus* spp.). Portions of the face and ears sandy, pale rufous, or greyish-red (Lönnberg 1907, Drake-Brockman 1930). Eyes large and black, surrounded by white; ears large with white interiors. Brown crest of long hairs on the crown is longer, coarser and brighter in ♂♂ than ♀♀ (Drake-Brockman 1930). Dorsal pelage grizzled yellowish-grey to greyish-brown, flanks light rust-red or sandy-white, and sandy-white on chin, throat, chest, belly and inside thighs; pelage colour varies geographically, although certain pinkish hues of the underparts are often the result of soil colour (Kingswood & Kumamoto 1996). Lumbosacral height is greater than shoulder height; legs are long and slender. Tail short, hirsute dorsally and naked ventrally. Hooves (more than 15 mm long) are black, with soft foot-pads, and minute lateral hooves (Roosevelt & Heller 1915). Pedal glands are present consisting of a deep invagination (ca. 9×4 mm) opening ventrally between the two digits on each foot. Preorbital glands are black and large in relation to body size compared with other antelopes, and larger in ♂♂ than ♀♀ (Sokolov *et al.* 1994, Spinage 1986). Females have two pairs of inguinal nipples. Males are smaller, weighing 15% less than ♀♀.

Horns are present in ♂♂ only, short and straight or slightly curved, elliptical at base and circular toward the tips, strongly ringed for about two-thirds of their length (Drake-Brockman 1930); small horn cores on the upper surface of the frontals occur on the skulls of some ♀♀ (Poggesi *et al.* 1982). The crest of long hairs on the forehead covers about two-thirds of the length of horns, sometimes making it difficult to distinguish the sexes (Drake-Brockman 1930).

Characteristic features of the skull include large orbits and lachrymal fossae (the latter accommodate preorbital glands), somewhat inflated tympanic bullae, small supraorbital foramina and small nasals that have greater width than length. Premaxillae are short, ending above P¹ and not reaching the nasals as in dik-diks of the *M. (kirkii)* complex (Frey & Hofmann 1996). Length of proboscidean nose amounts to 60–70% of skull length providing much room for respiratory heat exchange and water recovery (Frey & Hofmann 1996). Skull measurements and photographs are given by Kingswood & Kumamoto (1996).

Geographic Variation

M. g. guentheri: eastern form, apparently not reaching the coast, where it is replaced by Kirk's Dik-dik *M. (kirkii) kirkii* (Drake-Brockman 1930); range extends from the Ogaden, south and westerly through Somalia and Ethiopia into NE Kenya. Relatively small, like *M. g. wroughtoni*, though it can be distinguished from this subspecies by its lighter colour and pinkish-buff underparts (Lydekker 1914).

M. g. wroughtoni: distribution extends from the northern bank of the Wabi R. in Ethiopia, south and east between the Shebelle and Juba Rivers (Drake-Brockman 1930). One of the smaller subspecies, although its ears are wider and longer than in other dik-diks, except Naivasha Dik-dik *M. (kirkii) cavendishi*, to which it bears a superficial resemblance.

M. g. hodsoni: known only from a single specimen collected at Mt. Mega, Ethiopia. Skull indistinguishable from *M. g. guentheri*. Palest of the subspecies, hairs lacking the grizzled appearance of other dik-diks; faint reddish-brown line on the flank.

M. g. smithii (including *nasoguttatus*): SE Sudan, NE Uganda, SW Ethiopia and N Kenya. Largest of the subspecies; more grey and less yellow than other subspecies, and the anterior portion of the face and proboscis are spotted with white. Middle of the body is reddish-brown; the sides of the face, back of the ears and lower legs are light buff; the snout is bright tawny.

Similar Species

Madoqua (kirkii) species group. Mainly found south of the Tana R., but sympatric in N Kenya, and perhaps Somalia. Similar to *M. guentheri*, but larger, weighing up to 20% more.

M. saltiana. Sympatric in Somalia and Ethiopia. Short, squared-off, furry nose, not showing the enlargement seen in Günther's Dik-dik.

M. piacentinii. Least arid-adapted species, inhabiting dense, low-level, green thickets along the Obbia coastal littoral of Somalia, and further inland in the upper reaches of the Shebelle R. in the Ogaden where known to be sympatric with Günther's Dik-dik (Wilhelmi *et al.* 2006); smallest dik-dik, with soft, fine, silvery-grey fur and bright red erectile crest; proboscis noticeably less developed.

Distribution Endemic to hot, semi-desert areas of East and north-east Africa centred around L. Turkana where mean annual rainfall is low (less than 500 mm) and highly variable. The distribution includes N and S Somalia, the eastern and southern lowlands of Ethiopia, SE Sudan (east of the Nile R.), NE Uganda, and N and W Kenya. In Somalia, Günther's Dik-dik does not occur near the coast except possibly in one small area at the Gulf of Aden. Occurrence south of the Shebelle R. is controversial, but the ranges of both *M. (kirkii) kirkii* and *M. guentheri* may overlap in the Juba–Shebelle drainage (Kingswood & Kumamoto 1996, Kingdon 1997). The north bank of the Tana R. appears to be the southern border of distribution (Hillman *et al.* 1988, East 1999).

Habitat Of all dik-diks, Günther's live in the driest, hottest and thickest thornbush (Kingdon 1997). They occur mostly on stony ground compared with Salt's and Silver Dik-diks, which prefer sandy soil. In Omo N. P., Ethiopia, the habitat types occupied (means, as percentage of total area) included *Combretum–Selima* bush (56%), *Acacia mellifera* savanna (33%), riverine forest (12%), human

Madoqua guentheri

settlements (10%), old fields (9%), *Ischaenum–Pennisetum* grassland (8%), *Combretum* forest (3%), *Acalypha–Sansevieria* thicket (3%) and *Acacia nilotica* savanna (1%) (Ono *et al.* 1988). Suitable cover seems to be an important habitat requirement as they are seldom seen far from cover. They occur from sea level to about 2100 m elevation (Yalden *et al.* 1996).

Abundance In Sudan, Günther's Dik-dik were common in the 1980s, but there is no recent information. In Ethiopia, they are widespread and common to abundant in the eastern and southern lowlands (East 1999). In Somalia, they are recorded as common in the bushland of the Haud plateau in the north but less abundant than Salt's Dik-diks, occurring at a ratio of about 1 : 10 (East 1999). In Uganda, they are thought to still occur widely in the north-east from Kidepo Valley N. P. to southern Karamoja where the species has benefited from expansion of evergreen scrub resulting from overgrazing (East 1999). In Kenya, they are widespread and common in suitable habitat in the north and east.

Population densities of 0.7–1.1/km² have been recorded in the Haud plateau, Somalia, and the Ogaden region of Ethiopia (East 1999, and references therein). In Omo N. P., a higher density of 23.8/km² was observed in 1988 within a 75 ha study area (Ono *et al.* 1988). In 2003, transect counts in the central Ogaden around Kebri-Dehar found a density of 25/km² (F. Wilhelmi pers. comm.). The total population has been estimated at around 511,000, assuming an average population density of 1/km² (East 1999).

Adaptations Günther's Dik-diks are adapted to heat and aridity. As described for dik-diks of the *M. (kirkii)* complex, water economy is high due to slow water turnover, the kidneys' ability to form highly concentrated urine and voiding very dry faecal pellets (Maloiy 1973, Kamau 1988, Maloiy *et al.* 1988, Hoppe 1997a). They are largely independent of surface water, relying on water within dicotyledonous plant cells, hygroscopic water on plant surfaces and

Günther's Dik-dik *Madoqua guentheri*.

water produced in metabolism (in rare instances when dik-diks drink, they lap water like a cat). Panting is employed for evaporative cooling, aided by the moist mucosal surface of the proboscis (Hoppe 1977a, Frey & Hofmann 1996). The cooled venous blood draining the proboscis selectively cools the carotid rete in the brain while peripheral body temperature is allowed to stay high. Excess heat stored by the body is dissipated during the night without expenditure of water (Kamau 1988). Sweating plays no role in thermoregulation. During the hottest hours of the day they lie or stand in the shade thus avoiding heat production from locomotion and heat uptake from solar radiation. Any movement at this time is in slow motion.

Günther's Dik-diks have a relatively large mouth, allowing the sideways stripping of branches or the gnawing of flowers or fruits (Hofmann 1989). Anatomically, the small rumen resembles a simple folded tube with dense papillation (which increases the absorptive mucosal surface 15–17 times) that lacks the food-retaining muscular pillars typical of grazing ruminants; the muscular omasum has horny papillation, probably for grinding and straining. The gastrointestinal tract is discussed in detail by Hofmann (1973), and is designed for rapid passage and rapid absorption of high quality food (Hofmann 1973, Hoppe 1977b). Food and feeding behaviour involves frequent short feeding periods ranging from 1 to 36 min alternating with equally frequent, short rumination periods of 5–15 min (Hofmann 1973, Hoppe 1984). This results in almost continuous supplementation of intra-ruminal fermentation with new substrate, in the release of intracellular nutrients that are more rapidly fermented to volatile fatty acids than cell-wall constituents like cellulose, and in a copious flow of saliva to buffer intra-ruminal pH (Hofmann 1973).

Behavioural adaptations to survive predators include the ability to dart away quickly (the back is rounded and the knee and tibio-tarsal joints are strongly flexed, possibly as an adaptation to rapid starts; Hofmann 1973), intimate knowledge of the territory, and permanent alertness (Hendrichs & Hendrichs 1971).

Foraging and Food Günther's Dik-diks are classed as browsers in a detailed analysis of dietary preferences in African bovids (Gagnon & Chew 2000), in agreement with studies involving stable carbon

isotopes (Cerling *et al.* 2003). They are highly selective feeders, classified as fruit and dicotyledon foliage selectors (Hofmann & Stewart 1972, Hofmann 1973) or 'concentrate selectors'. Forty-five food plants were identified in Kenya including six *Acacia* species, three *Commelina* species, representatives of the families Euphorbiaceae, Salvadoraceae, Rhamnaceae and Papilionaceae, and two grasses, of which only seeds appear to be eaten (Hofmann 1973). Leaves are selected foremost and are frequently taken up as litter. Flowers, fruits, seeds and pods of shrubs and trees are eaten, but few stems are taken. Plant selection may be based on olfactory cues. They sometimes make use of a foreleg to pull browse within reach or feed standing on their hindlegs like the Gerenuk *Litocranius walleri*. They also dig for roots and tubers with their hooves and horns (Kingswood & Kumamoto 1996). They are most active from dawn to early morning and in late afternoon to dusk, but are sometimes active during a full moon (Kingdon 1982). Kingdon (1982) has suggested that Klipspringers *Oreotragus oreotragus* could be competitors for food in some localities during the dry season.

Social and Reproductive Behaviour Günther's Dik-diks are territorial and monogamous, usually occurring in groups of three or four, typically comprising an adult pair with one or two offspring (Bryden 1899, Estes 1991a). Occasionally, groups of 6–12 are found within sight of one another (Kingdon 1982). The pair usually occupy a fixed territory, although in areas of high density more than one adult ♀ may share a territory. Members of a pair are sometimes seen singly.

During the day they are believed to remain in their territories. At night they may forage far beyond their territorial boundaries, the pair remaining close together (Ono *et al.* 1988). Home-ranges vary from 4 to 13.7 ha, with large ranges during dry seasons (Ono *et al.* 1988); home-ranges of ♂♂ may overlap by 65% so home-range size does not correspond directly to territory size. Distances between pairs range from 200 to 600 m (Kingdon 1982). Pair bonds are independent of territorial bonds, with pairs occasionally shifting their territories to neighbouring regions (Ono *et al.* 1988).

Territories are defended by ♂♂. Scents from preorbital and pedal gland secretions are used for marking territories, as are urine and faeces that are deposited on dung piles along territorial

borders (Kingdon 1982). Preorbital gland secretions are deposited as a black mass on branches at head-height throughout the territory and dung piles tend to demarcate boundaries. Dung piles are used repeatedly and may be up to 5 m² in size. Urination and defecation proceed in a ceremony where the ♀ defecates and urinates first and the ♂ smells and tests her urine, scrapes over her deposit and then urinates and defecates on the same spot (Kingdon 1982). Male territorial behaviour peaks when ♀♀ are in oestrus and constantly attended by their ♂. Aggression between territorial ♂♂ involves dominance or threat displays and fighting behaviour such as chasing, mock fighting, horn contact and horn-stabbing. Serious fighting is unusual, and dik-diks mostly use mock fighting maintaining an 'air-cushion' between them (Kingdon 1982, Ono *et al.* 1988, Estes 1991a).

Females in oestrus exhibit lordosis, and receptive ♀♀ respond to genital licking by raising their tail and squatting slightly. Genital licking may be followed by urine testing, but is less common in dik-diks, which Kingdon (1982) suggests could be related to water economy and might have been augmented by the revelation of circular ruffs of brilliantly white hair on each haunch. Males mount bipedally without claspings or resting on the ♀ (Kingdon 1982, Estes 1991a).

After parturition, the ♀ eats the afterbirth. Female and sire stay near the newborn for the first day of life. Thereafter, the ♀ attends to it four times a day at about sunrise, noon, dusk and midnight for about 15 min each for suckling (about 1–2 min) and grooming (Kingdon 1982). The ♂ remains on the lookout for predators while the ♀ feeds. The young is concealed for 2–3 weeks then follows the parents for a few months.

When excited or frightened Günther's Dik-diks erect the crest, vocalize with a whistling hiss ('zik-zik') with a downward extension of the proboscis, and freeze or race into the nearest vegetation. The dik-diks profit from hyraxes and guinea-fowls that alert them to the presence of large predators. Anti-predator behaviour discriminates between predators: for example, the dik-diks will whistle at Leopards *Panthera pardus*, but not at hyaenas.

Reproduction and Population Structure In the wild, in Ethiopia, births have been recorded during Aug and Sep, but throughout the year in captivity. Sexual maturity is reached before one year of age, although, in captivity, ♀♀ can conceive at less than four months of age. Duration of oestrus and interval between oestrus ranges from 1–7 and 13–21 days, respectively (Fitzgerald & Hnida 1994). Gestation period is 170–180 days (Fitzgerald & Hnida 1994). A single young is born. Offspring are precocious and colouration at birth is identical to adults. Mean birth-weight in captivity was 684 ± 100 g, about 15% of maternal weight; ♀♀ are heavier than ♂♂ although weight gain in captivity is the same in both sexes. Young are nursed for 3–4 months, but begin eating browse after one week; adult mass is attained between 12 and 18 months. A postpartum oestrus occurs about ten days after birth, which means ♀♀ can be pregnant most of the year while still having dependent young. In captivity, inter-birth intervals range from 169 to 289 days ($n = 71$; Kumamoto 1995). Longevity in the wild is believed to average 3–4 years (Kingswood & Kumamoto 1996) or 7–8 years (Hofmann 1973, Haltenorth & Diller 1980); in captivity, longevity is extended, with one wild-born specimen about 17 years old when it died in captivity (Weigl 2005).

A population in Raume Erer, Ethiopia, comprised 52–78% ♀♀ and 22–48% ♂♂ (Kurt, in Kingswood & Kumamoto 1996). The sex ratio in the wild is largely unknown, but of 126 births in captivity, 60 were ♀♀ and 66 ♂♂ (Kumamoto 1995).

Predators, Parasites and Diseases Predators include Black-backed Jackals *Canis mesomelas*, Spotted Hyaenas *Crocuta crocuta*, Caracals *Caracal caracal*, Serval *Leptailurus serval*, Leopards, Cheetahs *Acinonyx jubatus*, Verreaux's Eagles *Aquila verreauxii*, Martial Eagles *Polemaetus bellicosus* and African Rock Pythons *Python sebae* (Kingswood & Kumamoto 1996). Not a great deal is known of parasites and diseases (see Kingswood & Kumamoto 1996 for review). The larval stage of the tapeworm *Taenia madoquae* occurs in the musculature; the adult tapeworm is found in Black-backed Jackals (Jones *et al.* 1988), indicative of the predator–prey relationship between dik-diks and jackals. Acute visceral toxoplasmosis (*Toxoplasma gondii*) was diagnosed in two captive dik-diks (Dubey *et al.* 2002).

Conservation IUCN Category: Least Concern. CITES: Not listed.

Günther's Dik-diks have probably benefited by the ecological changes resulting from overgrazing by domestic stock. Traditionally, no hunting by resident nomadic pastoralists was permitted except by the odd individual, and although these dik-diks are probably subject to some poaching in areas, the current population trend appears to be stable. They are common in several protected areas, including: Omo, Mago, Yabelo and Nechisar National Parks (Ethiopia) and Marsabit, Sibiloi and Meru National Parks and Samburu National Reserve (Kenya) (East 1999). However, the bulk of the total population occurs in unprotected rangelands. If current trends continue, their status is likely to remain secure (East 1999).

Measurements

Madoqua guentheri

TL (♂♂): 588 (500–680) mm, $n = 11$

TL (♀♀): 600, 670 mm, $n = 2$

T (♂♂): 32 (20–50) mm, $n = 7$

T (♀♀): n.d.

HF c.u. (♂♂): 183 (165–205) mm, $n = 6$

HF c.u. (♀♀): 203 mm, $n = 1$

E (♂♂): 72 (60–80) mm, $n = 6$

E (♀♀): n.d.

Sh. ht (♂♂): 324–355 mm, $n = 9$

Sh. ht (♀♀): 355–365 mm, $n = 5$

WT (♂♂): 3.72 (3.5–3.9) kg, $n = 3$

WT (♀♀): 4.5, 4.6 kg, $n = 2$

Throughout geographic range (Kingswood & Kumamoto 1996)

A single adult ♀ found dead on a road (killed by a vehicle) just a few km north of Baragoi, Kenya, had the following measurements: TL: 650 mm; HF: 196 mm; E: 71 mm; Sh. ht: 385 mm; T: 32 mm; WT: 3.2 kg (Y. de Jong & T. Butynski pers. comm.)

Maximum recorded horn length is 10.8 cm for a pair of horns from Kenya (Rowland Ward)

Tribe ANTILOPINI

Gazelline Antelopes

Antilopini Gray, 1821. London Med. Repos. 15: 307.

Tentative phylogenetic tree of Antilopini (modified after Hassanin *et al.* 2012).

The genera of antelopes judged to belong to the tribe Antilopini and distinctions between tribe and subfamily have been the source of considerable confusion right up to the present. In fact, the present picture is probably even more confused than it was in the past. However, a core of ‘gazelline’ species have been consistently recognized as representing the Antilopini. These are the gazelle-like Indian Blackbuck *Antelope cervicapra* and the true gazelles, now subdivided into *Gazella*, *Eudorcas* and *Nanger*, the Dibatag *Ammodorcas clarkei* and the Gerenuk *Litocranius walleri*. It has long been questioned whether the Springbok *Antidorcas marsupialis* belongs to this group (partly because there are very early fossils with antidorcine features). Knottnerus-Meyer (1907) even erected a subfamily, Antidorcatinae, which accommodated the Springbok and some other gazelline antelopes (and see Haltenorth 1963 and Kingdon 1997). Until further research suggests otherwise, we tentatively retain *Antidorcas* as a part of Antilopini. Further, Gentry (1992), Matthee & Robinson (1999a), Groves (2000) and others unequivocally support inclusion of the extralimital Saiga *Saiga tatarica* in the Antilopini; the exact affinities of *Procapra* remain unresolved.

In recent years several authors have substantially enlarged the number of taxa in Antilopini by inserting many of the genera and species formerly clustered under Neotragini (Grubb 1993c, 2005, Hernández Fernández & Vrba 2005). Before molecular science confirmed the long-held suspicion that several of the small antelopes traditionally called ‘neotragines’ were probably living survivors of

root stocks from which more advanced lineages emerged, authors were content to use Neotragini as a convenient ‘waste-paper basket’ to accommodate a diverse collection of conservative and/or specialized small antelopes (Kingdon 1982, 1997). Wholesale allocation of ‘neotragines’ to the Antilopini, *before* their affinities have been convincingly elucidated, effectively transfers a clutch of acknowledged uncertainties from one taxon to another. This course is not followed here.

Instead of emptying problem taxa from one basket to another we have accepted that a proliferation of taxa (even if temporary and tentative) more usefully reflects current efforts to come to grips with the intricacies of antelope evolution, while acknowledging the many uncertainties and current inability of genetics to resolve many important questions. We are confident that molecular techniques will steadily improve to the point where such questions can be convincingly settled. In the meantime, it is important to advertise the challenges that antelope evolution poses and to emphasize the ecological and behavioural bases for their historical radiations.

Because most molecular studies have allocated basal positions to all the taxa formerly classed as Neotragini (Georgiadis *et al.* 1990, Allard *et al.* 1992, Gatesy *et al.* 1997, Hassanin & Douzery 1999, 2003, Matthee & Robinson 1999a) we have therefore excluded them from Antilopini and very provisionally broken up the former Neotragini into five tribes: Neotragini for *Neotragus* and *Nesotragus*, Oreotragini for *Oreotragus*, Raphicerini for *Raphicerus* and *Dorcatragus*, Madoquini for *Madoqua* and Ourebinii for *Ourebia*. Molecular analyses have been consistent in showing that *Pelea*, sometimes included in Neotragini and sometimes the only occupant of its own tribe, is a sister taxon to the Reduncini.

The Antilopini, in the sense proposed here, represents gazelle-like antelopes supposed to have adapted initially to very dry thicket in north-eastern Africa. It has been proposed that at a very early date at least one lineage entered Asia and gave rise to the Saiga. Later emigrations took gazelles and the ancestor of the blackbuck to Asia. As gazelles evolved some became larger and most adapted to open plains and deserts, acquiring exceptional resistance to scarcity of water and to heat stress. Adaptive trends toward dry-and-hot and to dry-and-cold have a strong regional bias, with the former predominantly African and the latter mainly Asian, suggesting that *Gazella* and *Antelope* may have Asian origins while *Nanger* and *Eudorcas* are decisively African.

Antilopines are small- to medium-sized, long-legged, long-necked antelopes with a light-coloured pelage, large eyes and ears, and a small mouth. Females are horned (*Gazella*, *Eudorcas*, *Nanger* and *Antidorcas*) or hornless (*Litocranius* and *Ammodorcas*), although where present they are markedly less developed than in ♂♂. Pedal and preorbital glands are generally present (*Ammodorcas* lacks pedal glands). Glandular knee-tufts are present in all members except *Antidorcas* (which, in turn, has dorsal glands). Inguinal glands are present in the true gazelles only (being absent in *Ammodorcas*, *Litocranius* and *Antidorcas*) as well as in the extralimital *Saiga*; females of *Ammodorcas* and *Litocranius* have two pairs of inguinal nipples (as

does *Saiga*), whereas all other members have one (though *Antidorcas* sometimes has two pairs). While advanced in their tolerance of heat and lack of water (most employ nasal cooling techniques), their land tenure systems, brains, dentition, dietary habits and stomachs tend to be conservative. The trend towards longer limbs and necks has been taken to extremes in *Litocranius* and *Ammodorcas*, greatly enlarging their vertical feeding zones.

This is one of the few groups of antelopes (other than caprines) that have been consistently successful outside Africa, notably in Arabia and the more arid regions of Asia. The major factors influencing their success must lie in their tolerance of heat, their ability to extract adequate moisture from their diet, and their speed and wariness. Upper limits on body-size are principally determined by their reliance on protein-rich diets.

Jonathan Kingdon

Thomson's Gazelle *Eudorcas thomsonii*.

GENUS *Gazella* Slender Gazelles

Gazella de Blainville, 1816. Bull. Sci. Soc. Philom. Paris 1816: 75.

This genus formerly embraced all the gazelle-like antelopes, except for the Springbok *Antidorcas marsupialis*, Gerenuk *Litocranius walleri* and Dibatag *Ammodorcas clarkei*, and the Indian Blackbuck *Antelope*. Because the genetic profiles of the last species have been shown to nest within the diverse forms of the genus *Gazella* (in the former, more inclusive concept of that genus) (Effron *et al.* 1976), the more distantly related *rufifrons*- and *granti*-groups were formally removed from *Gazella* by Groves (2000), and placed in separate genera, *Eudorcas* and *Nanger* respectively, thereby leaving *Gazella* as a monophyletic genus. Grubb (2005) recognized ten species, four of which occur in Africa: Slender-horned Gazelle *Gazella leptoceros*, Cuvier's Gazelle *G. cuvieri*, Speke's Gazelle *G. spekei* and Dorcas Gazelle *G. dorcas*.

The horn cores are less compressed than in related genera, and the rings are comparatively less marked. In the teeth, the lingual stylids and anterior folds of the molars are well developed. Unlike the related

genera, the nasofrontal sutures are straight, forming together either a V-shaped wedge into the frontals, or a mild arch. Characteristic of the genus is the noticeably long and narrow basioccipital, with only small anterior and posterior tuberosities with a wide, smooth space between them rather than a narrow channel. The auditory bullae are greatly enlarged, as expected in arid zone animals. The rhinarium extends all along the dorsal rims of the nostrils.

Most members of the genus are unambiguously arid-adapted, and are noticeably pale in colouration, usually pale fawn, with any trace of flank stripe being only somewhat darker than the overall body tone, and rarely black; the facial markings however may be quite well expressed. In Africa, the distribution is centred around the Sahara and in the northern part of the Somali Arid zone or Horn of Africa.

Colin Groves

Gazella dorcas DORCAS GAZELLE

Fr. Gazelle dorcas; Ger. Dorkasgazelle

Gazella dorcas (Linnaeus, 1758). Syst. Nat., 10th edn, 1: 69. 'Habitat in Africa'; restricted to Lower Egypt by Blaine (1913: 292), west of the Nile R. (Osborn & Helmy 1980: 508).

LEFT: Dorcas Gazelle *Gazella dorcas*.ABOVE: Lateral view of skull of Dorcas Gazelle *Gazella dorcas*.

Taxonomy Polytypic. Six subspecies are generally recognized (Groves 1981b, 1985a, Yom-Tov *et al.* 1995, Grubb 2005), with the extinct Saudi Gazelle *G. saudiya* once considered a subspecies, but now regarded as distinct (Groves 1988, Rebholz *et al.* 1991, Grubb 2005; and see Hammond *et al.* 2001). The Indian Gazelle or Chinkara *Gazella bennetti* was also formerly included as a subspecies of *G. dorcas* (Groves 1969, Corbet 1978), but is also now considered distinct (Furley *et al.* 1988, Groves 1988, Grubb 2005), as supported by genetic evidence showing *G. bennetti* grouping in a clade with the Goitered Gazelle *G. subgutturosa*, Slender-horned Gazelle *G. leptoceros* and Cuvier's Gazelle *G. cuvieri* (Hammond *et al.* 2001, R. Hammond pers. comm.). In previous classifications, Lange (1972) and Gentry (1972) retained the forms *littoralis* and *neglecta* as separate subspecies of *G. dorcas*, while Groves (1981b) considered *neglecta* as a synonym of *osiris* and included *littoralis* in *G. d. isabella*; Alados (1986/87) included *osiris* in *G. d. dorcas*. However, one recent phylogeographic analysis, involving only mitochondrial DNA, found no evidence for any clear-cut geographic pattern of genetic structure and sheds doubt on the

validity of any proposed subspecies (Lerp *et al.* 2011). The treatment presented here provisionally follows Grubb (2005), pending the availability of studies involving nuclear markers. *Gazella d. pelzelni* has sometimes been considered a separate species (Haltenorth 1963), a viewpoint that was contested by Gentry (1972) and Groves (1985b); the form remains of uncertain taxonomic status (Lerp *et al.* 2011). Synonyms: *beccarii*, *cabrerae*, *corinna*, *isabella*, *isidis*, *kevella*, *littoralis*, *maculata*, *massaesyra*, *neglecta*, *osiris*, *pelzelni*, *rueppelli*, *sundevalli*. Chromosome number: $2n = 31$ in ♂, $2n = 30$ in ♀; the karyotype has an X-chromosome translocation; all autosomes are metacentric, but the Y is a small acrocentric (Effron *et al.* 1976).

Description A small gazelle, pale sandy-fawn in colour with paler sandy stripes on the flanks bordered underneath by a dark-brown stripe that extends to the hindquarter and there merges with the white belly. The dark brown varies in expression, being sometimes distinct and sometimes faint and grading into the paler zone. The dark stripe is darker in winter and fades in summer (Groves 1981b). The forehead

is darker and bristles surround the mouth. There is a tawny stripe on the cheeks, starting from the preorbital gland and ending above the mouth, separated by a white band from the base of the horn to the upper lip. Eyes large, with white circumocular rings. Tawny colour darker above the base of the tail and there is a black, hairless patch on the buttock just beneath the tail. Anus forms a horizontal bar beneath the tail in ♂♂; perineum includes the vulva and appears as a wide 'T' in ♀♀. Upper buttock white with dark, tawny stripes on periphery. Tuft of hair on hock of hindleg and at the end of tail. Horns in ♂ are medium-sized, lyrate and strongly ringed (20–24 rings); in ♀ horns are thin, and weakly ringed (usually 16–18 rings).

Geographic Variation

- G. d. pelzelni* (Pelzel's Gazelle): N Somalia (northern coastal plain of districts of Awdal, Ouest Galbeed and Ouest Sanaag), below 1000 m in Djibouti and Eritrea, and Ethiopia (Afar, Harar, Tigray and Wollo). Distinct large-bodied, long-necked race. Long horns with tips hardly or not at all turned inwards, widely flared, and sparsely ringed; colour brightly sandy-ochre with well-marked lateral flank band and dark face stripes, dark knee-tuft and a trace of dark nose-spot.
- G. d. isabella* (includes *isidis* and *littoralis*) (Isabelline Gazelle): east of the Nile R., in N Ethiopia and Eritrea, Sudan (including the Red Sea Hills, Mohamed Gol range, Atra Rabai Hills, Khorasot, Berha, Suakin, Khor Hadhad, Jebel Bawati), extending into Egypt and S Israel; perhaps Gaza; probably SW Jordan. A large race, darker and less lively coloured than *pelzelni*; brown-grey with reddish tones and dark markings, including the dark nose-spot; horns shorter, stouter, more widely spread than *pelzelni* with inwardly turned tips.
- G. d. beccarii*: Baraka and Bogos, in the highlands of the upper Anseba R., Eritrea. Richer, more chestnut coloured than *G. d. isabella*; flank-band is red-brown; nose-spot absent; very large skull and nasals are long.
- G. d. osiris* (includes *neglecta*): Sudan (Nakheila, Dongola, Sennaar, Singa, Omdurman, Abu Hamed Bapr, Kassala, Shendy, between Aswan and Khartoum, Kordofan, El Fasher, El Baja), west into Chad, Niger, Burkina Faso, Mali, Mauritania (between Rosso and Nouakchott), Western Sahara (Rio de Oro, Rio de Oro–Mauritania border, loom radius of Villa Cisneros, Peninsula of Dakhla), Morocco (Lower Drâa R.) and Algeria (Hoggar, Tadmeit). Much paler than the previous three subspecies; dark band not well marked, though pygal band more so; face markings paler, with light face stripes pure white; no nose-spot; skull small; horns longer, more narrowly ringed in ♂ and relatively longer in ♀.
- G. d. massaesyla* (includes *cabrerai*): Algeria (between Constantine and Biskra, Biskra, Weinat el Aries, Bled Salawin, Medjedj, Chott el Honda, between Ain Tabia and Messegem) and the Rif Plateau of Morocco. Richer, more ochre-coloured than *osiris*; skull narrow across the horn-base; horns lyrate and more widespread, tips less inwardly turned than in *osiris*. A small distinct population occurs in M'Sabih Talaa (Sidi Chiker) Reserve (middle Atlantic Morocco) (Alados 1986/87, Godinho *et al.* 2012).
- G. d. dorcas*: Egypt (Western Desert including Aswan), Sudan (Wadi Halfa), Libya, Tunisia, Chad (Tibesti). Brighter, less ochre and more rich-fawn than *massaesyla*; flank-band well marked and well expressed; pygal band clearer; lateral face-stripes dark; skull short-snouted and broad; horns long in both sexes, lyrate in ♂ with numerous close rings.

Similar Species

Gazella leptoceros. Sympatric. Slightly larger, with more elongated upright horns; paler-coloured and almost without head marks (Dragesco-Joffé 1993).

Eudorcas tilonura. Sympatric with the Isabelline Gazelle *G. d. isabella*. Larger, with a straight back when standing; forehead and bridge of the nose are rufous; horns very short, inwardly hooked at the tips and prominently ringed in ♂♂; deep reddish band on flanks, extending from the shoulder to the hindquarters; tail relatively long, its base rufous and gradually changing to black.

E. rufifrons. Sympatric with *G. d. osiris*. Larger, with more robust build. Deep reddish in colour with a uniformly tan-coloured upper coat; forehead red; faint red and cream-coloured lines run from the eyes to the nose; horns fairly long, slightly S-shaped over their length and diverging towards the tips; flanks with thin dark-brown stripe, which runs along the side between the legs, demarcating the edge of the white underparts; tail relatively long, ending in a black tuft that contrasts sharply with the white buttock.

Distribution The most widely distributed Sahelo-Saharan antelope, Dorcas Gazelles are also the only African gazelle species to occur outside of the continent, their range extending into the Sinai, S Israel and W Jordan (Mallon & Kingswood 2001a); may also persist in S Syria (Masseti 2004).

Historical Distribution Dorcas Gazelles once ranged widely from Morocco, Western Sahara, Mauritania and Senegal (as vagrants during droughts only; Bourlière *et al.* 1976) in the west, throughout the Sahelo-Saharan region to the Red Sea and the Afar region in Eritrea–Ethiopia west of longitude 50°E (see East 1999, Mallon & Kingswood 2001a, Lafontaine *et al.* 2005).

Current Distribution Populations have been massively reduced north of latitude ca. 31° 14' N and disjunct populations extend southwards to latitude ca. 13° 30' N. In Morocco, only one group remains north-west of the Atlas in the M'Sabih Talaa Reserve (near Chichaoua) (Cuzin 1996), whereas east and south of the Atlas small groups are widely scattered throughout the Moulouya River Valley; along the Moroccan–Algerian border; on the plains between Zagora and Tafilalet, and throughout the Oued Drâa Valley; small groups survive in Western Sahara, particularly in the south in the Adrar Soutouf (Cuzin 1996, 2003, Aulagnier *et al.* 2001).

The species' distribution in the other northern range states remains poorly known and scattered. In Algeria, where its current range still includes much of the Algerian Sahara, the northern limit is now generally marked by the Saharan Atlas, although a few Dorcas Gazelles are reported to survive on the Hauts Plateaux near the border with Morocco (Kowalski & Rzebiak-Kowalska 1991, De Smet & Smith 2001). In Tunisia, Dorcas Gazelles had largely disappeared from the northern part of the country by the 1960s, and today are limited to the southern half of the country, south of a line running from Tamerzna, at the Algerian border, eastward to Gafsa and Maknassy, southward to Matmata, and south-eastward to Medenine and Ben Gardane, near the Libyan border (Kacem *et al.* 1994, Smith *et al.* 2001). There is limited information on their current distribution and status in Libya, where Misonne (1977) reported them as quite common in the south-east in 1968–69 (estimating

more than 100 in the Jabal Uweinat region, with a further 30–40 in Wadi Ghazal) and where Essghaier (1980) reported on herds of up to 100 Dorcas Gazelles seen in the 1960s in the Hamada al Hamra in W Libya. They are now extirpated in many areas, but are probably still the most widespread antelope in the country (Khattabi & Mallon 2001). In Egypt, they are still found in highly fragmented populations scattered throughout the Western Desert. In the north they occur in the western Qattara Depression, westwards to the Libyan border (including around the Siwa oasis). Small populations are found in the depressions west of L. Nassir, and in uninhabited oases of the Nubian Desert and in wadis of the Gilf El Kebir Plateau. Dorcas Gazelles are found in small numbers in the wadis east of the Nile R., with the largest population in the southern part of the Eastern Desert towards the Sudan border (Saleh 1987, 2001, Saleh *et al.* 2003, El Alqamy & Baha El Din 2006).

South of the Sahara there is limited information on the status of the species in Mauritania, where it has been largely extirpated and survives only in small numbers in very remote areas (Sournia & Verschuren 1990); a few animals survive in the south-eastern corner of Banc d'Arguin N. P., while a small population of ~40 individuals survives on Tidra, an island situated in the south-west of Banc d'Arguin N. P. (Araújo *et al.* 2005, Lamarque *et al.* 2006). In Senegal, animals were reintroduced from Mauritania to Djoudj N. P. in the north-west (Dupuy 1984), but there is no recent information on this population; they were also reintroduced to enclosures in Guembeul Special Reserve in 2007 (Abáigar *et al.* 2008) and Ferlo-Nord in 2009 (not mapped). In Burkina Faso, where they occurred in the northern Sahel zone, they may survive in the northern part of Sahel Partial Faunal Reserve, while in Nigeria, where they used to occur in the north-east in the vicinity of L. Chad (Anadu & Green 1990), they are now probably extinct. The strongholds for Dorcas Gazelles are North Tamesna in Mali (south-west of the Adrar des Iforas), Termit in E Niger (Newby *et al.* 2004, Wacher *et al.* 2004a, b, 2008), and Manga and the Ouadi Rimé–Ouadi Achim Faunal Reserve in Chad (Monfort *et al.* 2004, Wacher & Newby 2010, Wacher *et al.* 2011). In Sudan, they still occur in the deserts in N Sudan and in the Red Sea Hills. In Djibouti, the Dorcas Gazelle is the most frequently encountered large mammal, occurring throughout the territory (Laurent & Laurent 2002, Heckel & Rayaleh 2008), while in Ethiopia, Eritrea and Somalia they still tend to occur relatively widely within their historical range (East 1999).

Habitat The Dorcas Gazelle occurs in a wide range of habitats. These include steppe-like coastal desert and stony coastal wadi outwash plains, uninhabited oases, (vegetated) wadis, edges of inland sabkhas, small marshes, acacia groves, open acacia woodland and undisturbed margins of rivers with sparse vegetation. Rainfall in the species' range varies from almost nil to 400 mm per annum. Although they occur in coastal plains and desert depressions (Osborn & Helmy 1980), and even the sparsely vegetated areas above 2000 m in Hoggar (Dupuy 1967), they are absent from hyper-arid deserts and upper elevations of the central Saharan massifs (Grettenberger 1987). Dorcas Gazelles are, however, found in vegetated depressions in the hyper-arid interior of the Egyptian Western Desert (Osborn & Helmy 1980, Saleh 1987, 2001).

During the hot season, Dorcas Gazelles concentrate in habitats associated with temporary water resources and river beds where

Gazella dorcas

trees and shrubs provide shade and cover. The gazelles disperse into less woody habitats during the wet and cooler season (Grettenberger & Newby 1990). Seasonal dispersion does not seem to take place in Egypt, where Dorcas Gazelles were frequently observed in areas without surface water throughout the year (M. Saleh pers. comm.). At the southern limit of its range, where the Red-fronted Gazelle *Eudorcas ruffifrons* occurs, the latter is generally found in the more wooded wadi valleys, whereas Dorcas occurs in the more open grasslands. In areas with high hunting pressure Dorcas Gazelles tend to frequent more often those habitats where access is more difficult, such as sand dunes and hills (Cuzin 2003).

Abundance Early reports from the nineteenth and early twentieth centuries generally recorded Dorcas Gazelles as common and locally abundant (e.g. Lavauden 1926a, Joleaud 1929). Despite a massive reduction in numbers and depletion of habitat by humans and their livestock, the Dorcas Gazelle survives, albeit in reduced numbers, in almost all range states, in which it is often the most common gazelle species.

Population numbers in Morocco totalled 200–600 in the mid-1990s, excluding Western Sahara where the population may number in the several hundreds (Cuzin 1996, Aulagnier *et al.* 2001); the current wild population has been estimated at 800–2000 animals (Cuzin *et al.* 2007). There are no recent reliable population estimates for Algeria, Tunisia and Libya, although the population in each country is unlikely to exceed 1000 individuals and only small groups are now encountered. A population of 1000–2000 is in rapid decline in Egypt, mostly outside protected areas (Saleh 2001).

South of the Sahara, numbers of Dorcas Gazelles are more substantial, and East (1999) estimated a total population for sub-Saharan Africa of 35,000–40,000 animals, although actual numbers are almost certainly lower. The strongholds for the species include: Mali, where the population is in the order of 2000–2500 (East 1999); Niger, where Dragesco-Joffé (1993) earlier estimated

the population at 20,000 (though these numbers are pre-1991); and Chad, where they survive in the thousands in the Manga and especially the Ouadi Rimé–Ouadi Achim Faunal Reserve (East 1999, Scholte 2001, Monfort *et al.* 2004, Wacher *et al.* 2004b, Wacher *et al.* 2011). A survey of the Termit Massif estimated the population of Dorcas Gazelles at 3000 gazelles, distributed primarily through the southern parts in association with trees (Wacher *et al.* 2008). Dorcas Gazelles also survive in good numbers in the Horn countries, although reliable population estimates are not available.

In the driest habitats, observed Dorcas Gazelle densities range from 0.1 to 0.6 gazelles/km². Even lower densities were found in habitats in proximity to human settlements: from 0.04 to 0.1/km² (Essghaier 1981, Hashim 2000). In higher-quality habitat, such as is found in large wadis and foothills, observed densities range from 0.31–3.2/km² in Sudan (Essghaier 1981, Hashim 2000), 1.2–7.3/km² in Chad (Monfort *et al.* 2004), and up to 9.6/km² in Morocco (Loggers *et al.* 1992). Encounter rates are reported by various authors, including 0.23/km in the Ahaggar in Algeria (Wacher *et al.* 2005) and 0.83/km in the Termit (Wacher *et al.* 2004b).

Adaptations Unlike camels and antelopes such as Beisa Oryx *Oryx beisa*, the Dorcas Gazelle is not bradymetabolic (i.e. having a low resting metabolism) and its main means of heat dissipation are thermal panting and sweating (Wilson 1989). Some protection is also obtained via the pelage. The coat consists of a short, dense undercoat with a covering of guard hairs up to 35 mm that can be erected to form an insulating barrier (Ghobrial 1970, Wilson 1989).

In Sudan, Dorcas Gazelles with access to free water drank an average of 3.1 and 4.5% per day of their body-weight in winter and summer, respectively (Ghobrial 1970). In winter, 69.1, 4.5 and 26.4% of total water was obtained by free, preformed and metabolic water, respectively. In summer, these percentages were 82.4, 2.4 and 15.2%, respectively (Ghobrial 1974, Wilson 1989). Often, however, there is no surface water available in the Dorcas Gazelles' range, particularly during the dry season. Dorcas Gazelles, as most other desert herbivores, react by reinforcing physiological mechanisms with behavioural ones. They resort to mechanisms of escape (southbound migration into the Sahel) and retreat (shade-seeking at mid-day) to survive (Wilson 1989). Dorcas Gazelles strongly depend on moisture-rich food throughout their range (Grettenberger 1987, Wilson 1989). However, they can survive extreme dehydration: animals maintained under minimal water conditions for 10 days showed a decrease in feed intake by 42%, while body weight was reduced by 29%, water content in faeces by 41% and urine volume by 66%. Serum concentrations of sodium, potassium and chloride increased by 23, 44 and 18%, respectively. The gazelles appeared normal after rehydration (Mohamed *et al.* 1988). Ghobrial (1974) presented lower values in what was probably a less extreme dehydration experiment.

Foraging and Food Under dry conditions Dorcas Gazelles primarily browse because of the high moisture content and availability of browse. Herbaceous plants, including many annual grasses, are the most important components of the diet during the wet season (Grettenberger 1987, Wilson 1989). In Morocco, faecal analysis of an enclosed population north of the High Atlas (M'Sabih Talaâ) indicated the shrub *Ziziphus lotus* as dominant forage in summer, while

forbs dominated forage in autumn. Grasses were only significant in spring when forming 46% of identified items (Loggers 1991). In S Morocco during a dry season, preferred plants were *Maerua crassifolia*, *Acacia raddiana*, *Nitraria retusa*, *Argania spinosa*, *Antirrhinum ramosissimum*, *Salsola sieberi* and *Launea arborescens*, and animals never seemed to drink (Cuzin 1998). Year-round observations (Essghaier 1981, Abdelhamid 1998), showed that ca. 26% of the diet comprised grass, 19% forbs and 55% trees, and especially (dwarf) shrubs. The latter include *Anabasis oropediorum*, *Atriplex mollis*, *Artemisia herba-alba*, *Astragalus armatus*, *Calligonum comosum*, *Helianthemum* spp., *Gymnocarpus decander*, *Leptadenia pyrotechnica*, *Periploca laevigata*, *Rhanterium suaveolens* and *Suaeda* spp. Trees include *Acacia raddiana*, *A. tortilis*, *Balanites aegyptiaca*, *Maerua crassifolia* and *Ziziphus lotus*. In addition to a selection of annual grasses, grasses include: *Aristida uniplumis*, *Cenchrus ciliaris*, *Panicum turgidum*, *Stipagrostis uniplumis* and *Stipa* spp. Forbs represented in the diet include *Chrozophora broechiana*, *Colocynthis vulgaris*, *Erodium* sp., *Lycium arabicum*, *Medicago trunculata*, *Plantago ovata*, *Salvia vermiculata* and *Tribulus* spp. In the Western Desert of Egypt, the diet comprised *Nitraria retusa*, *Calligonum comosum*, *Alhagi maurorum*, *Calligonum comosum*, *Phragmites australis*, *Sporobolus spicatus*, *Acacia raddiana*, *Panicum turgidum* and *Zygophyllum album* (Salem & Saleh 1998).

The Dorcas Gazelle exhibits seasonal movements in response to the availability of forage. In El Baja, Sudan, the movement is southerly during the late dry season and northerly immediately after the beginning of the wet season and lasts often throughout the cold season (Hashim 2000).

Social and Reproductive Behaviour Dorcas Gazelles form groups varying in size, depending on the season and the extent of disturbance. Occasionally, aggregations of several groups can be found, totalling over 100 individuals, most often in areas with sudden ample food resources, as may occur after locally abundant rains (Scholte 2001, Laurent & Laurent 2002, Monfort *et al.* 2004). In heavily poached and disturbed habitats in Sudan, the mean group size was 1.9 ± 0.3 ($n = 21$). The groups were smaller (mean 1.6 ± 0.2 , range 1–3, $n = 14$) during the wet season compared with the dry season (mean 2.4 ± 0.8 , range 1–7, $n = 14$), suggesting pairing up for breeding (Hashim 2000). Pairing for breeding has been reported in hostile conditions, but larger groups are formed in response to disturbance by humans or dogs (Loggers 1992). Mean observed group size of Dorcas Gazelles in Niger was 2.5 ± 81 (range 1–13), varying in four different habitats from 2.2 ± 1.5 ($n = 297$), 2.4 ± 1.3 ($n = 141$), 2.6 ± 1.9 ($n = 133$) and 3.3 ± 2.2 ($n = 46$); these differences in group sizes were attributed to seasonal changes in localized areas as habitat quality changes (Grettenberger 1987). In Feb–Mar 2002, Dorcas group sizes ranged between 2.5 and 3 in three different habitats in Niger (Manga, Termit and Aïr–Ténéré) (Newby *et al.* 2004). In C Chad in September 2001 (the Manga and Ouadi Rimé–Ouadi Achim Faunal Reserve), most frequent group sizes encountered were ones and twos, but mean group size averaged 3.5 (S.D. 4.66, $n = 1145$ groups) with 87% of individuals in groups up to 20 strong and the remainder in scattered assemblages of 50–100 or more (Monfort *et al.* 2004, Wacher *et al.* 2004b). Generally, groups are highly mobile and on many occasions mingle with Red-fronted Gazelles *Eudorcas rufifrons* in the southern parts of the Dorcas Gazelle's distribution.

Females groups consist of adult ♀♀ and their young, juvenile ♀♀ and juvenile ♂♂ less than about 18 months old. These female groups frequent (male) territories and when accompanied by the ♂ their groups average 1.5 young (range 1–5) and 2.5 ♀♀ of reproductive age (range 1–8). Single adult ♀♀ were also often seen (Loggers 1992). Males either live alone, territorially or in bachelor groups of up to ten individuals (Loggers 1992). Temporary associations of ♂♂ and ♀♀ occur when bachelors encounter a female group that is not attended by a territorial ♂; these bachelors attempt to court ♀♀ but are usually unsuccessful.

Adult ♂♂ occupy territories throughout the year, and establish dung heaps throughout territories rather than concentrating them on the peripheries (Essghaier & Johnson 1981, Loggers 1992). Territories are apparently delineated by topographic features such as the tops of ridges and sebkhas (Essghaier & Johnson 1981). A conspicuous display is used in the formation of the faecal heaps: first a ♂ paws at the ground, then stretches the scraped area to urinate and finally crouches with his anus just above the ground to deposit dung heaps. Males periodically scrape old dung from heaps especially during peaks of sexual activities (Essghaier & Johnson 1981).

The ♀ comes into oestrus between the beginning of Nov and the end of Dec (I. Hashim pers. obs.), when she attracts the ♂ by lifting the tail and slightly curving her back. The ♂ sniffs the female's perineum, retracts his lips, lifts the head and stretches his lips. If the ♀ gallops, the ♂ gallops behind her, showing a series of courtship manoeuvres, including licking the face and muzzle of the ♀, nose-forward posture, flehmen, following in a walk, circling with horn clashes, touching the buttocks with the base of the horn, and standing beside the ♀ with the head alongside her neck and belly with an erect penis. Mounting is preceded either by the ♂ tapping the ♀ at the buttock or striking her underside with his foreleg (laufs Schlag). In mounting, the ♂ does not hold the ♀, but rather stands on his hindlegs, holding his forelegs, bending backward from the knee, above the ♀. He then makes a quick pelvic thrust with penetration lasting only a few seconds. After mating, the ♂ almost immediately leaves the ♀ (Essghaier 1981, Sayeid 1999).

Newborn Dorcas Gazelles are well developed, with eyes fully open, and attempt to stand within the first hour of birth. The ♀ eats the afterbirth. Young lie down for three weeks during the day and during the night, with the neck and the head stretched on the ground. They show no tendency to escape when approached by an intruder. Nursing usually takes place away from the delivery place and the neonate suckles only for a very short time, but on several occasions during the day. Mothers induce defecation in nursing young and ingest faeces, probably a means of water conservation and protection (Dragesco-Joffé 1993). The mother produces milk for six months after birth but the neonate starts foraging at 17 days of age (Sayeid 1999).

Reproduction and Population Structure In Niger, births peak in Dec with a ratio of one juvenile to 4.7 adults (Grettenberger 1987). In Morocco, young are born mainly during late Oct and Mar; the ratio of young to adult ♀♀ is 0.91 in Sep and 0.83 in Jan–Feb (Loggers 1992). In Djibouti, births occur in the cold season (Nov–Jan) and the wet season Feb–May (Laurent & Laurent 2002).

Gestation period is about six months (Slaughter 1971, Dittrich 1972). One young is born, rarely two (Furley 1986, Grettenberger

1987, Sayeid 1999). Young weigh about 910 g at birth (Mohamed Nour 1998), and birth-weight is positively correlated with the longevity of the ♀ (Alados & Escos 1991). In captivity, the age of the ♀ at first birth varies from 346 to 929 days (Mentis 1972, Loggers 1992). It has been suggested that sexual maturity and age at first birth follow an allometric pattern among *Gazella* species (Cassinello 2005).

Loggers (1992) reports longevity in the wild at 4.2 years ($n = 12$) for adult ♂♂, 5.4 years ($n = 5$) for adult ♀♀ and nine years for oldest specimens of both sexes; Weigl (2005) gives longevity in captivity as more than 23 years. As a general rule, and as expected in polygynous mammals, ♀♀ live longer than ♂♂, high inbreeding coefficients causing a generalized decrease in female longevity (Cassinello 2005).

Sex ratio in Dorcas Gazelles is skewed (68 ♂♂ : 100 ♀♀), possibly due to the males' vulnerability to predators while holding territories (Grettenberger 1987). Fecundity in captivity ranges from 0 to 2.18 calves per year, being lower in young ♀♀ than middle-aged ♀♀ (Alados & Escos 1991).

It has been suggested that Dorcas Gazelles may experience sperm competition due to their relatively high gonadosomatic index (testes weight/body weight), which might explain its higher sperm quality in comparison with other *Gazella* spp. (Cassinello *et al.* 1998).

Predators, Parasites and Diseases Large predators such as the Cheetah *Acinonyx jubatus* have been mostly exterminated throughout the range of Dorcas Gazelle. Remaining predators are Golden Jackals *Canis aureus*, while young may be taken by smaller predators such as Red Foxes *Vulpes vulpes* and Rüppell's Foxes *Vulpes rueppellii* and large eagles. In populated areas, domestic dogs are important predators.

In Morocco, low levels of nematode ova were reported from six individuals and *Strongyle* ova from one gazelle (Loggers 1992); Hufnagl (1972) reported that gazelles usually harboured stomach and intestinal worms such as *Strongyloides* and *Trichurus*, and the faeces often contained eggs of Anoplocephalidae (cestodes) and *Oxyurus*. Haenichen *et al.* (2002) reported on infection of pregnant gazelles with an unusual form of algae, *Chorella*, which causes the green granulomatous inflammation known as 'Chlorellosis'. In captivity, the presence of nematode eggs in faeces was relatively low in a comparative study with other gazelle species, and not related to individual inbreeding coefficients (Cassinello *et al.* 2001). Diseases such as myocardial infarct and aortic arteriosclerosis are reported by Griner (1983), and Furley & Wardman (1985) recorded necrotic stomatitis in Al Ain Zoo. Dittrich (1970) attributed some deaths in captivity to septicaemia and gastroenteritis. In Egypt, diseases transmitted by domestic herbivores to gazelles are becoming a serious problem (Baha El Din 1998).

Conservation IUCN Category: Vulnerable A2cd. CITES: Appendix III (Tunisia). CMS: Appendix I.

Since the late 1800s, the distribution of Dorcas Gazelles in the northern Sahara has been in decline, and by the mid-1900s Dorcas had largely disappeared from the Atlas Mts and Mediterranean coastal areas (Mallon & Kingswood 2001a, Lafontaine *et al.* 2005). From the 1950s onwards numbers south of the Sahara declined rapidly as well (East 1999). Motorized hunting has had a major impact on populations aggravated by drought, as well as habitat loss and degradation due to expanding agriculture and overgrazing by sheep and goats. In N Niger only 0.3% of Dorcas Gazelle observations

were made in the vicinity of nomads, 0.6% with goats, 1.9% with donkeys and 10.9% with camels (Grettenberger 1987). On the other hand, Dorcas Gazelles survive in El Baja, Sudan, amongst large herds of sheep and camels that intensively utilize the area during the dry season, but they avoid close contact with humans and livestock (Hashim 2000). Competition with livestock and capture of young for the pet trade are said to be the main threats to the survival of Pelzeln's Gazelle in Djibouti (Laurent & Laurent 2002). In addition to persecution by local communities and militia, there have been reports of massive slaughters by visiting Arab hunting 'parties' in parts of Africa, including the Sahel (Cloudsley-Thompson 1992), Egypt (Saleh 1987, 2001) and Morocco (Cuzin 2003).

Dorcas Gazelles still occur, in much reduced numbers, in all range states (Lafontaine *et al.* 2005). Even in areas under severe pressure, such as in the coastal plain of N Somalia, tens of Pelzeln's Gazelles were observed close to the expanding cities of Berbeira and Bosaaso (Laurent & Laurent 2002). Relatively large numbers were observed in central grasslands of Oudi Rimé–Ouadi Achim Faunal Reserve in Chad in 2001, when more than 4000 were counted over 20 days, with groups of 70–100 animals seen in some places (Monfort *et al.* 2004, Wachter *et al.* 2004b; and see Wachter *et al.* 2011). The survival of Dorcas Gazelles, relative to some other congenics, may be explained by their high fecundity rate, and its ability to make seasonal shifts that allow it to exploit localized areas with high-quality and moisture-rich forage (Dragesco-Joffé 1993, East 1999).

When protected, Dorcas Gazelle populations recover rapidly, as shown in Djibouti after the 1971 hunting ban (Künzel *et al.* 2000, Laurent & Laurent 2002). In Israel, an annual population growth of 8% was observed during 1964–85 following the implementation of appropriate conservation measures (Yom-Tov *et al.* 1995). Protected areas known to hold important populations of the species include: M'Sabih Talaa Reserve and El Kheng Reserve, established near Tarda (Morocco); Tassili and Ahaggar National Parks (Algeria); Bou-Hedma, Sidi Toui, Dghoumes, Oued Dekouk and Djebil National Parks (Tunisia); New Hisha N. R., Sabratha, and Surman (enclosed) and El-Kouf N. P. (Libya); Elba N. P. (Egypt); Banc d'Arguin N. P. (Mauritania); Ouadi Rimé–Ouadi Achim Faunal Reserve (Chad); and Mille-Sardo Wildlife Reserve (Ethiopia). Numbers in Aïr–Ténéré National Nature Reserve (Niger), a former stronghold, have declined dramatically (J. Newby pers. comm.).

In managed breeding programmes *G. d. osiris* is the best represented subspecies with around 170 captive individuals (T. Abáigar pers. comm.). The limited information available suggests that other subspecies are poorly represented. However, Dorcas Gazelles are believed to be widely present in privately owned, captive collections in the Middle East. Most of these stocks are imported from Egypt, the horn of Africa and Sudan, although in most situations little attention is paid to managing them according to origin. A notable exception are the stocks at Al Wabra in Qatar where separate groups from Egypt, Sudan and the southern Red Sea coast (*G. d. pelzelni*) have been managed with the objective of keeping them separate.

In Morocco, a stock of captive Dorcas Gazelles has been maintained at 100–200 animals for many years at the Royal Hunting Park at Bouznika, from which many have been exported to the zoo community, though comparatively few have survived. There are no records as to the precise origin of this stock. They are believed to be exclusively Moroccan (P. Rousselon pers. comm.), although it

is suspected that they may represent animals from both north and south of the High Atlas (F. Cuzin pers. comm.), in which case they might represent a mix of putative *massaesyia* and *osiris*. Up to 150 of this stock were placed in a high-altitude enclosure at Enjil, in habitat normally occupied by *G. cuvieri*. They have not flourished and only three ♀♀ and some 20+ ♂♂ were present in 2006.

Two important enclosed populations in Morocco are believed to be based on animals of local wild origin from north and south of the major ecological barrier in the region, the High Atlas mountain chain. These populations offer an opportunity to investigate any biological basis for subspecific differences between *massaesyia* and *osiris*. At M'Sabih Talaa near Marrakesh, Dorcas Gazelles from the plains north of the High Atlas (putative *massaesyia*) have been protected since 1952 and fenced for most of that time, numbering more than 250 in 2006 (HEFLCD, Morocco). A smaller group (ca. 30 in 2006) enclosed south of the High Atlas at El Kheng should represent the southern form and should compare directly with the Dorcas Gazelles of southern origin held at Almeria in Spain (and see Godinho *et al.* 2012).

In summary, the species seems to do well in captivity when properly managed. The future conservation of Dorcas Gazelles would greatly benefit from a comprehensive update of its taxonomy over the entire range, more effective protection of the species' remaining populations and strongholds, and well-managed captive-breeding programmes.

Measurements

Gazella dorcas

G. d. dorcas

HB (♂♂): 902 (871–958) mm, n = 8

HB (♀♀): 869 (830–924) mm, n = 6

T (♂♂): 152 (120–180) mm, n = 8

T (♀♀): 138 (120–179) mm, n = 6

E (♂♂): 125 (120–130) mm, n = 8

Dorcas Gazelle *Gazella dorcas*.

E (♀ ♀): 125 (120–129) mm, n = 6
 WT: 15.4 (14.0–18.0) kg, n = 5
 Egypt (Osborn & Helmy 1980)

G. d. osiris

TL (♂ ♂): 938 (910–1000) mm, n = 8
 TL (♀ ♀): 920, 1030 mm, n = 2
 T (♂ ♂): 173 (150–195) mm, n = 9
 T (♀ ♀): 155, 175 mm, n = 2
 E (♂ ♂): 150 (136–170) mm, n = 9
 E (♀ ♀): 155, 160 mm, n = 2
 Sh. ht (♂ ♂): 668 (650–695) mm, n = 9

Sh. ht (♀ ♀): 640, 695 mm, n = 2
 WT (♂ ♂): 15.8 (14.0–17.5) kg, n = 3
 WT (♀ ♀): 13.3, 16 kg, n = 2
 Air, Niger (Brouin 1950)

Maximum recorded horn length is 39.6 cm for a pair of horns (attributable to *G. d. isabella*) from Ethiopia (Rowland Ward)

Gazella spekei SPEKE'S GAZELLE

Fr. Gazelle de Speke; Ger. Spekegazelle

Gazelle spekei Blyth, 1863. Cat. Mamm. Mus. Asiat. Soc., p. 172. 'Somâli-land' (= Somalia).

Speke's Gazelle *Gazella spekei*.

The species is named for Captian John Hanning Speke, who explored the region in 1855 and recorded the existence of this species.

Taxonomy Monotypic (see Gentry 1972, Groves 1985a, 1988). Synonyms: none. Speke's Gazelle has a highly derived karyotype and is closely related to *Gazella dorcas*. Like many of its relatives, Speke's Gazelle carries an X-autosome translocation. As a result, the diploid number is $2n = 32$ for ♀ ♀ and $2n = 33$ for ♂ ♂ (♂ has an XY1Y2 configuration) (Effron *et al.* 1976).

Description A relatively small gazelle, differentiated from other gazelles by the presence of a flabby, corrugated patch of pale grey skin on the muzzle that can be inflated to the size of a human fist when alarmed (a sharp snort is produced when the air is expelled). The light tan face contrasts with a dark cheek band that extends from the eye to the corner of the mouth. Dorsal pelage is light tan, flank band dark brown to black, and ventral pelage white. White buttocks

Lateral view of skull of Speke's Gazelle *Gazella spekei*.

are bordered by a vertical dark stripe. The tail is black. Horns slightly divergent, strongly curved backwards, with tips recurved upwards; ♀ is distinguished by shorter horns, which are thinner, straighter and less deeply annulated than in ♂.

Geographic Variation None recorded.

Similar Species

Gazella dorcas. Pelzeln's Gazelle (*G. d. pelzelni*) occurs sympatrically in coastal N Somalia. Horns lyrate.

Nanger soemmerringi. Observed in mixed herds on the coastal grasslands in Ceel Dhere District, Somalia, in the late 1980s; however, there is no recent information to confirm whether the Soemmerring's Gazelle still occurs in this area. Larger, and lacks a dark flank band.

Distribution Endemic to the Horn of Africa. Inhabits the 20–40 km wide grassland plain that extends along the Indian Ocean coastline of Somalia (hunting has eliminated Speke's Gazelle from coastal grasslands south of 2° 30' N latitude). Northern limit delimited by steep hills of the Gulis Range. Kingdon (1997) noted that the Nugal Valley in north-central Somalia was once considered the centre of its range. Scattered groups of Speke's Gazelles were still rarely encountered in the northern Ogaden in E Ethiopia in the mid-1980s (Hillman 1988a), but relentless hunting was on the verge

Gazella spekei

of eliminating the species from the Ogaden at that time and there is no recent information to indicate that they are still present there (Wilhelmi *et al.* 2006).

Habitat Most common on semi-arid grasslands, but found throughout dwarf shrub (e.g. *Indigofera intricata*) and barren rangelands, at altitudes below 2500 m. The presence of a biting tabanid fly (*Haematopota* sp.) during the mid-growing season prompts movements to the coast or large inland sand dunes where the breeze disperses the flies. They also move to these areas in the late dormant season because the sparse vegetation stays green longer on these sites, possibly because the roots access soil moisture stored deeper in the dunes.

Abundance Speke's Gazelle is one of the most widespread and abundant Somali gazelles (Funaioli & Simonetta 1966), and observations in the 1990s indicate this is still the case (Thurrow 1996, East 1999), although numbers have been reduced in portions of the range as a result of hunting, drought and overgrazing of existing habitat by domestic livestock (East 1999). Densities of Speke's Gazelle have been estimated at 2.0 ind/km² in the eastern Nugal Valley, and 0.2/km² in the central Nugal Valley (East 1999). Thurrow (1996) recorded an average density of about 4/km² on good condition coastal plains grasslands of C Somalia (Ceel Dhere region); occurrence is more scattered and much less dense on dwarf shrub and barren rangelands. Based on this evidence, East (1999) suggests that total numbers are in the tens of thousands.

Adaptations The most striking peculiarity of this species is the inflatable nasal sac. The more obvious functions for this sac include: (1) an auditory signal made by expelling air with a loud snort (this may advertise the callers' whereabouts, as in other gazelle species, but its relative loudness may provide a measure of the size and vigour of the caller); (2) at close quarters it may help disperse scent from the facial glands; (3) a visual signal (when inflated) of the status and

mood of the signaller; and (4) all the above may derive from a nasal mechanism for evaporative cooling as air passes over moist skin inside the nasal cavity.

Foraging and Food Classed as an intermediate browser–grazer by Gagnon & Chew (2000) in their review of dietary preferences of African bovids. *Cyperus chordorrhizus* and *Indigofera intricata* are the most common forage species consumed on the coastal grasslands where they respectively comprised 26% and 18% of the growing season diet, and 15% and 16% of dormant season diet. Other commonly consumed species include *Tephrosia* spp. and the grasses *Sporobolus brockmanii*, *Enneapogon schimperanus* and *Leptothrium senegalense* (Thurrow *et al.* 1995).

Social and Reproductive Behaviour Most of what is known of the ecology of wild Speke's Gazelles comes from the work of Thurrow (1996), on which the discussion that follows is based. Adult ♂♂ generally restrict their movements to a home-range, which may vary in size from about 1.5 to 5 km² and are broadly overlapped by home-ranges of neighbouring ♂♂. The home-range is not defended but represents an area in which a ♂ concentrates his activities. The home-range is marked throughout by dung heaps that average 0.7 m in diameter and several centimetres deep, which appear to function as sources of information about which ♂♂ are in an area rather than as territorial markers.

Adult ♂♂ defend a harem of 1–18 ♀♀ by maintaining a 50–100 m territory around the mobile harem. Thus, while the home-range of the ♂ is not defended, the ♂ attempts to possess the ♀♀ present within his home-range. Adult ♀♀ determine the direction in which the harem moves and the ♂ follows. If the direction of movement takes the harem near the edge of the male's home-range, he attempts to turn them back by blocking their progress with a broadside presentation that forces the harem to alter course. Males not occupying a home-range congregate in bachelor herds numbering up to 40 individuals; these herds reside on poor-condition rangeland.

If an intruding ♂ approaches within 100–200 m of a harem, the defending ♂ positions himself between the harem and the intruder. The defending ♂ stands rigid, staring at the intruder while holding his forelimbs straight and hindlimbs normal and occasionally inflating his nasal sac and snorting. If the intruding ♂ is clearly smaller than the harem ♂, the harem ♂ lowers his head slightly, holding horns perpendicular to the ground, and gallops toward the intruder who usually flees. In cases where the two ♂♂ are closely matched in size, a broadside presentation is made with the two gazelles ending up standing about one metre apart facing opposite directions. While in these broadside positions they engage in head-flagging (i.e. incline their necks sideways in a variety of positions). If neither ♂ leaves the site after head-flagging, they both back away, directly face each other at a distance of several metres, then lower their heads so that the horns are perpendicular to the ground. After lowering their heads several times, both charge and lock horns for several seconds, repeating this process until one leaves the area.

When a predator approaches, Speke's Gazelles stand with straight legs and stare intently, occasionally inflating their nasal sac and snorting. Their tails, which are generally flipped back and forth throughout the day, are flipped at a much more rapid speed when a predator is near. This rapid movement of a black tail across a white rump serves as a visual signal to other gazelles. Other visual signals

include stotting, brief erection of body hair producing a contrasting flash of pelage colour, and perhaps the light grey bulge produced by the inflated nasal sac.

A ♂ investigates the reproductive status of a ♀ by following her with nose extended and the horns laid along its back. Females often respond to this attention by urinating, which prompts flehmen behaviour by the ♂ (i.e. standing with head erect, mouth open and ears back). This interaction apparently gives a signal to the ♂ about the female's reproductive status because after flehmen he either breaks off courtship or continues to pursue the ♀. While pursuing her, the ♂ occasionally delivers stiff leg kicks (*laufschlag*) to the female's hindquarters and emits short cough-like grunts. Males frequently combine these actions with a nose-upward posture. Copulation is preceded by the ♀ responding to sexual pursuit by running in a zig-zag pattern, which then slows to trotting and finally to a slow walk. In the later stage the ♀ walks in a defensive/submissive posture of lowered head with her posterior toward the ♂. During copulation, the ♀ continues walking so the ♂ has to accomplish intromission with a single ejaculatory thrust. He accomplishes this by taking several steps while walking erect on his hindlegs. The front legs normally do not touch the ♀. When copulation is completed, the ♂ immediately loses all apparent interest, but after about an hour the cycle of courtship may be renewed.

Reproduction and Population Structure Breeding is aseasonal and copulations and newborn lambs have been recorded in every month of the year. Sexual activity is bimodal with the peaks coinciding in the mid-growing seasons (i.e. late May and mid-Nov). Peak birthing coincides with the onset of the growing season. Based on information from captivity, Read & Frueh (1980) recorded gestation at 169–190 days, and birth-weights of the single young at 1344–1792 g. Females remain apart from a harem for several weeks after the lamb's birth (Thurow 1996).

The adult sex ratio is about 40% ♂♂ and 60% ♀♀. Eight per cent of the population comprises young less than approximately six months old. The sex ratio distribution is not evenly dispersed across the landscape. In barren areas or grass/shrub ecotones, the ♂ : ♀ ratio is 1 : 1.1, and mean harem size is 2.0 ♀♀; grasslands in good condition have a ratio of 1 : 2.2, and the mean harem size is 4.5 (Thurow 1996).

Predators, Parasites and Diseases Large predators (i.e. large cats, hyaenas and large raptors) have been virtually eliminated throughout the range of Speke's Gazelle, but Common Jackals *Canis aureus* and Black-backed Jackals *Canis mesomelas* prey on young. There is limited information on parasites or diseases, although Iori & Lanfranchi (1996) report on the helminths recorded from Speke's Gazelle, including *Teladorsagia hamata*.

Conservation IUCN Category: Endangered A2cd. CITES: Not listed.

The native ungulate community that historically inhabited the grassland and dwarf shrubland were primarily Speke's Gazelle and the Beisa Oryx *Oryx beisa*. The soft, durable hide of the Beisa Oryx is highly prized by pastoralists, and they have been hunted to extinction through most of the range of Speke's Gazelle. In contrast, Speke's Gazelles are not molested by the pastoralists, who take pride in relying on their livestock to meet their food needs; there is a stigma among

coastal plain pastoralists against hunting Speke's Gazelles (referred to as the devil's livestock). However, in areas of civil conflict (e.g. along the Somalia/Ethiopia border and between clans of N and C Somalia) the influx of armed soldiers has eliminated gazelle populations near the few roads in the region. The spread of this sort of activity over the past several decades is the primary reason for their threatened status. Furthermore, there is increasing evidence of the illegal trade and export (to Gulf countries) of Speke's Gazelles (as well as other Somali antelopes), aided by the introduction of new hunting and trapping techniques and improved transportation methods such as wooden boxes (rarely seen in the 1980s and 1990s) (Amir 2006). The absence of any protected areas or measures means that its conservation status is likely to decline further unless some means of effectively protecting existing populations is developed (East 1999).

The small number of breeding stock present in zoos has resulted in Speke's Gazelle being the subject of captive-breeding programmes designed to simultaneously maintain genetic diversity while reducing the severity of inbreeding depression; both goals appear to have been achieved (Templeton & Read 1998, Templeton 2002).

Measurements

Gazella cuvieri CUVIER'S GAZELLE (ATLAS GAZELLE, EDMI GAZELLE)

Fr. Gazelle de Cuvier (Gazelle de montagne); Ger. Echtgazelle

Gazella cuvieri (Ogilby, 1841). Proc. Zool. Soc. Lond. 1840, p. 35 [1841]. Morocco, Mogador.Cuvier's Gazelle *Gazella cuvieri*.

Taxonomy *Gazella cuvieri* is generally considered a monotypic species (Gentry 1972, Grubb 1993c, 2005). Groves (1969) treated it as a northern representative of the Red-fronted Gazelle *Eudorcas rufifrons*, but later (Groves 1985a, 1988) confirmed its position as a distinct species, though possibly allied to the Goitered Gazelle *G. subgutturosa* and Slender-horned Gazelle *G. leptoceros*. Genetic analyses have indicated that it forms the westernmost representative of a group of mainly twin-producing gazelle species comprising Slender-horned Gazelles, Goitered Gazelles and the Asian Chinkara *G. bennetti* (Hammond *et al.* 2001, R. Hammond pers. comm.). Synonyms: *corinna*, *cineraceus*, *kevella*, *setifensis*, *subkevella*, *vera*. Chromosome number is $2n = 32$ in ♀, and 33 chromosomes in ♂. This is due to a Robertsonian translocation of the X chromosome to an autosome (Kumamoto & Bogart 1984). Vassart *et al.* (1995) delineated the cytogenetic arrangements of gazelle chromosomes, using the caprine banded karyotypes as the presumed ancestral form. These authors found the karyotypes to be similar to that of the Slender-horned Gazelle.

Description A tallish, dark grey-brown gazelle, with broad, lighter and darker brown bands across the flanks, white belly and buttocks, and black tail. Comparatively bulky body, dark brown and greyish tones and upright horns are all useful for identifying the species at long distances. The top of the nose has a prominent dark spot on a brown face. Typical gazelle face-stripe pattern, with pale patches in front of each eye with light and dark bars running from the eye to the corner of the mouth. Ears are pale, long and narrow. Pelage is long and thick. Dark tufts on metatarsals prominent and very dark pygal bands characteristic.

Horns of ♂ are long (25–37 cm), strongly annulated, rising vertically before diverging out and back, with the smooth tips curving in and

Lateral view of skull of Cuvier's Gazelle *Gazella cuvieri*.

forwards (Dupuy 1964, Groves 1985a, 1988). Female horns are shorter, thinner and less heavily annulated, but still characteristically upright on the top of the head.

Geographic Variation None recorded.

Similar Species

Gazella dorcas. Sympatric mainly in N Morocco, though historically there was greater overlap in distribution. Brighter rufous tawny body colour; smaller size; more visible bands across the flanks; usually lacks prominent black spot on the nose; horns shorter, more backswept and typically lyrate in front view. Usually found at lower altitudes, and in less rugged terrain.

Confusion with the Slender-horned Gazelle, which shares similar horn and body shape, but is generally much paler with less robust horns, and usually in sandier lower altitude habitats, may account for the report of a single *G. l. loderi* ♂ shot near Boumia in Morocco in 1954 (Loggers *et al.* 1992) in an area otherwise inhabited only by Cuvier's Gazelle. Ambiguous preliminary genetic results indicating unexpectedly close similarity between samples of *G. cuvieri* and *G. leptoceros* collected in Tunisia (but not between Moroccan *G. cuvieri* and Tunisian *G. leptoceros*), indicate that additional sampling is required to clarify the relationship between these two species (R. Hammond pers. comm.).

Distribution Cuvier's Gazelle is endemic to the mountains of the Maghreb, and historically occupied the Atlas Mts, and neighbouring ranges, in Morocco, Algeria and Tunisia, to the lowlands in W Morocco.

Historical Distribution Formerly reached the Mediterranean and Atlantic coast in certain localities (e.g. Ben Slimane and the Ajou Mts). In Morocco it occupied all the mountain chains (eastern Rif, High Atlas, Middle Atlas and Anti-Atlas, pre-Saharan mountains, Aydar south of the Drâa) and the associated plateaux with the exception of the western Rif (Cabrera 1932, Panouse 1957). In

Algeria it occupied the slopes of the Tellian mountain chains, those of the more southern massif formed by the Saharan Atlas, and the massifs in the eastern part of the country (Joleaud 1929, Heim de Balsac 1936, De Smet 1991). In Tunisia, in the nineteenth century, Cuvier's Gazelle was present throughout the northern half of the country, occurring in all the Tunisian mountains, especially in the high chains of the Ridge in the region of Kasserine, in the northern chains of the Ridge near Ghardimaou, Tunis and Zaghuan, and in the southern pre-Saharan chains around Gafsa and Tamerza (Sclater & Thomas 1899, Kacem *et al.* 1994, Smith *et al.* 2001).

De Beaux (1928) notes the discovery of a Cuvier's Gazelle horn in Al Jaghbub, in the east of Libya, specifying that its source was unknown. It is the only mention of the species for the country. In 1994, six Cuvier's Gazelles were introduced from Tunisia into Kouf N. P. in the north of Libya (K. De Smet pers. comm.).

Current Distribution In Morocco, Cuvier's Gazelle has undergone a marked decline in its distribution range, and today populations are fragmented along the southern side of the eastern Middle Atlas, the southern High Atlas and the Anti-Atlas, extending to the northern Sahara (Aulagnier *et al.* 2001). The range diminished considerably in the first half of the twentieth century; in the 1960s it disappeared from the region of Rabat and Casablanca. The species disappeared from several localities in the Middle Atlas at the same time. In the mid-1980s, the species vanished from the north-east (eastern Rif), and it also disappeared from numerous localities around Agadir in the 1990s (Cuzin 1996). The species has been nearly extirpated from the Jbel Saghro, where it was abundant in 1981 (Cuzin 1996). Recently, this species was discovered on the southern gradient of the eastern Middle Atlas, towards Outat Oulad El Haj and Missouri, as well as on the High Plateaux, slightly further south, until the area of Figuig (Cuzin 1996, 2003, Caron *et al.* 2004). Some small, transient groups were also seen on the southern gradient of the central and eastern High Atlas, from the region of Ouarzazat to that of Rich, reaching an

altitude of 2600 m south of Imilchil (Cuzin 1996). A small population of 12–17 animals survives north of Ouarzazat (F. Cuzin pers. obs.). In the Sahara, a group of three animals was observed south of Fom Zguid in 1994. A larger population was recorded in 1995 in a region situated from the Drâa Wadi, about a hundred kilometres upstream from its mouth, to the last hills north-east of Smara in the Aydar. This confirmed older data (Morales Agacino 1950, Aulagnier & Thévenot 1986) and pushed the southern limit of known distribution about 60 km further south (Cuzin 1996, 2003).

In Algeria, the distribution of Cuvier's Gazelle is limited to the northern part of the country: it is not found either in the north of the Tell Atlas nor south of the Saharan Atlas. The species has only recently disappeared from a few localities and these are mainly in the north of its range of distribution. It was still noted on the Mediterranean coast until about 1930 (Lavauden 1926b, Joleaud 1929, Seurat 1930). The populations of the western Tell Atlas, Batna-Biskra and the Aurès mountains are no longer contiguous, and some groups of the Saharan Atlas were recently eliminated (De Smet & Smith 2001). In the north-west of the country Cuvier's Gazelle is much more widespread than was previously thought. Almost all the large national forests of Aleppo Pines *Pinus halepensis* shelter small populations and there are contact zones between the majority of these populations. It is also relatively common in the hills between Mascara, Relzane, Tiaret and Frenda, living in open countryside with a mosaic of grain crops, vineyards and pasture lands at the top of the hills. In the Saharan Atlas, most of the summits that are higher and less disturbed still harbour small groups of Cuvier's Gazelles, the most important being near Djelfa (Khirredine 1977). The most recent information indicates that some of these populations are growing. The most eastern populations are found in the Aurès, the Némentcha Mts and the hills near the Tunisian border. Near Tebessa there is a concentration of Cuvier's Gazelles, which move to and from Djebel Chambi N. P. in Tunisia.

In Tunisia, the species was still fairly abundant in the 1930s in the entire Tunisian Ridge from the Algerian border to the Djébel Bou Kornine, 17 km south of Tunis (Kacem *et al.* 1994), but numbers declined steeply due to overhunting and the events of World War II. The species no longer survived in the 1970s except in the vicinity of the Djebel Chambi and Khchem El Kelb between Kasserine and the Algerian border (Kacem *et al.* 1994). However, the population currently seems to be increasing, essentially as a consequence of efficient conservation measures implemented in and around Djebel Chambi N. P. (Kacem *et al.* 1994). Observations made in 1991, in the region of Siliana, indicate that the species is spreading towards the north-east in the Ridge, mainly from the principal population core in the surroundings of Djebel Chambi N. P. Kacem *et al.* (1994) listed the species from 13 hunting reserves and massifs, covering an area of around 720 km².

Habitat Cuvier's Gazelle is associated with the middle and low slopes of the folds in the Maghreb, occupying the relatively dry, and now increasingly open, forests of semi-arid Mediterranean type that are dominated by *Pinus halepensis*, *Juniperus phoenicea*, *Tetraclinis articulata* scrub, *Cedrus atlantica*, *Quercus ilex*, *Q. coccifera*, *Argania spinosa* and *Olea europaea*. These areas are characterized by an undergrowth of maquis or garrigue, which can be relatively thick or relatively open, and that often includes *Rosmarinus* spp., *Phyllirea*

angustifolia and *Globularia alypum* (Sclater & Thomas 1899, De Smet 1989, 1991, Loggers *et al.* 1992, Karem *et al.* 1993, Kacem *et al.* 1994, Cuzin 2003, Beudels-Jamar *et al.* 2005b). The Mediterranean forests were formerly much more widespread, steppes of *Stipa tenacissima* representing the first stage of substitution and which themselves have greatly regressed. Cuvier's Gazelles are frequently found in association with these steppes (De Smet 1991, Karem *et al.* 1993). In such dry areas the availability of complementary and richer pastures (for example, with *Cynodon dactylon*) seems to be important (F. Cuzin pers. obs.). In summer, Cuvier's Gazelle may be found in high-altitude habitats, with low sclerophyllous bushes, such as *Artemisia negrei*, *Alyssum spinosum*, *Bupleurum spinosum* and locally scattered trees such as *Juniperus thurifera* and isolated patches of dense herbaceous vegetation (F. Cuzin pers. obs.). In the south-western part of its distribution, in the northern Sahara, Cuvier's Gazelle occurs in areas where it is associated with *Argania spinosa*, spiny *Euphorbia* and *Acacia* spp. (Aulagnier *et al.* 2001, Cuzin 2003). In Algeria, their habitat also includes desert hamadas near Bechar and open oak forests (a mixture of *Quercus suber* and *Q. ilex*) in the Mascara region (De Smet & Smith 2001, Beudels-Jamar *et al.* 2005b).

Cuvier's Gazelles have been recorded from sea level up to 3300 m altitude (F. Cuzin pers. obs.), and although found mainly in hills and small mountains, animals are able to live on very steep slopes (up to 45 degrees) (Cuzin 2003). They avoid heavy snow-cover areas, where they may be present only in summer (Cuzin 2003).

Abundance Historically, Cuvier's Gazelle was reputed to be common and locally abundant (e.g. Heim de Balsac 1936). Cabrera (1932) mentioned it as particularly numerous in the central part of the Middle Atlas, the territories of Beni Mguild and Ait Aiach, and the length of the contact line between this chain and the High Atlas. Carpentier (1932) notes that it was formerly abundant in the Zaïan district near Sidi Lamine and Khenifra (C Morocco).

The total population of Cuvier's Gazelles currently is estimated in the region of 1750–2950 individuals. In Morocco, the population is estimated at between 900 and 2000 individuals, including a population of several hundred individuals recently rediscovered in the lower Drâa (Cuzin 1996, 2003, Aulagnier *et al.* 2001, Cuzin *et al.* 2007). The main populations are in the western Anti-Atlas (where the population is increasing) and in the Lower Drâa–Aydar area (where the population is decreasing), and in SE Morocco (including the southern slopes of the Middle Atlas, High Plateaux and Saharan Atlas). Small groups are spread on the southern slopes of the High Atlas, in the eastern High Atlas, in the central Anti-Atlas and in the western part of the High Atlas (north and east of Agadir) (Cuzin 1996, 2003).

In Algeria, a study of the distribution and numbers of the species carried out at the end of the 1980s estimated the population at 445 individuals (Sellami *et al.* 1990); based on field observations made in 1987, De Smet (1989) estimated the population to be between 400 and 500 individuals. In 1991, his estimate was revised to 560 individuals, with 235 in the Tell Atlas, 140 in the Saharan Atlas, 135 in the east and 50 in the central group of Mergueb N. R. (De Smet 1991).

In Tunisia, the number of Cuvier's Gazelles is not known with precision, but probably numbers less than 500 (Smith *et al.* 2001). The main population in the region of Djebel Chambi N. P. was estimated at 300 individuals in the early 1990s (Kacem *et al.* 1994),

and the total population is likely a little higher. A few individuals were reintroduced from Almeria (Spain) to Boukornine N. P. in Tunisia in the 1990s (Abáigar *et al.* 2005).

Adaptations Extrapolating from their distribution and biogeographic history, Cuvier's Gazelles are likely to possess physiological adaptations to cold and to rough terrain, but no studies have been made.

Foraging and Food Cuvier's Gazelle is a mixed feeder, taking herbs, shrubs and grasses. In Tunisia, it feeds mainly on grasses, acorns of *Quercus ilex* and young leaves of legumes (Smith *et al.* 2001), while in Morocco preferred plant species during the dry season include: *Chrysopogon aucheri*, *Nitraria retusa*, *Argania spinosa*, *Maerua crassifolia*, *Rhus tripartitum*, *Launea arborescens*, *Asparagus pastorianus*, *Periploca laevigata*, *Caylusea hexagyna*, *Acacia raddiana* and *Lavandula stricta* (Cuzin 1998). In E Morocco, Cuvier's Gazelles have been observed feeding on *Olea silvestris*, *Periploca laevigata*, *Teucrium polium*, *Salsola vermiculata*, *Stipa parviflora*, *Cynodon dactylon*, *Plantago* sp. and young shoots of *Nerium oleander* (a reputedly toxic plant) (F. Cuzin pers. obs.). It can utilize water from plants as well as dew, but, in areas with no dew, it needs to drink frequently. Normally, animals spend the day in the hills, descending to the valleys to feed at night or in the early morning.

Social and Reproductive Behaviour Cuvier's Gazelle generally occurs in small groups of three to five individuals, rarely more than eight, but occasionally as large as 20 (Pease 1896, Lavauden 1920). Joleaud (1929) mentions erratic movements and a somewhat nomadic life. On the southern slopes of the High Atlas, animals moved to higher altitudes (up to 2600 m) in summer, but were absent in winter (Cuzin 2003).

Reproduction and Population Structure Middle-aged ♀♀ can produce two litters in one year when food and water resources are available (Alados & Escos 1991). In captivity, mating occurs in early winter, with births occurring in spring (Apr–May) and secondarily in autumn (Oct–Nov) (Olmedo *et al.* 1985, Abáigar & Cano 2005). Calving also has been observed in the fall in Mergued reserve, Algeria (K. De Smet pers. comm.). The gestation period is between 161 and 180 days (Furley 1986, Olmedo *et al.* 1985, Abáigar & Cano 2005).

There is usually a single offspring, but in captivity twinning is frequent (40%) (Olmedo *et al.* 1985, Abáigar & Cano 2005); twins were of the same sex in 69% of litters and were thus (statistically) considered to be dizygotic. The high frequency of twin births observed in this species is in keeping with its known genetic relationship to other twin-producing species (Slender-horned Gazelles, and all forms of Goitered Gazelles), but is otherwise unusual in view of the rarity of twins in other *Gazella* species (Furley 1986). Longevity in captivity has been recorded at nearly 18 years (Weigl 2005).

Predators, Parasites and Diseases Golden Jackals *Canis aureus*, Caracals *Caracal caracal* and Golden Eagles *Aquila chrysaetos* reportedly prey upon Cuvier's Gazelle, primarily calves (Loggers, in De Smet 1989, Sellami *et al.* 1990). Toxoplasmosis has been reported by Stiglmair-Herb (1987), and a variety of helminths were found in captive animals in Spain (Ortiz *et al.* 2001).

Conservation IUCN Category: Endangered C2a(i). CITES: Appendix I. CMS: Appendix I.

Cuvier's Gazelle has declined over its entire range owing mainly to increases in human pressure, particularly hunting, and the transformation of forested zones into cropland and pastures for livestock (and also for charcoal) (Cuzin 2003, Beudels-Jamar *et al.* 2005b). Predation by dogs, on young gazelles at least, is also a threat, and foiled an attempt to introduce Cuvier's Gazelle into Souss-Massa N. P., south of Agadir in Morocco (Loggers *et al.* 1992).

In Morocco hunting was banned in 1985, but this came too late for some populations and did not, in any case, prevent declines experienced in other populations. For instance, the species seems to have been extinct in the north-east since 1985, and was greatly reduced in the Ida massif or Tanane, north of Agadir, where the species seems to have disappeared in 1993 following a local drought of several years. However, recent discoveries of new populations have been made, and the range of the species has even expanded southwards somewhat.

The state of conservation of the species in Algeria was detailed by De Smet (1989, 1991) and De Smet & Smith (2001). The species was officially legally protected in Algeria in 1975, although poaching continued and it is only through increased protection in reserves that numbers have been able to increase.

The distribution range and population numbers had decreased considerably in Tunisia until the 1970s, before the Forest Office took appropriate conservation measures. In 1975, a 300 ha protected area was established at Mt Keche, and in 1980 Djebel Chambi N. P. was gazetted primarily for this species. Such measures to protect the species, combined with other important measures of habitat management for Cuvier's Gazelle, have enabled the Tunisian Forest Office to greatly improve the state of conservation of this species; the objectives of the Tunisian programme aim to naturally recolonize its historical range.

Important protected areas across the range include Outat el Haj in Morocco (containing remnants of a larger group of 40-plus animals caught from a local wild population that persists in the area; T. Wachter pers. comm.), Saharan Atlas N. P., Belezma N. P. and Mergueb N. R. in Algeria, and Djebel Chambi N. P. in Tunisia. Mallon & Kingswood (2001b) highlighted Djebel Chambi as of extreme importance as it holds the largest population in Tunisia and is important for the recolonization of the historical range. These authors also called for stringent protection from hunting for all

populations in Morocco and Algeria, and the establishment of a number of new protected areas that had been proposed in Morocco (including Western Sahara) and Algeria. A captive population, originating from animals in Western Sahara, is maintained in Almeria, Spain (Abáigar & Cano 2005). Cuvier's Gazelle also has been re-introduced in Djebel BouKornine N. P. in Tunisia, with individuals originating from the Almeria station in Spain (Abáigar *et al.* 2005).

Elucidating the taxonomic and ecological relationship between *G. cuvieri* and *G. leptoceros* is a priority for North African gazelle conservation.

Measurements

Gazella cuvieri

TL: 1050–1160 mm

T: 190–210 mm

E: 170 mm

Sh ht: up to 680 mm

WT (♂♂): 20–35 kg

WT (♀♀): 15–20 kg

Throughout geographic range (Beudels-Jamar, Lafontaine *et al.* 2005)

Maximum recorded horn length is 38.1 cm for a pair of horns from Midelt, Morocco (Rowland Ward)

Key References Abáigar & Cano 2005; Beudels-Jamar *et al.* 2005b; Cuzin 1996, 2003; De Smet 1989, 1991; Mallon & Kingswood 2001a (and chapters therein).

Roseline C. Beudels, Pierre Devillers & Fabrice Cuzin

Cuvier's Gazelle *Gazella cuvieri*.

Gazella leptoceros SLENDER-HORNED GAZELLE (RHIM GAZELLE, LODER'S GAZELLE)

Fr. Gazelle leptocère (Gazelle leptocère, Gazelle blanche, Gazelle à longues cornes); Ger. Dünengazelle

Gazella leptoceros (F. Cuvier, 1842). In: E. Geoffroy & F. Cuvier, Hist. Nat. Mammifères, pt. 4, 7 (72): 1–2, pls 473, 474, 'Antilope aux longues cornes'. 'rapportés du Sennaar [=Sudan, Sennar] par M. Burton'; corrected to 'desert between Giza and Wadi Natron, lower Egypt, as the type-specimen was brought to Paris by James Burton, circa 1833' (Flower 1932: 438).

Taxonomy *Gazella leptoceros* has been included along with the Goitered Gazelle *G. subgutturosa* in the subgenus *Trachelocele* (Groves 1988). The species comprises two subspecies, which seem geographically isolated and ecologically distinct, although Gentry (1972) thought they may not warrant subspecies recognition. Subspecific differentiation was made at an early stage in the discovery of the species by western

science and has always rested on very few specimens. It requires verification with modern techniques since knowledge of the species' habitat preference and wide-ranging ecology, combined with results of genetic studies of its close relative, the Arabian Sand Gazelle *G. s. marica*, both suggest that genetic partitioning would be slow to form in this nomadic desert-adapted species (T. Wachter pers. comm.).

LEFT: Slender-horned Gazelle *Gazella leptoceros*.ABOVE: Lateral view of skull of Slender-horned Gazelle *Gazella leptoceros*.*Gazella leptoceros*

Synonyms: *abuharab*, *cuvieri*, *loderi*. Slender-horned Gazelles have a translocation of the X chromosome to an autosome (Effron *et al.* 1976), which results in ♂♂ having $2n = 33$ and ♀♀ only $2n = 32$ (and see Vassart *et al.* 1995).

Description A medium-sized gazelle, of a very pale yellowish-beige to grey-brown body colour separated from the white belly by a faintly marked flank band. Face markings similarly poorly defined. Ears are long and narrow. Outer hooves are broader than inner ones, which facilitates movements on sand. Tail short, terminated by a tuft of blackish-brown hair (Groves 1988). Horns are long and nearly straight (appreciably thicker and longer in ♂), with 20–25 well-defined rings.

Geographic Variation

G. l. leptoceros: Western Desert of lower Egypt and NE Libya. Smaller, longer horned (33.7 ± 2.8 cm, $n = 6$; Groves 1969).

G. l. loderi: W and C Sahara. Reported to be larger, but shorter-horned (29.8 ± 1.6 cm, $n = 6$; Groves 1969).

Similar Species

Gazella dorcas. Sympatric in its entire distribution on the margins of ergs. Reddish colouration; smaller size; horns lyrate and curved.

Distribution Endemic to Africa, where confined to the sand dune regions of the Sahara, west of the Nile R.

Historical Distribution The nominate subspecies *Gazella l. leptoceros* formerly occurred in the northern part of the Western Desert in Egypt, south of the Mediterranean coastal belt, where it seems linked especially to the great oases, characteristic of this desert, and to the interdunal valleys populated with *Acacia* spp. (Flower 1932, Osborn & Helmy 1980, Goodman *et al.* 1986, Le Houérou 1986, Zahran & Willis 1992, Saleh 1987, 2001). It is, or was, noted in Siwa in the north-west, the Quattara Depression, Wadi Natroun and Wadi el Ruwayan near the lower Nile, in the Nile Valley, in dune fields between Faiyum and the Quattara depression (Osborn & Helmy 1980), in Bahariya (Saleh 1987) and in Kharga (Elbadry 1998). It has also been found in the same chain of oases beyond the Libyan border in the surroundings of the Jaghbug oasis (Bundy 1976, Essghaier

1980, Goodman *et al.* 1986), where small groups of 10–20 were observed. The Slender-horned Gazelles noted more to the west in Libya, in particular near Ajdabiyah in western Cyrenaica and near Dahra, north of Zella (NC Libya) (Hufnagl 1972, Essghaier 1980), probably also belong to this form.

The subspecies *G. l. loderi* is believed to have had a wide Saharan distribution, although there are few historical data for this taxon.

Current Distribution The nominate subspecies *G. l. leptoceros* has been eliminated from the greater part of its range in the Egyptian Western Desert. In the 1980s, the species was considered extinct in five of its six known localities in the eastern part of the Western Desert and very rare in the sixth, the complex of the Wadi el Ruwayan and its extension, the Wadi Muweilih; in the western part of the desert, around the Quattara depression and the Siwa oasis, its status was uncertain (Saleh 1987). A small group of about 15 animals that survived in the Wadi el Ruwayan has since been exterminated (Saleh 2001). However, small groups (2–6) of Slender-horned Gazelles were observed and photographed west of the Siwa oasis in 1998 (T. J. Wachter pers. comm.), although the situation has become uncertain since reports of more than 20 being killed by a single hunting party in that region in 2005. Small numbers may persist in other parts of the Quattara Depression, the Jaghbub oasis, the Farafra oasis, and the Kharga (Saleh 2001, Devillers *et al.* 2005a, El Alqamy & Baha el Din 2006). The current status of this subspecies in Libya is unclear.

Gazella l. loderi is a characteristic species of the central Sahara (Dragesco-Joffé 1993). The centre of its distribution is found in the Great Western Erg, the Great Eastern Erg, and the sandy zone that stretches from the Hamada de Tinrhert in Algeria to the Fezzan in Libya. Although formerly present in the smaller ergs in the periphery of the central Saharan massifs of the Hoggar and the Tassili des Ajers, especially the Erg Amder and Erg Tihodaine (Setzer 1957, Dupuy 1967, De Smet 1989, Kowalski & Rzebik-Kowalska 1991, Dragesco-Joffé 1993, Kacem *et al.* 1994, De Smet & Smith 2001, Khattabi & Mallon 2001, Smith *et al.* 2001), they have not been observed in recent years, though they do still exist in the Erg of T'im Merzouga (K. De Smet pers. comm.).

In the ergs of the southern and eastern Sahara, the status of this species is unclear. It has been observed in the Great Ténéré Erg in small numbers in the contact zone between the Aïr and the Ténéré (Jones 1973, Grettenberger & Newby 1990, Poilecot 1996), although there have been no confirmed records for some years. In the Tibesti, the species was noted by Malbrant (1952) near Bardaï and Soborom, in the north of the massif, but there is no recent information on its presence here. The species is also thought to be present between the zone of the Erdi and the Mourdi depression in the Borkou of NE Chad and the Jebel Uweinat at the borders of Libya, Sudan and Egypt. This is a region in which a number of dunal systems stretch more or less from the south-west towards the north-east. At the Chadian extremity of this zone, Edmond-Blanc *et al.* (1962) gathered secondhand information of presence. At the Libyan extremity, Misonne (1977) found three skulls on the border of the Jebel Uweinat massif. Recent data also exist from the Gifl El Kebir in SW Egypt (Elbadry 1998). Although Setzer (1956) doubted their presence in Sudan, there are records from the north-west (Wilson 1980, K. De Smet pers. comm.). The subspecific affinities of these

animals are not known, but what is known of their ecology suggests that they are *G. l. loderi*.

Outside these regions, the species is mentioned as occurring in Mali (Heringa 1990, Duvall *et al.* 1997), where it may occur in the Adrar des Iforhas, although Sayer (1977) and Sidiyène & Tranier (1990) declared it absent from the entire country. The only observation of Slender-horned Gazelles in Morocco is from the region of Boumia south-east of the High Atlas, during the 1950s (Loggers *et al.* 1992), but this is far outside the species' normal habitat and very probably represents a misidentified Cuvier's Gazelle *Gazella cuvieri*.

In summary, the species is believed to have had a very wide Saharan distribution until relatively recently. However, in the last ten years, firm evidence for its presence is limited to the Great Ergs of Algeria, Tunisia, Libya and the extreme Western Desert of Egypt. No reports of occurrences to the south of these locations have been supported by photographs or any other hard evidence during this period.

Habitat In Egypt, the Slender-horned Gazelle occurs in hyper-arid desert areas, in particular sandy depressions with sparse vegetation and isolated *Acacia raddiana* woodlands, to sandy outskirts of oases supporting *Nitraria retusa*, and to interdunal depressions of *Cornulaca monacantha* (Osborn & Helmy 1980). *Gazella l. loderi* is principally linked to ergs (Schnell 1977, Ozenda 1991), which seem to constitute its only habitat, at least in the central Sahara (Sclater & Thomas 1899, Lavauden 1926a, b, Heim de Balsac 1936, Dupuy 1967). It has been suggested that they were once found in a variety of habitats, but that persecution has probably driven them to living in remote, inaccessible regions (Dupuy 1967).

Abundance At the beginning of the 1980s, the population of Slender-horned Gazelles surviving in Egypt was small and widely dispersed, especially near uninhabited oases, and in the Wadi El Rayan (Saleh 1987). The numbers that seem to survive in NW Egypt and perhaps in Kharga are certainly low, although current population size is unknown (Saleh 2001, Devillers *et al.* 2005a). Population numbers in Libya are similarly unknown.

The figures for Slender-horned Gazelles in the western part of its range are very difficult to estimate. However, it seems clear that it was much more abundant in the Algeria–Tunisia Great Ergs at the end of the nineteenth and beginning of the twentieth century than it has been in recent years. Large numbers were found, apparently relatively easily, by several naturalists of this period (Sclater & Thomas 1899, Lavauden 1926a, Heim de Balsac 1936), whereas Le Houérou (1986) notes having seen only one throughout 25 years of prospecting while mapping the vegetation of North Africa. The species was observed in small numbers by Jones (1973) and by Grettenberger & Newby (1990) on the edge of the Aïr–Ténéré, but there are no reliable estimates of abundance.

Surveys in Tunisia (Jan–Feb and Apr–May 2006) confirm that the Slender-horned Gazelle is still present through the Tunisian part of the Great Oriental Erg from Djebil N. P. to Senghar N. P., but that densities are probably very low. Evidence of poaching and disturbance is high. Observations suggest that the Tunisian population may number a few hundred individuals but more data are needed to verify this preliminary assessment (Wachter 2006, T. Wachter pers. comm.).

Adaptations Clearly, the restriction of the Slender-horned Gazelle to sandy ergs where few other large mammals can live must be facilitated by special adaptations. The sandy substrate has demanded some modification of the hoof structure and/or techniques of locomotion. Extreme exposure to insolation and reflected radiation probably involves species-specific physiological adaptations. The degree to which these gazelles escape predation as a result of their preference for ergs might also have been significant in their original adoption of such a difficult environment. None of these topics has received attention.

Foraging and Food In the eastern part of the range the Slender-horned Gazelle consumes a significant amount of foliage, including *Nitraria retusa*, a halophyte plant, *Deverra tortuosus* and *Acacia raddiana*, *Cornulaca monacantha*, *Launaea capitata* and *Calligonum comosum* (Osborn & Helmy 1980). In the western part of the range the species grazes mainly on *Aristida pungens* (Heim de Balsac 1936), but it also uses plants with an elevated water content, such as *Anabasis articulata*, *Arthrophytum schmittianum*, *Helianthemum kahiricum*, and the fruits of *Colocynthis vulgaris*, to meet its water needs (Kacem *et al.* 1994). Following good rainfall early in the year, Slender-horned Gazelles in the Tunisian Grand Erg were recorded selectively browsing on flowering plants of *Helianthemum confertum*, *Lotus pusillus*, *Herniaria* sp., *Echium* sp. and the leguminous shrub *Genista saharae* in Apr and May (T. Wachter pers. comm.).

They are mostly nocturnal and somewhat crepuscular, foraging and moving during these periods of the day, and resting during the hot hours in the shade or in hollowed depressions (Osborn & Helmy 1980). They appear to be highly nomadic, moving frequently between desert depressions in search of food (Kacem *et al.* 1994, Saleh 2001). Larger movements, carrying the species far from its preferred habitat, take place under the effect of long and severe droughts (Heim de Balsac 1928).

Social and Reproductive Behaviour Like other desert gazelles and antelopes, social organization is likely to be flexible and adaptable to variation in conditions. In good conditions, Slender-horned Gazelles may become territorial during the mating season, typically Aug–Sep. In general, they have been observed to form groups of 3–10 individuals, comprising one dominant ♂, several adult ♀♀ and their young. The ♂ remains vigilant, rounding up his group and attempting to herd additional ♀♀ into his territory to gain extra-mating opportunities. But not all ♀♀ will cooperate and younger satellite ♂♂ who may try to intervene in the resulting confusion.

Reproduction and Population Structure Birth season is typically in winter and early spring. The length of gestation is between 156 and 169 days (Furley 1986). One, sometimes two, young are born; twinning, which is not uncommon (Flower 1932, Kacem *et al.* 1994), is a trait shared with its closest relatives, the Goitered Gazelle and Cuvier's Gazelle (Hammond *et al.* 2001). The calves are weaned at three months, but do not mature until 6–9 months in ♀♀ and 18 months in ♂♂. Longevity has been recorded up to 14.6 years in captivity (Weigl 2005).

Predators, Parasites and Diseases Historically, the major predator sharing the habitat of Slender-horned Gazelles has been the Cheetah *Acinonyx jubatus*, but this species is now radically diminished or extirpated from most of the known range and no locations are currently known where the two certainly overlap. Golden Jackals *Canis aureus* are frequent at known gazelle areas such as the margins of the Great Ergs and west of Siwa oasis, and are likely to be opportunistic predators of young calves. At the margins of its range, Slender-horned Gazelles may encounter other large carnivores such as African Wild Dogs *Lycaon pictus*, Leopards *Panthera pardus* and Striped Hyenas *Hyaena hyaena*.

Conservation IUCN Category: Endangered C2a(i). CITES: Appendix I. CMS: Appendix I.

The Slender-horned Gazelle is reported to be nearly extinct in Egypt, and there is limited current information on its population status other than that the population is small and scattered in small groups; in the westerly part of the range, recent observations from the southern extent of their original distribution range are lacking, despite suitable habitat, and they are now presumably largely confined to remote and inaccessible areas.

Across the range, the main threat is undoubtedly modernized hunting/poaching, though disturbance and degradation of natural habitats (especially erg vegetation) through desertification also play a negative role (Devillers *et al.* 2005a). Protected areas known to be important for the species include Djebil and Senghar National Parks in Tunisia, Tassili N'Ajjer N. P. in Algeria (where still present in the Erg of T'im Merzouga; K. de Smet pers. comm.), and possibly Aïr–Ténéré National Nature Reserve in Niger. Enforcement of bans on hunting across the range, additional land and air surveys of regions of suitable habitat to determine population numbers, and the protection of existing populations in protected areas (such as Djebil and Senghar National Parks and those of Siwa and White Desert in Egypt) are immediate conservation priorities (Mallon & Kingswood 2001b, Devillers *et al.* 2005a).

The species is present in captivity in about 20 institutions in North Africa, Europe and North America (Devillers *et al.* 2005a).

Measurements

Gazella leptoceros

HB (♂♂): 937 (885–999) mm, n = 4

HB (♀♀): 955 mm, n = 1

T (♂♂): 162 (155–166) mm, n = 4

T (♀♀): 125 mm, n = 1

E (♂♂): 140 (132–145) mm, n = 4

E (♀♀): 130 mm, n = 1

Egypt (Osborn & Helmy 1980)

Kingdon (1997) gave estimated weight as 14–18 kg

Maximum recorded horn length is 41.2 cm for a pair of horns from Egypt (Rowland Ward)

GENUS *Eudorcas*

Ring-horned Gazelles

Eudorcas Fitzinger, 1869. Sitzb. K. K. Akad. Wiss., Wien, math.-nat. Cl., 59 (sect. 1): 159.

Thomson's Gazelle *Eudorcas thomsonii* myology.

Thomson's Gazelle *Eudorcas thomsonii* skeleton.

The gazelles of this genus have traditionally been placed in the genus *Gazella*. It was Vassart *et al.* (1995) who first pointed out that *Eudorcas* and *Nanger* are more closely related to each other, whereas *Gazella* is closer to the Indian *Antelope*. Groves (2000), based on a cladistic analysis mainly of cranial, dental and horn characters, found that at the very least the four can be considered about equally related, and, wishing to preserve the generic distinction between *Gazella* and *Antelope*, raised *Nanger* to generic rank and revived the name *Eudorcas* for the present group.

Eudorcas form a group of comparatively large, relatively short-legged, less arid-adapted gazelles, differentiated from the generally smaller, more slender, longer-legged, more desert-living gazelles of the genus *Gazella* by a number of features of teeth and horns. In the ♂ the horns back at 45 degrees to the plane of the head, whereas they are more upright in other gazelles; the horn cores are more strongly compressed, their transverse diameter being only about 60% of the anteroposterior diameter; the horn rings are also more prominent. The molar teeth are less elongated than in other gazelles, with better-developed styles on the upper molars, less developed lingual stylids and less developed anterior folds. The shape of the posteriorly lower molar is distinctive: its lingual is closed off distally, whereas in other gazelles it is open both distally and mesially. In the skull, the lacrimal bone does not extend so extensively on the face as in *Gazella*; the ethmoid fissure is longer; the nasofrontal sutures are curved forward; and, perhaps most distinctively, the median tips of the nasal bones are very long, the lateral prongs being relatively inconspicuous.

The colour pattern in all species is conspicuous and 'disruptive': the main body tone varies from light brown to quite reddish, the

underside is strikingly white, and there is always a strongly marked black band along the flanks, which may either border the white of the underside directly or be separated from it by a red band. The dark longitudinal stripes on the face, from muzzle to eye, are conspicuous and black, but the white stripes are often largely obliterated, leaving little but a white eye-ring. Characteristically, the rhinarium hardly extends at all along the upper margins of the nostrils.

The karyotype possesses not only the X-autosome translocation characteristic of *Gazella*, *Nanger* and the related genus *Antelope* (Effron *et al.* 1976, Vassart *et al.* 1995), but also, like *Nanger*, a Y-autosome translocation in addition.

Eudorcas contains at least two species, the Red-fronted Gazelle *E. rufifrons* and Thomson's Gazelle *E. thomsonii* (which have been considered conspecific by several authors; see species profiles), and there are grounds for raising *albonotata* and, especially, *tilonura* to specific rank, which is the treatment provisionally followed herein. They are much less arid adapted than species in the genus *Gazella*, being distributed mainly through the Sahel, from Senegal east to the Ethiopian Highlands, whence they extend north into Aïr and south through the grasslands of the southern Sudan into the East African savanna, south to the Wembere flood-plain.

The Red Gazelle *Eudorcas rufina* from N Algeria is an enigmatic form known only from three male specimens (one in the BMNH in London, another in the MNHN in Paris and a third in the collections of the University of Algiers) bought in Algeria and of unknown origin (Kowalski & Rzebik-Kowalska 1991, De Smet & Smith 2001). Although it has been listed as a subspecies of Red-fronted Gazelle (e.g. Ellerman & Morrison-Scott 1951; and see Joleaud 1929), other authors have recognized it as a distinct form (Gentry 1964, Corbet

1978, Grubb 2005). According to Gentry (1972), the form (which he noted shared some similarities to Cuvier's Gazelle *Gazella cuvieri*) was characterized by: fur thick and reddish-brown; dark flank band with brown fur below it; pygal band very slight; reddish-brown face markings; skull with heavily built bones; ♂♂ with large horns; large preorbital fossae; posterior suture of nasals in an almost transverse

plane; and ethmoid fissure small or absent. According to Lavauden (1930), the Red Gazelle inhabited forests and bushes in the region of Saida. The form has sometimes been considered a valid extinct species, but is not considered a valid species here.

Colin Groves

Eudorcas rufifrons RED-FRONTED GAZELLE

Fr. Gazelle à front rouge; Ger. Rotstirngazelle

Eudorcas rufifrons (Gray, 1846). Ann. Mag. Nat. Hist., ser 1, 18: 214. Senegal.

Red-fronted Gazelle *Eudorcas rufifrons*.

Eudorcas rufifrons

Taxonomy The number of subspecies recognized in the past has varied depending on whether *E. rufifrons* was treated as conspecific with related forms, namely Thomson's Gazelle *E. thomsonii*, the Mongalla Gazelle *E. albonotata* and Heuglin's Gazelle *E. tilonura* (Gentry 1972, Groves 1975, 1985a, Kingdon 1997, East 1999). In this account, *E. rufifrons sensu stricto* occurs west of the Nile R. only; *E. tilonura* and *E. albonotata*, which Grubb (2005) considers subspecies of *E. rufifrons*, occur east of the Nile, and are treated as separate species. Schwarz (1914) and Lydekker (1914) divided this species into five subspecies: *rufifrons* from Senegal; *hasleri* from Kano, Nigeria; *kanuri* from lower Chari; *centralis* from upper Chari; and *laevipes* from Sudan. Gentry (1972) followed this treatment, although he included *tilonura* as a subspecies noting that it appeared largely indistinguishable from *rufifrons*. Groves (1975), based on skull examination, considered *centralis* to be synonymous with *kanuri*; although this latter subspecies is sharply bordered, in some respects it is intermediate between *laevipes* and *rufifrons*. The form *hasleri* was considered synonymous with *laevipes*.

The Red Gazelle *E. rufina* is an enigmatic taxon, known only from three specimens obtained from Algeria towards the end of the nineteenth century (De Smet & Smith 2001). The gazelle was listed as a possible subspecies of *E. rufifrons* by Ellerman & Morrison-Scott (1951), but based on skull morphology Gentry (1964) argued that it represented a separate species related to Cuvier's Gazelle *G. cuvieri*. Synonyms: *centralis*, *hasleri*, *kanuri*, *laevipes*, *salmi*, *senegalensis*, *typica*. Chromosome number: $2n = 58$ (Vassart *et al.* 1995); the karyotype is nearly identical to that of Thomson's Gazelle.

Description Medium-sized, deeply reddish-coloured gazelle, with a uniformly tan-coloured upper coat. Forehead red, from which the name of the species is derived. Faint rufous and cream-coloured lines run from the eyes to the nose. Eyes large and black with a faint white ring. Flanks with dark band, 20–40 mm broad, running from the shoulder to the haunches, demarcating the edge of the white underparts. Legs slender, rufous on their outer side and whiter on the inside. Tail relatively long, ending in a black tuft that contrasts sharply with the white buttocks. Horns fairly long, slightly S-shaped over their length and diverging towards the tips; thick and strongly ringed in ♂ compared with ♀.

Geographic Variation

- E. r. ruffrons*: Senegal to Mali. Reddish-chestnut; mid-face bright rufous; light face-stripes light buff, dark ones rufous; no dark spot on the nose, thin red stripe present below the black flank-band.
- E. r. laevipes*: Niger to the Nile R. Larger, less reddish; light face-stripes whitish in colour.
- E. r. kanuri*: south of L. Chad. Intermediate in size; cinnamon-coloured.

Similar Species

- Eudorcas albonotata*. Allopatric, in SE Sudan, east of the Nile R., in the Sudd ecosystem. More brown in colour, with horns in ♂♂ curving backwards and then slightly forwards.
- E. tilonura*. Allopatric, ranging east of the Nile R. and the Blue Nile.
- Gazella dorcas*. Sympatric with *G. d. osiris* (for example, in the Sahelian rangelands of C Chad). Smaller, paler in colour; dark flank-band not well marked, but more clearly bordered above with very pale band; pygal band slightly marked; face markings paler, no nose-spot; face stripes pure white; ears paler; little or no darkening on knee-tufts; skull small; horns longer, narrowly ringed in ♂ and relatively longer in ♀.

Distribution Endemic to Africa. Confined to the Sahelian bushland and grassland from Mauritania and N Senegal to the western side of the Nile R. in Sudan, between the deserts in the north and the moist savanna woodlands in the south (East 1999). From Senegal to Niger only small scattered remnant populations of Red-fronted Gazelles remain, except in and around W N. P. (Niger, Burkina Faso), where it still occurs in good numbers (East 1999, Lamarque 2004). They are probably now extinct in Ghana, where they were always restricted to the Bawku district in the extreme north-east, or otherwise only occur as a rare vagrant from neighbouring countries (Ankudey & Ofori-Frimpong 1990, East 1999). There have never been any reliable confirmed records from Benin (Sayer & Green 1984), but they may occur in the north in Benin's W N. P.; however, they have never been recorded from Pendjari N. P. (Green & Chardonnet 1990, Sinsin *et al.* 2002, Rouamba & Hien 2004). There are also records from just north of Keran N. P. in Togo during the late 1970s and 1980s, which are well to the south of the species' range in Burkina Faso (see Chardonnet *et al.* 1990), but there is no recent information on their occurrence. No recent confirmed reports from Nigeria, but stragglers from Niger and especially Cameroon are expected to occur. The former occurrence of this species in Gambia is unclear, but if they did ever occur it was as a rare vagrant (see Grubb *et al.* 1998 for discussion).

Farther east, Red-fronted Gazelles still persist in many parts of their former range, particularly in Cameroon, Chad and Sudan. In Cameroon, Red-fronted Gazelles seem to have increased since 1960 in Kalamaloué N. P. and Waza N. P., due to the extension of open habitat induced by flood-plain degradation and damage by elephants (Scholte 2003, 2005, Scholte *et al.* 2007), but increased poaching is expected to have greatly reduced numbers more recently (P. Scholte pers. obs.). However, outside protected areas, numbers of Red-fronted Gazelles have declined considerably. In Chad, the gazelle is locally common south and west of L. Fitri, and also occurs locally in small to moderate numbers in largely unexploited rangelands in the Dourbali-Boussou region east of the Chari R. in Chari-Baguirmi, in parts of Mayo Kebi in the south-west, and in Ouaddai and the northern Salamat in SE Chad (Scholte

2001). There is a healthy population in Zakouma N. P. (but see Mackie 2004), and lower population numbers in Siniaka Minia Faunal Reserve (Dejace *et al.* 2000). There is a continuous presence of a very small population in the northern section of Manovo-Gounda-St Floris N. P., Central African Republic, on the southern limit of its distribution area (East 1999). Red-fronted Gazelles occur widely in C Sudan, west of the Nile R., in Jebel Marra, Southern Kordofan and Northern and Southern Darfur States (Wilson 1979, 1980, I. Hashim pers. obs.).

Habitat Inhabits dry grassland and open *Acacia* and *Combretum* shrubland. In the southern parts of the range, where rainfall reaches 1000 mm, Red-fronted Gazelles prefer open habitats and hence may be found in proximity with humans and cultivation. In the northern parts of the range, with an average annual rainfall sometimes as low as 100 mm, these gazelles prefer the wooded wadi areas. Much of the species' habitat is fragmented by agricultural encroachment, and generally grazed by domestic herbivores.

Abundance Numbers of Red-fronted Gazelles are decreasing rapidly due to poaching and habitat loss and degradation resulting from drought and agricultural and pastoral encroachment. This gazelle now occurs in low numbers in mosaic habitats throughout most of its range. The total number of Red-fronted Gazelles has been estimated at about 20,000 (correcting for undercounting biases), with large numbers known to survive in Niger (ca. 4000) and Mali (ca. 3000) (East 1999).

In protected areas density estimates range from 0.1/km² in W N. P., Niger (H. Talatou pers. comm.), 0.2/km² in Zakouma N. P., Chad (Dejace *et al.* 2000), 0.35/km² in Waza N. P. (Scholte 2005) to as high as 4.0–9.0/km² in Kalamaloué N. P. (Scholte 2003), albeit inflated by temporary immigration. In prime gazelle habitat in Waza N. P. (open *Lannea humilis* shrubland) densities ranged from 0.5 to 2.5/km² in a 7 km² plot surveyed by total counts from 1974 to 1998 (Ecole de Faune mission reports).

Adaptations The Red-fronted Gazelle is the least arid-adapted of Sahelo-Saharan gazelles, unable to inhabit the Saharan regions, but successfully exploiting the desert's southern margins.

Foraging and Food The Red-fronted Gazelle is a mixed feeder, preferring grasses during the wet season, and trees and shrubs during the dry season. The principal food plants include *Acacia* spp. (including *A. mellifera*, *A. tortilis*), *Balanites aegyptiaca* and *Boscia senegalensis* (Dorst & Dandelot 1970).

In regions devoid of water Red-fronted Gazelles obtain most of their moisture requirements from their food. However, they are more water-dependent than other gazelle species in the same region (Koster 1983). Some seasonal movements are known (north during the wet season, returning to the south in the dry season), especially from Chad and Sudan, but increasingly limited by human settlement.

Social and Reproductive Behaviour Red-fronted Gazelle social behaviour has not been studied in detail; the only quantitative information available is from wildlife counts in Kalamaloué N. P. (Scholte 2003) and Waza N. P. (Scholte 2005). Group composition (n = 294 individuals) comprised mixed groups (38%), pairs and young (24%), single ♂♂ (14%), harems (14%), single ♀♀ (4%), bachelor groups (3%), and ♀♀ plus young (2%) (P. Scholte pers.

obs.). Single individuals and pairs dominate during the dry season, as well as mixed groups and possible temporary harems that do not normally exceed 5–7 individuals (Koster 1983, Grettenberger & Newby 1990, P. Scholte pers. obs.). Occasionally, mixed groups of up to 19 have been observed during the wet season in Kalamaloué N. P., suggesting the short-term creation of assemblages as known from other gazelle species, related with food availability. Mean herd size was 1.98 ± 0.28 (Waza N. P., Apr), 3.04 ± 0.96 and 3.12 ± 1.16 (Kalamaloué N. P., Feb and Jul, respectively) (P. Scholte pers. obs.).

Breeding ♂♂ defend territories, the boundaries of which are marked with dung piles and secretions from preorbital glands. Frequent and fierce fighting between ♂♂ has been recorded, as also indicated by the occasional presence of ♂♂ with only one horn (see also Malbrant 1952). Like other gazelle species, mounting in Red-fronted Gazelles lasts for a few seconds in which the ♂ stands erect on the hindlimbs and holds the forelimbs bent backwards from the knee, above the female's back.

Reproduction and Population Structure Red-fronted Gazelles reproduce throughout the year, but births are skewed towards the wet season and early dry season (Malbrant 1952) or first part of the dry season (Bourlière *et al.* 1976). Reported gestation periods are 184 and 198 days (Mentis 1972). A single young is born, which remains hidden. Weaning takes place at about three months; ♀♀ reach maturity at about nine months of age, ♂♂ at 18 months. Longevity of captive gazelles is to 14.5 years (Weigl 2005). No systematic studies have been undertaken on population structure. Sex ratio (♂ : ♀) in all observations ($n = 278$ individuals) in counts in Waza and Kalamaloué National Parks was 1 : 1, yet varied from 1.3 : 1 (Kalamaloué, Feb 1994) and 1.2 : 1 (Waza, Apr 1998) to 0.57 : 1 (Kalamaloué, Jul 1994). Juvenile percentage in these observations increased from 3% in Feb to 7% in Apr to 9% in Jul (P. Scholte pers. obs.).

Predators, Parasites and Diseases Main predators in the past would have included Cheetahs *Acinonyx jubatus*, African Wild Dogs *Lycaon pictus*, Lions *Panthera leo*, Leopards *Panthera pardus*, Spotted Hyenas *Crocuta crocuta* and African Rock Pythons *Python sebae*. Most of these species are now locally extinct or extremely rare in the range of the Red-fronted Gazelle, with the exception of some protected areas. Domestic dogs, jackals *Canis* spp. and birds of prey (particularly on calves) are presently the main predators; in Sudan, the Secretary Bird *Sagittarius serpentarius* may take young (I. Hashim pers. obs.). Red-fronted Gazelles strictly avoid regions infested with tsetse flies (see also Malbrant 1952). There is no other information on parasites or diseases.

Conservation IUCN Category: Vulnerable A2cd. CITES: Not listed.

Populations of the Red-fronted Gazelle have decreased due to poaching, especially for skins and as pets. Jeannin (1936) reported on a group of hunters that, with dogs and nets, had collected more than 1600 skins in a three-and-a-half month period in N Cameroon. The hundreds of gazelles kept in cities such as N'Djamena have generally been taken as young from the wild and subsequently raised with goats. Drought, habitat loss, and competition with livestock have further reduced the presence of Red-fronted Gazelles to scattered remnants throughout its former range. Viable populations survive in Burkina Faso, Mali, Niger, Cameroon, Chad and Sudan, but numbers are decreasing except in a few protected areas such as W N. P. (Niger, Burkina Faso), Waza N. P. and Kalamaloué N. P. (Cameroon) and Zakouma N. P. (Chad) (Dejace *et al.* 2000, Scholte 2005, Scholte *et al.* 2007).

Only a very limited number of individuals are maintained in captivity in zoos (<25), in San Diego, Warsaw and Dubai, without formal captive breeding programmes (E. Handrus pers. comm.).

Measurements

Eudorcas rufifrons

E. r. kanuri

Head (♂♂): 339 ± 27 mm, $n = 59$

Head (♀♀): 309 ± 17 mm, $n = 36$

Body (♂♂): 892 ± 68 mm, $n = 59$

Body (♀♀): 923 ± 49 mm, $n = 36$

T (♂♂): 294 ± 33 mm, $n = 59$

T (♀♀): 323 ± 24 mm, $n = 36$

E (♂♂): 150 ± 9 mm, $n = 59$

E (♀♀): 159 ± 16 mm, $n = 36$

Sh. ht (♂♂): 687 ± 62 mm, $n = 59$

Sh. ht (♀♀): 695 ± 43 mm, $n = 36$

WT (♂♂): 30.7 ± 2.4 kg, $n = 59$

WT (♀♀): 28.1 ± 1.5 kg, $n = 36$

Cameroon (Nchanji & Amubode 2002)

Two adult *E. r. laevipes* ♂♂ from Aïr, Niger, had the following measurements: TL (1140–1200 mm); Sh. ht (770–810 mm); T (145–170 mm); and WT (26.0–29.0 kg) (Brouin 1950)

Maximum recorded horn length is 35.2 cm for a pair of horns from the White Nile, Sudan (Rowland Ward)

Eudorcas tilonura HEUGLIN'S GAZELLE

Fr. Gazelle d'Eritrée; Ger. Eritreagazelle

Eudorcas tilonura (Heuglin, 1863). Nova Acta Acad. Caes. Leop.-Carol., Jena 30 (2): 6. Plains near Ain-Saba, Bogosland, Abyssinia.

Taxonomy Monotypic. Usually considered a subspecies of the Red-fronted Gazelle *E. rufifrons* (Gentry 1972, Grubb 1993c, 2005), but here considered a distinct species. It has been assumed that this species has hybridized with *E. r. laevipes*, but the distribution of *E. tilonura* lies east of the Nile R. and the Blue Nile (P. Grubb pers. comm.). *Eudorcas tilonura* is redder than *E. r. laevipes*, and smaller, with horns bowed

outwards and hooked inwards at the tips (Groves 1985a). Synonym: *melanura*. Chromosome number: not known.

Description A small gazelle, having a straight back in profile. Forehead and bridge of nose rufous, bordered by white stripes that encircle the eyes and extend down to the mouth; there is no dark

spot on the nose. The space between the horns is white. Preorbital glands are more conspicuous in ♂ than ♀. A deep reddish band along flanks extends from the shoulder to the hindquarters, separating the sandy-fawn colouring above and white below. The intensity of this band changes with season, being fainter in summer and darker in winter; the band is also darker in younger animals. Buttocks white. Tail relatively long, its base rufous and gradually changing to black. Horns very short, inwardly hooked at the tips, and prominently ringed in ♂. Female horns weakly ringed; they grow straight at first, curve outward and then inward.

Geographic Variation None recorded.

Similar Species

Eudorcas rufifrons. Allopatric, confined to the Sahelian bushland and grassland regions from Mauritania and N Senegal to west of the Nile R. in Sudan. See also Taxonomy.

Nanger soemmerringi. Largely allopatric, but ranges overlap in SW Eritrea (and formerly in NE Sudan, although Soemmerring's Gazelle is now probably exterminated from its historical range in this country). Larger, paler gazelle with extensive white on the rump; facial blazes strongly marked; horns heavy, short and swept backward, the in-pointed, hooked tips forming a lyrate shape; legs long with big hooves; tail with many white fringes of short hair.

Gazella dorcas. The Isabelline Gazelle *G. d. isabella* is sympatric. A more gracile gazelle, brown-grey with reddish tones and dark markings, and a dark nose-spot; horns lyrate, short, stout and widely spread with in-turned tips.

Distribution Endemic to Africa (see species profile of Mongalla Gazelle *E. albonotata* for map). Confined to the eastern side of the Nile R. and the Blue Nile between the southern part of the Red Sea hills in Sudan and the southern foothills of the Ethiopian massif in W Eritrea and NW Ethiopia (East 1999). Currently, Heuglin's Gazelle is thought to occur through much of its historical range, but in localized patches as a result of poaching, agricultural encroachment and overgrazing by domestic herbivores.

Habitat Heuglin's Gazelle inhabits dry grassland, open steppe and thorn bushland, ranging up to 1400 m in the savannas of NW Ethiopia (Yalden *et al.* 1996). Rainfall varies between 1000 mm in the southern part and 100 mm in the northern part of its range. Part of the habitat in the southern range is characterized by heavy, cracking clay ('black cotton') soils that swell when they are wet and become sticky. The gazelles avoid the sticky clay by moving to lighter, better-drained soils during the wet season, but return to the clayey sump areas during the dry season. Here they favour a mosaic of habitats, including woodland, which are subject to seasonal burning (Hashim 1998). They avoid thick cover. As Heuglin's Gazelle inhabits arid regions devoid of water, water is consumed when it is available but it is not an essential habitat requirement.

Abundance Heuglin's Gazelles are now found in low numbers in disjunct patches of remaining habitat and in localized areas such as the Dinder N. P. of Sudan where a density of ca 1.0 ind/km² has been recorded (Hashim 1998). East (1999) estimated a total population size of 3500–4000 animals.

Eudorcas tilonura

Adaptations Heuglin's Gazelle has been isolated from other members of its genus by the Nile R. and by mountains, and has adapted primarily to living on the plains on either side of the Atbara R.

Foraging and Food Heuglin's Gazelles both browse and graze, grazing during the wet season when grasses and forbs are readily available. *Ipomoea* spp. are preferentially selected, particularly in secondary successional areas (Hashim 1998). Heuglin's Gazelles forage in small groups of 3–4 and feeding usually takes place early in the morning and in the evening. In arid savanna regions such as Dinder N. P., where the habitat is unfavourable during the wet season, the gazelles move outside the park to habitats with short grasses that are more nutritious compared with the tall grasses inside the park (Hashim 1998).

Social and Reproductive Behaviour Heuglin's Gazelles occur in groups ranging from two to four (mean = 1.8; n = 11; Hashim 1998). During the heat of the day they take shelter under large trees or shrubs, depending on the type of habitat. In arid savanna the preferred tree is *Balanites aegyptiaca* under which the gazelle scrapes shallow bedding sites. Usually a couple of gazelles use the bedding site for a considerable period of time as indicated by the accumulating dung heaps. In habitats dominated by shrubs, *Acacia nubica* is preferred (under which deeper bedding sites are excavated). Apparently, in these habitats, the gazelle uses these bedding sites only for short periods as indicated by the few tracks and the absence of dung heaps (Hashim 1998).

There is no information concerning territorial behaviour in free-ranging animals. However, in captivity, the ♂ shows signs of territorial behaviour by making dung heaps at the peripheries of the fence, sniffing the heaps and scratching the ground surrounding them. This is followed immediately by urination and defecation. Objects close to the fence are frequently marked with well-developed preorbital glands. Mounting lasts for a few seconds, when the ♂ stands erect on his hindlimbs

holding the forelimbs bent back from the knee, above the back of the ♀. At this time, ♂ and ♀ may be moving slowly or standing still.

Reproduction and Population Structure In free-ranging Heuglin's Gazelle, births occur during the wet season (I. M. Hashim pers. obs.). The gestation period is approximately six months. No other information on reproduction and population structure is available.

Predators, Parasites and Diseases Little information is available, but of the predators now found in areas inhabited by the Heuglin's Gazelle the most common are jackals *Canis* spp., which probably prey on young. Hyenas are less common but in a small forest reserve like Wad Kabu in E Sudan, it is possible that they could play a significant role in controlling the population of this gazelle.

Conservation IUCN Category: Vulnerable C1 (listed as subspecies of *E. rufifrons*). CITES: Not listed.

Heuglin's Gazelle have been reduced to small fragmented populations throughout their range because of illegal hunting, competition with domestic livestock and habitat degradation resulting from drought, overgrazing and agricultural encroachment. Viable populations survive in Sudan and Eritrea, but their numbers are decreasing. The gazelle is protected in Dinder N. P., but East (1999) noted that it does not receive effective protection here, as the open sites that it prefers are utilized intensively by camel herders

who trespass into the park in the dry season and destroy the gazelle's favourite shade trees to feed their camels and goats. This species is also subject to heavy poaching, particularly during the wet season, when animals move outside the boundary of the park. The declining trend of this gazelle species can be reversed by improved management of existing protected areas, and the extension of effective protection to additional populations besides those in Dinder N. P. (East 1999).

Measurements

Eudorcas tilonura

HB (♂): 678 mm, n = 1

HB (♀): 550, 590 mm, n = 2

T (♂): 290 mm, n = 1

Eudorcas thomsonii THOMSON'S GAZELLE

Fr. Gazelle de Thomson; Ger. Thomsongazelle

Eudorcas thomsonii (Günther, 1884). Ann. Mag. Nat. Hist., ser. 5, 14: 427. 'the range of country from Kilimanjaro to Baringo and at various heights above 6000 ft [1830 m]'; restricted to 'Kilimanjaro district' (Lydekker 1914) in Kenya (G. M. Allen 1939).

Thomson's Gazelle *Eudorcas thomsonii*.

The species is named for the British explorer, Joseph Thomson, who was the first to discover the gazelle.

Taxonomy It has recently been proposed that Thomson's Gazelle be moved from the genus *Gazella* to the genus *Eudorcas* (Groves 2000), along with the Red-fronted Gazelle *E. rufifrons* and the Mongalla Gazelle *E. albonotata*. This change is the result of genetic analysis that shows that although there is very little genetic difference between these species, they are collectively distinct from the other members of the genus *Gazella* (Groves 2000). *Eudorcas* was originally coined by Fitzinger (1869) in reference to *E. laevipes*, currently considered a subspecies of the Red-fronted Gazelle (Groves 1985a, 2000, Grubb 2005). Groves (1969) included *thomsonii* in Cuvier's Gazelle *Gazella cuvieri*, and many authors (Groves 1985a, 1988, Kingdon 1997, East 1999, Rebholz & Harley 1999) have included *thomsonii* in *E. rufifrons*. However, Gentry (1964, 1972) presented evidence that they are distinct from both (and see Grubb 2005).

The Mongalla Gazelle *E. albonotata* from the S Sudan is sometimes regarded as a subspecies of Thomson's Gazelle (Gentry 1972, Grubb 1993c), but is here treated as a distinct species. Grubb (2005) noted that skull and horn proportions associate *albonotata* with *rufifrons* rather than *thomsonii* (and see Gentry 1972). Synonyms: *arushae*, *baringoensis*, *behni*, *bergeri*, *bergerinae*, *biedermanni*, *dieseneri*, *dongilanensis*, *langheldi*,

Lateral view of skull of Thomson's Gazelle *Eudorcas thomsonii*.

macrocephala, *manyarae*, *marwitzi*, *mundorosica*, *nakuroensis*, *ndjiriensis*, *ruwanae*, *sabakiensis*, *schillingsi*, *seringetica*, *wembaerensis*. Chromosome number: $2n = 58$ (Effron *et al.* 1976, Vassart *et al.* 1995).

Description A small, compact gazelle with a cinnamon-brown back, cream underparts and prominent dark brown or black side-stripe under a buff band. Tail black, contrasting markedly with the cream rump patch, although the cinnamon-brown back colour extends down to base of tail. Face boldly marked with cream and dark brown/black stripes. Ears are of moderate length and narrow. Male slightly larger than ♀ both in weight and body length (Brooks 1961, Robinette & Archer 1971); the two sexes look alike except for the horns and the fact that the neck is thicker in ♂. Horns of ♂ relatively long, mildly undulating and heavily annulated. Females have short, smooth horns or they may be absent completely. The preorbital glands are prominent in adult ♂♂. Carpal, pedal and inguinal glands are also present. The skull follows the typical patterns of the family Bovidae with no incisors in the upper toothrows and unlobed canines in the lower toothrows. When horns are present, there is no suture separating the horn from the frontal bone (Gentry 1972).

Animals can be aged on external characteristics and behaviour (Walther 1973a), as follows:

- 0–2 weeks. Darker in colour than older age classes. At this age the neonate lies out and joins its mother only to suckle and be cleaned.
- 3 weeks to 2 months. When standing beside its mother, the juvenile's

back is below the mother's belly or level with it. Sometimes juveniles have a little white mane on the neck near the chest. Horns are not present, or at least not visible in the field. Increasingly out of 'hiding', accompanying mother for more and more of the time.

- 3 months to 4–6 months. When standing beside an adult ♀, the dorsal surface of the half-grown juvenile is approximately at the level of half of the adult's body. At the end of the half-grown stage, the tips of the horns are usually visible in the field; however, they do not yet allow a distinction between ♂ and ♀. The lying out period is over.
- 5–8 months (adolescents). Still smaller than adult ♀♀ and have a proportionally shorter snout. The horns of adolescent ♂♂ are shorter than their ears or, at maximum, equal in length. Although the horns of adult gazelle ♀♀ are about the same length or even longer, the horns of adolescent ♂♂ are much sturdier than those of ♀♀. At the beginning of this age class, they are about 3 cm tall and look like little cones. Later, they also show the typical rings of male horns. The horns of adolescent ♀♀ may or may not be visible under field conditions. They are much thinner than in adolescent ♂♂ and reach, at maximum, three-quarters, but in most cases only one-third, of the length of the ears. The little white mane near the chest may still be visible. Thus, in many cases, only the smaller size and different body proportions are the criteria for distinguishing an adolescent ♀ from an adult. Adolescents of both sexes are for the most part weaned.

The above two ages classes overlap and cannot be entirely distinguished.

- 8–12 (possibly up to 15) months (subadults). Subadult ♂♂ are very similar in size to adult ♀♀, but tend to have a slightly thicker neck; but, the neck is clearly thinner than an adult male's. The horns are longer than the ears, with a characteristic 'tilde' or recurved shape, but have not reached full length. Subadult ♀♀ are difficult to distinguish from adult ♀♀, but are a little smaller, with a more slender body and neck. Their horns may be half to full length of the ears.
- 16–24 months (young adults). This age group is impossible to recognize in the case of ♀♀ but in ♂♂ the horns are about 20 cm long and show the beginning of the lower curvature of

Thomson's Gazelle *Eudorcas thomsonii* head.

Thomson's Gazelle *Eudorcas thomsonii* head myology.

mature horns. The body is full size but with a slightly thinner neck than the adult ♂. Widely spaced annulations at the horn base also distinguish young from mature bucks.

- *Full adulthood seems to be reached at the end of the second year of life.* Adult ♂♂ have full-length double-arched horns, ca. 25–43 cm long. The horns of adult ♀♀, when present, are ca. 8–15 cm (Haltenorth 1963), but are often broken or bent. Generally, by about ten years Thomson's Gazelles seem to reach 'very old age' (Walter 1973a), in which the belly hangs deep, the ribs are often visible and sometimes the lower lip appears somewhat protruded. The normally brown forehead may become completely white.

Geographic Variation Geographic variation in Thomson's Gazelle is uncertain and no genetic differentiation within the species has been reported apart from work to identify differences between Thomson's Gazelle and the Red-fronted Gazelle. However, several authors have recognized two subspecies:

E. t. thomsonii: Rift Valley and east, south of a line from the L. Eyasi escarpment to Speke Gulf on L. Victoria.

E. t. nasalis: west of the Rift Valley, and north of the line from the L. Eyasi escarpment to the Speke Gulf.

Brooks (1961) contended that there were four geographically definable variants of Thomson's Gazelles, their distinctness, perhaps, reinforced by social behaviours (Kingdon 1982).

Similar Species

Eudorcas albonotata. Very similar in appearance, but occurs further north, being restricted to the Sudd ecosystem in SE Sudan. Sometimes considered conspecific (see Taxonomy).

Nanger (granti) granti. Sympatric; larger and paler, and also has longer horns. Immatures of the two species can be confused, but the white rump patch extends over the tail onto the croup in Grant's Gazelles.

Distribution Endemic to Africa. Thomson's Gazelles currently inhabit a relatively small range in N Tanzania and S Kenya, largely restricted to the high plains and *Acacia* savannas above 500 m (Estes 1991a, East 1999). Its upland distribution is essentially associated with the highest areas of the Eastern Rift Valley, spilling over to the east and west. This distribution suggests contraction from a wider range during the Ice Age (J. Kingdon pers. comm.).

Habitat Thomson's Gazelle is usually found on short grassland with dry, firm footing although it will move into tall grassland and open wooded habitats during migration (Estes 1991a). Principally a grazer, it tends to concentrate in open areas (plains or grassland patches in woodlands) with short grass, preferring heavily grazed, trampled or burnt grassland with emergent vegetation (Vesey-Fitzgerald 1960, Wilmshurst *et al.* 1999a). It stays on grasslands long deserted by other, larger herbivores as long as some grass remains. In Serengeti N. P. it has been highly successful, along with the Common Wildebeest *Connochaetes taurinus* and Plains Zebra *Equus quagga*, at exploiting the seasonal productivity of semi-arid savanna (Vesey-Fitzgerald 1973), taking advantage of the naturally short grasslands in the south and east of the ecosystem during the rains and migrating to wetter areas to the north-east mostly to the Kirawira, Nyasirori and Ruwana

Eudorcas thomsonii

Plains (rarely further north than the Togoro Plains) in the dry season. Although Thomson's Gazelles pass through the high grass plains during migration, they tend not to remain there for long periods.

Abundance Locally common. East (1999) estimated the population size at around 550,000 animals. The migratory population of this species in the Serengeti–Mara ecosystem on the Tanzania/Kenya border is Africa's largest and most spectacular protected gazelle population. Data from the 2003 wet season in the Serengeti ecosystem estimates the Thomson's Gazelle population at 174,015 ($\pm 37,406$ S.E.) (Mduma 2003). In the early 1970s, numbers stood at 0.66 million animals but had decreased to less than 0.25 million animals in 1985 (Borner *et al.* 1987). East (1999) reported a figure of 342,000 in 1996. However, changes in survey methodologies over the years and large variance in population estimates make determination of true population trends difficult (Borner *et al.* 1987). Nevertheless, this decline is consistent and concurrent with a substantial loss of large wild herbivores in the Masai Mara ecosystem in Kenya (Ottichilo *et al.* 2000, 2001, Ogotu *et al.* 2011).

There are smaller resident populations of this gazelle in the western and northern Serengeti N. P., particularly on the Togoro Plains and in the open woodland towards Bologonja (ca. 10,000; East 1999) and Ngorongoro Conservation Area (estimated to be ca. 1300 in 1992 by Runyoro *et al.* 1995, and an average of ca. 1400 between 1986 and 2005 by Estes *et al.* 2006). There are an estimated 20,000 Thomson's Gazelles in Arusha region, outside the Ngorongoro Conservation Area (East 1999). The species also occurs in Tarangire N. P., Tanzania, where the resident, wet season population of ca. 600 is augmented in the dry season by a migratory population of ca. 3000 that spends the wet season on the Simanjoro Plains (East 1999). A southern population of ca. 1000 animals occurs in the north-east of Tabora region and on the Wembere Plains (East 1999).

In Kenya, Thomson's Gazelles are present in the west of the country, including Masai Mara National Reserve, where the population declined

from about 20,000 in 1977–79 to 8100 in 2007 (Ogutu *et al.* 2011). A further 2500 animals are present in the Laikipia district (Georgiadis *et al.* 2003), and ca. 10,000 in the Ewaso Ngiro basin (including Mt Kenya N. P., Aberdares N. P., the Samburu N. R., Buffalo Springs N. R., Shaba N. R. and Meru N. P.) as of 1997, a decline from ca. 33,000 in 1977 (Muchoki 2000).

Adaptations Thomson's Gazelles are relatively drought-resistant, enabling them to remain out on the dry plains, long after most other ungulates have moved off to find wetter habitats (Vesey-Fitzgerald 1960, Bell 1969). They are less adapted to arid conditions than Grant's Gazelles (Taylor 1970a), relying on evaporative cooling by panting to keep their body heat several degrees below the ambient temperature (Taylor 1972). However, when water supply is restricted, evaporation is reduced and the body temperature of the gazelles increases to a point where they are in thermal balance with their environment without panting (Taylor 1972). Selective cooling of the blood to the brain may enable the gazelles to survive high body temperatures (Taylor 1972, Jessen 1998). Although gazelles will travel long distances (up to 16 km) to water every other day or so (Brooks 1961) in the dry season, some individuals remain out on the short grass plains in Serengeti N. P. at considerable distance from rivers and pools, and appear to be independent of water.

Thomson's Gazelles are ruminants and have been classified as 'intermediate feeders preferring grasses' based on analysis of stomach morphology (Hofmann & Stewart 1972, Hofmann 1989), stable carbon isotope analysis (Cerling *et al.* 2003) and comparative anatomy of dental wear patterns (Fortelius & Solounias 2000). Skull proportions suggest that they are adapted to be selective feeders with the narrowest muzzle of all the gazelles (Janis & Ehrhardt 1988). This would appear to be an adaptation to dry season conditions during which dicotyledonous plant material is being selected from within swards of coarse grasses. During the wet season Thomson's Gazelles graze on more uniform swards of prostrate grasses (Bell 1969, Stewart & Stewart 1971), for which fine selection may not be advantageous. Nevertheless, their relatively small body size constrains the amount of forage that a Thomson's Gazelle can consume and digest daily (Arman & Hopcraft 1975, Meissner & Paulsmeier 1995). Hence, they appear to be adapted to foraging on sparse but high-quality plant material (Wilmschurst *et al.* 1999a).

In Serengeti N. P. a large proportion of the population migrates between the open plains and the woodlands, enabling Thomson's Gazelles to take advantage of ephemeral food resources and maintain higher numbers than would otherwise be possible. Movement patterns vary, but the gazelles tend to leave the open woodland when rains start, around Nov, and migrate towards the open plains in the south-east of the ecosystem. They stay there, moving between L. Ndotu and Lemuta Hill, until the end of the long rains (ca. May). As the plains dry up, they cross the central Serengeti Plains in a north-westerly direction, heading towards the 'corridor' (i.e. the area of the park towards L. Victoria) or the Grumeti and Ikoma areas until the onset of the rains. Not all the Thomson's Gazelles migrate out onto the open plains during the wet season – some remain in the woodland, concentrated in the open woodland and clearings (Schaller 1972, Durant *et al.* 1988). The number of Thomson's Gazelles on the eastern Serengeti Plains is closely associated with rainfall levels (Durant *et al.* 1988). McNaughton (1985) noted that Thomson's Gazelles arrived on the Serengeti Plains within three days of significant rainfall there.

There is no close association between rainfall and gazelle numbers in the north and west of the plains, suggesting that they are unlikely to have moved there in response to growth of new shoots; instead they may be feeding on high protein dicotyledons which maintain higher dry-season levels of protein than grasses (Stelfox & Hudson 1986) and which are made accessible by wildebeest feeding in the same area earlier in the year (Bell 1971, Maddock 1979) or because of their need for water. Thomson's Gazelles do collect in areas previously grazed by wildebeest (McNaughton 1976).

On account of their size, Thomson's Gazelles are preyed upon by a wide range of predator species. Living in open habitats and unable to rely on crypsis to avoid predation (except as juveniles in hiding), they have evolved a number of other strategies to minimize predation. Other than their physical adaptations of high speed (80 km/h; Christiansen 2002) and agility (Walther 1969), they have a range of behavioural anti-predator strategies (Walther 1968, FitzGibbon 1988, FitzGibbon & Lazarus 1995), the main ones being grouping and vigilance (see below). In addition to grouping with conspecifics, Thomson's Gazelles are often found in mixed-species groups with Grant's Gazelles (Estes 1967, Sinclair 1985, FitzGibbon 1990a). However, Grant's Gazelles are less water-dependent and a higher proportion remain on the open Serengeti Plains in the dry season. In the plains during the wet season and in the woodland during the dry season they are also found together with Common Wildebeest, Plains Zebra, Topi *Damaliscus lunatus jimela*, Kongoni *Alcelaphus buselaphus cokii*, Impala *Aepyceros melampus*, Waterbuck *Kobus ellipsiprymnus* and Giraffe *Giraffa camelopardalis* (Walther *et al.* 1983).

In contrast to the adults, the young, unable to outrun predators, rely on crypsis, remaining hidden for the first few weeks of their life. Predators have considerable difficulty in finding hidden juveniles: Cheetahs *Acinonyx jubatus*, Spotted Hyaenas *Crocuta crocuta* and jackals *Canis* spp. have all been observed to walk within 5–10 m of hidden gazelle juveniles without detecting them. The cryptic colouration and lack of scent, resulting from the inactivity of its scent glands (Gosling 1969a, Walther 1969) and the ingestion of urine and faeces by the mother, help to make the young gazelle difficult to find. In addition, antelope young in the prone response have been shown to have lower respiration and heart-beat rates than young in the normal resting position (Jacobsen 1979).

Thomson's Gazelles constantly twitch their tails from side to side. The function of this behaviour is unknown, but it may be a species recognition signal (Estes 1991a).

A study in Serengeti N. P. found that four basic activities – lying, standing, grazing and moving – were recorded regularly through the day (Walther 1973b). Grazing was concentrated in four major periods, in the early morning, at noon, in the evening and around midnight. Generally activity was slightly higher during daylight than at night. Adult gazelles spent about half their time lying down, in bouts of 0.5–5 hours. They slept for ca. 0.5–1 hour/day with eyes closed a few minutes at a time. At the hottest time of day, in the afternoon, the gazelles sought shade, but sometimes sunbathed in the morning, seeking open areas and orienting their hindquarters or flanks towards the sun (Walther 1973b). Young and subadult gazelles sometimes participated in running and jumping games (play), usually with several animals participating at once. The games were concentrated in the morning and evening (Walther 1973b). Aggression also peaked early and late in the day, sexual activities in early morning, mid-day and midnight (Walther 1973b).

Foraging and Food During the wet season, their diet consists of 80–90% grasses (Talbot 1962, Stewart & Stewart 1970), but during the dry season when only coarse grasses are available, they include considerably more forbs and fruits in their diet (Stewart & Stewart 1971, Hoppe *et al.* 1977), up to approximately 40% (Gwynne & Bell 1968, Bell 1969). Stomach content and tooth enamel analysis using stable carbon isotope analysis has found Thomson's Gazelles' diet to be approximately 64–68% grasses (identified via their C_4 carbon structure) and 32–36% forbs (identified via their C_3 carbon structure) (Cerling *et al.* 2003).

As specialists on sparse, but relatively high-quality, grasses (Arman & Hopcraft 1975, Wilmshurst *et al.* 1999a), they will tend to segregate in space and time from larger grazers (Jarman & Sinclair 1979). This pattern has led some observers to suggest that they form the final stage of a 'grazing succession' based on timing of grazing patches and local topography (Vesey-Fitzgerald 1960, Gwynne & Bell 1968, Maddock 1979). However, it seems unlikely that this pattern is solely the result of the larger species improving the grazing conditions for Thomson's Gazelles (de Boer & Prins 1990, Huisman & Olff 1998). Further research has shown that Thomson's Gazelles concentrate in areas of higher than average food quality (Fryxell *et al.* 2004), including aggregating on patches of grass regrowth following recent fires (Wisley 1996). Details of food plants, including seeds, in the more wooded southern parts of their range have been listed by Burt (1929) and use of the herb layer has been studied in detail, for Serengeti N. P., by Bell (1969, 1970, 1971).

Social and Reproductive Behaviour The social organization of Thomson's Gazelles is characterized by the occurrence of mixed herds ($\sigma\sigma$ and ♀♀), female groups (♀♀ with or without offspring), all-male groups (or 'bachelor' groups containing $\sigma\sigma$ of all age classes) and single territorial $\sigma\sigma$ (Brooks 1961, Walther 1964b, Estes 1967, Hvidberg-Hansen & de Vos 1971). The typical group size is 6–60 animals, but far larger groups of over 1000 animals may occur at some times (Jarman 1974). In Ngorongoro Conservation Area, Tanzania, female herds averaged 23 animals, compared with an average of 13 $\sigma\sigma$ in bachelor herds (Estes 1967). In Serengeti N. P., groups are larger on the short-grass plains than in tall-grass areas (FitzGibbon & Lazarus 1995), probably because of a change in food distribution and the difficulty of maintaining contact when visibility is restricted.

Mixed herds are typical during migration or may occur when a bachelor group intermingles with a group of ♀♀ . Females may be found on their own or in small groups when keeping watch over hidden young, and other gazelles have moved away. Bachelor groups tend to be found in more marginal areas, with the ♀♀ and young on the best habitat contained within the network of male territories (Estes 1991a). Social groupings of Thomson's Gazelles are very loose and open, especially during migrations and at high densities.

Reproduction is mainly carried out by the territorial $\sigma\sigma$ (Walther 1964b, 1968, Estes 1967). The ♀♀ roam their home-ranges and 'visit' the territorial $\sigma\sigma$, usually only for a few hours per day. The territories of $\sigma\sigma$ are usually between 10 and 30 ha in area and of irregular shape (Walther 1978a). However, they may be as small as 2.5 ha or as large as 200 ha (Walther 1978a). The territories are often close together. Non-territorial $\sigma\sigma$ are driven away when they happen to enter a territory.

Thomson's Gazelle *Eudorcas thomsonii* rear view.

Males mark grass stems and branches with their preorbital glands, depositing a dark sticky secretion at the tip of the object, and they urinate and defecate sequentially and in striking postures (Walther 1964b, Estes 1967). When a σ stays in a territory for some time, he may repeatedly urinate and defecate at the same spots, establishing dung piles. The creation of these dung piles and secretion marks serve to mark a territory, although non-territorial σ in bachelor groups may also perform these activities. It seems that it is the concentration of marks by one individual within a limited space that marks the territory. In one territory mapped (Walther 1978a), one or two dung piles were in the centre of the territory, with ca. 10–20 around the boundary. The secretion marks were also concentrated around the boundary (Walther 1978a), particularly in areas that bordered another male's territory. Territories are rarely defended for a whole year, at least in Serengeti N. P. (Walther 1978a). Once a territorial σ moves into an area, it takes ca. 1–2 weeks to fully mark the territory and territorial activity often declines after 3–5 months (Walther 1972a).

Territoriality is not limited to a particular season. A territorial σ may establish a territory, keep it and abandon it at any time of year. However, there are seasonal peaks in territoriality, linked to levels of reproductive behaviour. Walther *et al.* (1983) noted that, in Serengeti N. P., a peak reproduction period begins with the end of the small rains (usually mid-Dec) and is continued with some fluctuations until the end of the long rains in May. Another peak seems to be in Sep. However, there is considerable variation from year to year and from place to place, depending on local conditions (e.g. the onset and duration of the rains). Reproductive behaviour appears to be at its lowest from the beginning of Jun to mid-Aug.

Thomson's Gazelle *Eudorcas thomsonii*.

Males defend their territories with a range of agonistic behaviours (Walther 1978b). They may present their horns towards an intruder (horn threat), showing their intention to fight. If the other ♂ reciprocates, the interaction usually leads to a fight. Otherwise, the recipient simply walks away, sometimes followed by the challenger in a 'pursuit march'. Fights normally involve the clashing and occasionally locking of horns; body attacks are rare. Fights may be interspersed with and normally end with ritualized grazing, in which opponents graze facing each other, then parallel to each other and then facing in opposite directions (some or all of these positions may be shown).

Among adult territorial ♂♂ fights normally take place between neighbours, serving to establish territory boundaries. Non-territorial ♂♂ who happen to enter a territory normally leave, after the initial horn threat, and are then driven out in a pursuit march or chased away at a full gallop by the territory holder, sometimes with the chaser uttering a typical 'chasing call' through the nose ('pferr-pferr-pferr-'). Fights also take place between bachelor ♂♂, particularly if an oestrous ♀ comes close. The ♀ usually runs away as the ♂♂ begin to fight (Walther 1978b).

Males herd ♀♀ that come within range, attempting to prevent them leaving their territories, trying to head off those threatening to escape, and trying to ensure they remain towards the centre of the territory. A ♂ may be successful in the short term but rarely in the long term, particularly when a group of ♀♀ decides to move off (Estes 1991a).

A courting ♂ usually approaches a ♀ with the head and neck stretched forward (neck-stretch). Typically, this is followed by a nose-up movement; in the most extreme version, the nose, head and neck are pointed straight upwards towards the sky and the ♂ performs a rapid goose-step called the 'drumroll' by Walther. A ♀ driven by a ♂ normally urinates. The ♂ will then sniff the urine and perform flehmen, after which he may either lose interest in her or begin to court her intently, with repeated neck-stretch and nose-up movements. When following the ♀, the ♂ often kicks with his rather stiffly straightened foreleg in the direction of the female's hindquarters and may contact her hindlegs (laufschiag). Mounting and copulation normally takes place while the ♂ and ♀ are walking.

The ♂ normally mounts the ♀ several times before copulation. Occasionally, a ♂ may copulate with the same ♀ a second or even third time, at intervals of up to several hours (Walther 1978b). While non-territorial bachelor ♂♂ may occasionally court ♀♀ and even mount them, copulation was never observed in a three-year long study by Walther (1978b).

Female herds are usually unstable with continual exchange between those in adjacent territories (Estes 1991a). In one study in Serengeti N. P., ♀♀ moved around within home-ranges of 1–3 km diameter in separate herds (Walther 1973b). The home-ranges overlapped and when the herds met, they combined, exchanged members and often fragmented into subgroups. One large herd varied in numbers from 50 to 200 head and ranged over an area of ca. 10 km², encompassing the territories of some 24 ♂♂, sharing this range with three other female herds and one bachelor herd. The large herd met and mingled with the bachelor herd and with another female herd almost daily in late afternoon (Walther 1973b, Estes 1991a).

Although Thomson's Gazelles are gregarious animals, in the wild they rarely groom or interact closely. Even during copulation, the body contact between ♂ and ♀ is kept to a minimum (Walther 1977). Mutual grooming is largely limited to mothers and offspring (Walther 1977). The preferred distances between adjacent individuals is usually greater when grazing than when resting or moving, and greater between ♂♂ than between ♀♀ (Walther 1977). Females typically remain 1–3 m from other group members while moving together and resting, and >3 m apart when grazing (Walther 1977). Bachelor ♂♂ generally remain further apart, often 7–12 m apart when grazing. The spacing of territorial ♂♂ is dependent on territory size, from ca. 300 m down to 100 m at high densities.

Between birth and maturity these gazelles pass through a series of growth stages with behaviour characteristic of each age (Walther 1973a). Neonates (0–2 weeks) lie out, hidden in vegetation (which on the short grass plains may only be a small clump of grass), only joining the mother to suck and be cleaned. Juveniles of 3 weeks to 2 months still spend time lying out and join the mother to suck and be cleaned. However, increasingly they come out of 'hiding' and accompany the mother for more and more of the time. Juveniles begin to take solid food towards the end of this stage. By the time the young animal is half-grown (3 months to 4–6 months) the lying out period is over. The young may still rest more frequently and for longer periods than the adults, but they now participate in adult activities and move around with their mothers. Thus, half-grown young are in female herds or mixed herds. The young of this age have converted to solid food but may still try to suck, with or without success. Adolescents (5–8 months) of both sexes are for the most part weaned. Male subadults, ca. 8–12 (possibly up to 15) months, are not usually found in female herds, but instead are in all-male groups or in mixed herds. By the age of 16–24 months gazelles have become young adults, but full adulthood, particularly for ♂♂, seems to be reached at the end of the second year of life when they acquire full-length, double-arched horns.

Reproduction and Population Structure Females generally give birth to a single offspring (Furley 1986), after a gestation period of approximately 180 days (Bradley 1977). In Serengeti N. P., young are born throughout the year, but there is a birth peak during the wet season (Hvidberg-Hansen & de Vos 1971, Sinclair *et al.* 2000). Caro

(1994) recorded most ♀♀ with attendant neonates or juveniles in Serengeti N. P. between Nov and Mar. Females typically come into oestrus within two weeks of giving birth (Estes 1991a). Some ♀♀ may give birth to two offspring per year, as heavily pregnant ♀♀ have been seen with adolescents (4–8 months of age: Brooks 1961, Hvidberg-Hansen 1970), but it is not known if this is related to animal density. The age at which ♂♂ and ♀♀ can first breed in the wild is uncertain, but, in captivity, ♂♂ can breed at 16 months and ♀♀ have been reported to give birth at 18 months (Furley 1986). The oldest gazelle that has been found in the wild was 11 years old (Robinette & Archer 1971); captive animals have lived to 20 years (Weigl 2005).

The Thomson's Gazelle population in Serengeti N. P. appears to be strongly female-biased. In the early 1970s, only 36.8% of the adult population were ♂♂ (Bradley 1977), although the sex ratios at birth and adolescence (approximately 4–8 months) did not appear to differ from parity (Hvidberg-Hansen 1970, Bradley 1977). Robinette & Archer (1971) found that the west Kilimanjaro population only comprised 19.6% ♂♂. Comparing data from Brooks' (1961) study of free-ranging populations in Tanganyika with age-class distributions on a fenced, predator-free ranch in Kenya, Hvidberg-Hansen & De Vos (1971) demonstrated the effects of heavy predation on wild stocks with vastly increased survival on the ranch. Several other studies have also concluded that the bias results from differential predation, because a preponderance of adult ♂♂ is found in the prey of a number of predator species, in particular African Wild Dogs *Lycaon pictus* (Estes & Goddard 1967, Fanshawe & FitzGibbon 1993) and Spotted Hyenas (Kruuk 1972).

Predators, Parasites and Diseases Many predators prey upon Thomson's Gazelles. In Serengeti N. P., the larger predators, such as Cheetahs, African Wild Dogs, Spotted Hyenas and Lions *Panthera leo* take both adults and immatures (Kruuk & Turner 1967, Kruuk 1972, Schaller 1972, FitzGibbon & Fanshawe 1988, Fanshawe & FitzGibbon 1993), while jackals, baboons *Papio* spp., Martial Eagles *Polemaetus bellicosus* and Lappet-faced Vultures *Torgos tracheliotus* generally concentrate on young (Kruuk 1967, 1972, Wyman 1967, Walther 1969, Bradley 1977, FitzGibbon 1988).

Cheetahs are particularly specialized at hunting gazelles; on the Serengeti Plains gazelles make up ca. 66–89% of their diet (Schaller 1972, Caro 1994, Hunter *et al.* 2007), rather less in the woodlands (S. Durant pers. comm.). Caro (1994) calculated that predators kill between 51% and 82% of the estimated 73,000–86,000 adult gazelles recruited into the Serengeti population each year. In Nairobi N. P., McLaughlin (1970) estimated that Cheetahs killed 64–92% of the gazelles recruited into the adult population annually.

Much of the predation of Thomson's Gazelles is concentrated on immatures, particularly young under 2 months of age, which are not only vulnerable to a greater range of predators as a result of their smaller size, but also have poorly developed flight responses (Walther 1969). Predation on adult gazelles appears to be concentrated on ♂♂ (Estes & Goddard 1967, Walther 1969, Kruuk 1972, Schaller 1972, FitzGibbon 1990b), contributing to the female-biased sex ratio in the adult population (Bradley 1977). The reasons for the increased vulnerability of ♂♂ are unclear, although such male-biased predation rates are observed in a number of ungulate species. Males may be more vulnerable to stalking predators, such as Cheetahs, on

account of their tendency to be found in smaller groups, to remain in exposed positions and to be less vigilant (FitzGibbon 1990b). Male gazelles may also be in worse condition than ♀♀, predisposing them to predation, particularly by coursing predators. African Wild Dogs take more Thomson's Gazelles in poor condition than do Cheetahs (FitzGibbon & Fanshawe 1989).

Thomson's Gazelles rely primarily on flight and vigilance to avoid predation. Crypsis is of limited utility in open habitats (Jarman 1974) and competes with other behavioural adaptations, such as attracting mates (Owen-Smith 2002). Infants remain hidden for the first few weeks of life (see adaptations section), behaviour which minimizes their exposure to predators at a time when their ability to outrun them is minimal (FitzGibbon 1990c, 1994a). FitzGibbon & Lazarus (1995) calculated that hiding results in an increase in survivorship per year of at least 2.6% from decreased predation by Cheetahs alone.

While feeding, Thomson's Gazelles intermittently raise their heads about a metre from the ground to scan for predators, reducing the time available for foraging (Illius & FitzGibbon 1994). The level of individual vigilance behaviour declines with increasing group size, in shorter vegetation and when closer to their nearest neighbours. Females are more vigilant on average than ♂♂ (FitzGibbon 1988). Gazelles that are less vigilant than others in a group may experience higher predation rates, as Cheetahs tended to select less vigilant animals (FitzGibbon 1989). Although grouping enables gazelles to reduce their vigilance level, it does not necessarily result in improved predator detection (FitzGibbon 1988). However, it still reduces an individual's risk of predation, as a result of the dilution effect.

Compared with remaining in a smaller group of conspecifics, joining Grants Gazelles to form larger mixed-species groups has anti-predator advantages; the Thomson's Gazelles can 'share' vigilance to some extent with the Grant's Gazelles, leaving more time available for feeding. In addition, when hunted by Cheetahs, the Thomson's Gazelles are safer as a result of improved predator detection, the lowered success rate of hunts and the tendency for Cheetahs to avoid hunting such mixed-species groups (FitzGibbon 1990b).

If a Thomson's Gazelle sees anything unusual, it adopts the stare or alert posture (illustrated in Walther 1969) and in some cases it may also alarm-snort (only audible from distances of less than 50–100 m). Once a gazelle has detected a predator, it may not immediately flee but may wait until the predator approaches closer. The flight distance depends on the predator species and its speed of approach and appears to be adjusted to the risk posed by the predator. On fleeing from predators, gazelles often twitch their flanks, possibly to alert other gazelles (Brooks 1961, Estes 1967). If the predator does not chase, the flight usually ends after 200–300 m. On some occasions, the group, rather than fleeing, may actually approach the predator, following it from 50–100 m away for periods even exceeding one hour (average 14 minutes) (FitzGibbon 1994b). This so called 'fascination' or predator inspection behaviour is primarily observed in response to ambush predators such as Cheetahs, Lions and Leopards. It seems likely that this behaviour has a number of functions: informing the predators that they have been detected, causing stalking predators to move out of the vicinity, enabling gazelles to monitor the predators' movements and providing an opportunity, particularly for younger animals, to learn about predators (FitzGibbon 1994b).

When fleeing from coursing predators, like Spotted Hyenas and African Wild Dogs, which run down their prey with long, wearing

chases, the gazelles frequently stot, leaping in the air with legs held stiff and straight (Walther 1969, Caro 1986a, FitzGibbon & Fanshawe 1988). Such behaviour may inform the predators of the gazelles' ability to outrun them. Stotting rarely occurs in response to ambush predators, like Cheetahs and Lions, which stalk their prey and then run it down with short, very fast chases. Caro (1986b) suggested that the occasional stotting in response to Cheetahs may serve to inform these predators that they have been detected.

Thomson's Gazelles can outrun many predators, running at up to 80 km/h (Estes 1991a) but with a relatively slow acceleration of 4.5 m/s (Elliott *et al.* 1977). However, they lack the endurance of cursorial predators, beginning to tire after 1–2 km and are exhausted within 4–6 km, partly due to a 5–6° rise in body temperature (Walther 1969, Taylor & Lyman 1972).

When chased by predators, Thomson's Gazelles often change direction very sharply, particularly at the end of chases, when they jink from side to side, frequently causing their pursuers to overrun. If a young animal is chased, the mother may perform a similar behaviour, running backwards and forwards between the predator and her young, apparently trying to distract its attention (Kruuk 1972, Caro 1986b). In certain cases, she may even attack the predator, butting it with her head and horns. Although usually only one ♀ is involved (presumably the mother), up to three other ♀♀ (possibly also with young hidden nearby) may also join in. In the case of jackals, attack behaviour is likely to be more effective when there is only one jackal, compared with when there are two (Wyman 1967). Adult gazelles have never been reported to actively defend themselves.

If hidden juveniles are disturbed from their hiding place they commonly stot. This behaviour may inform mothers that their offspring have been disturbed and are in need of assistance (Caro 1986b). If actually chased by predators, the young animal may drop down, adopting a prone position. Predators have been observed to walk within 5–10 m (Kruuk 1972) of hidden juveniles without apparently noticing them. Adults have only rarely been observed to drop down when chased by predators.

No comprehensive review of the parasites associated with Thomson's Gazelles has ever been conducted; however, partial information from them and other gazelles is available. The susceptibility of gazelles to diseases and parasites varies from wild to captive populations, from dry to wet years, and can vary among wild populations with different conservation status. *Neospora caninum*, a parasite commonly found in domestic dogs, has been reported for Thomson's Gazelles (Ferroglia *et al.* 2003). Faecal egg counts conducted at Mpala Ranch in Kenya showed 525 internal parasite eggs per gramme of Thomson's Gazelle faeces in normal rainfall years and an increase to 1622 eggs per gramme of faeces in dry years (Ezenwa 2004b). Strongylida nematodes and coccidians were detected in faeces in a subsequent study and their prevalence increased with group size (Ezenwa 2004a). However, in studies of several threatened gazelles (Cuvier's Gazelle *G. cuvieri*, Dama Gazelle *N. dama* and Dorcas Gazelle *G. dorcas*), lower group size correlated with inbreeding depression contributed positively to nematode density in faeces (Cassinello *et al.* 2001).

Sarcoptic mange (*Sarcoptes scabiei*) caused by ectoparasitic mites has been reported for Thomson's Gazelles (Sachs & Sachs 1968, Bornstein *et al.* 2001) and ticks are commonly found in wild and captive populations (Olubayo *et al.* 1993). Isolates from Thomson's Gazelles have caused mild infections in cattle due to tick-borne

anaplasmosis (Potgieter & Stoltz 1994). Grooming, although rare in Thomson's Gazelles, is observed in captive ♀♀ (Mooring *et al.* 2004), suggesting the presence of mites and ticks.

The viral and bacterial diseases of Thomson's Gazelles are by and large those shared with other Bovidae, with again great variation between wild and captive populations. Rinderpest has been reported in wild populations (Plowright 1963). Other local diseases such as malignant catarrhal fever (Reid *et al.* 1975, Bedelian 2004) and lumpy skin disease (LSD) (MacOwan 1959) have not been found, although field tests and studies with zoo animals suggest that gazelles may be susceptible (MacOwan 1959, Griner 1983). Infectious bovine rhinotracheitis antibody has been reported for Thomson's Gazelles in Tanzania (Rweyenanu 1974, Rampton & Jessett 1976). In addition, antibodies to the bluetongue virus have been found in wild Thomson's Gazelles in Tanzania (Hamblin *et al.* 1990).

Conservation IUCN Category: Near Threatened. CITES: Not listed.

The species is protected in a number of national parks and protected areas. The core areas of the Serengeti–Mara population are protected by Serengeti N. P. and Masai Mara National Reserve, where wildlife tourism is the only permitted land use. The core areas are surrounded by buffer zones: Maswa G. R., Grumeti G. R. and Ikorongo G. R. to the south-west, Ngorongoro Conservation Area (NCA) and Loliondo Game Controlled Area (LGCA) to the south-east and the Mara Ranches (MR) to the north. The Game Reserves allow tourism and hunting, the NCA and MR allow tourism, settlement, livestock and cultivation but no hunting, and the LGCA allows all of the above and hunting (Thirgood *et al.* 2004). Poaching is a major concern in the west and north of the Serengeti–Mara ecosystem (Arcese *et al.* 1995a) and may, therefore, affect population levels. In Tanzania, Thomson's Gazelles are also protected within Tarangire N. P., although the park protects at most one-half of the annual home-range of local Thomson's Gazelles and excludes their breeding grounds (Voeten 1999). In Kenya, these gazelles are protected within Tsavo West and Hell's Gate National Parks and in Lewa Wildlife Conservancy, a conservation area owned and managed by a charity.

As noted already under Abundance, there is evidence from monitoring studies that some populations are declining. In the Serengeti ecosystem, the population of Thomson's Gazelles in Serengeti N. P., Tanzania declined by almost two-thirds over a 13-year period from 1972 to 1985. The population seems to have recovered to ca. 340,000 in 1996 and then declined sharply until the survey in 2003 at which time a small recovery was recorded. Runyoro and colleagues (1995) recorded a 63% decline in the Thomson's Gazelle population in the Ngorongoro Conservation Area between 1974 and 1992, which they attributed to the removal of pastoralists. A subsequent reanalysis of the most consistent data from that era has confirmed the decline (60% from 1978 to 1995) (Estes *et al.* 2006) and cites many complex reasons for it (water, tourist impacts, habitat modification due to exotic plant invasion, fire management and road development).

Measurements

Eudorcas thomsonii

TL (♂♂): 1219 (1135–1290) mm, n = 40

TL (♀♀): 1163 (1040–1246) mm, n = 18

T (♂♂): 231 (200–270) mm, n = 40
 T (♀♀): 221 (195–260) mm, n = 18
 HF c.u. (♂♂): 309 (290–325) mm, n = 40
 HF c.u. (♀♀): 292 (280–305) mm, n = 18
 E (♂♂): 111 (105–124) mm, n = 40
 E (♀♀): 110 (100–122) mm, n = 18
 Sh. ht (♂♂): 606 (570–655) mm, n = 40
 Sh. ht (♀♀): 578 (550–615) mm, n = 18
 WT (♂♂): 20.4 (17.5–23.4) kg, n = 40
 WT (♀♀): 16.2 (12.1–19.9) kg, n = 18

Serengeti N. P., Tanzania (Sachs 1967)

Kingdon (1982) notes that there is a north-to-south decrease in average measurements

Maximum recorded horn length is 43.8 cm for a pair of horns from Gurumeti, Tanzania (Rowland Ward)

Eudorcas albonotata MONGALLA GAZELLE

Fr. Gazelle de Mongalla; Ger. Mongallagazelle

Eudorcas albonotata (Rothschild, 1903). Nov. Zool., vol. 10, p. 480. East side of White Nile, 40 miles north of Kero or Kiri, Mongalla Province (Sudan).

Mongalla Gazelle *Eudorcas albonotata*.

Mongalla Gazelle *Eudorcas albonotata*.

Taxonomy Monotypic. The Mongalla Gazelle is usually regarded as a subspecies of Thomson's Gazelle *Eudorcas thomsonii* (Gentry 1972, Grubb 1993c), which in turn has been widely treated as conspecific with the Red-fronted Gazelle *E. rufifrons* (e.g. Groves 1985a, Kingdon 1997, East 1999; and see Rebholz & Harley 1999). Gentry (1972) and Grubb (2005) noted that skull and horn proportions associate *albonotata* with *rufifrons* rather than *thomsonii*. The species is to some extent intermediate between *E. r. laevipes* and the East African Thomson's Gazelle, and is similar in size to *laevipes*, but with a narrower skull and slightly longer rostrum (Groves 1969). Synonym: *albonota*. Chromosome number: not known.

Description The Mongalla Gazelle is a medium-sized gazelle, brown-coloured with a white belly and buttocks. Forehead entirely white and eyes surrounded with a white ring. Tips of ears pointed. Lateral band broad with a rufous shadow stripe beneath it. Knee tuft large. Tail short with hair all along its length. Horns short and prominently ringed in ♂, curved backwards and then slightly forward, and slightly in-turned at the tips. Female horns thin and straight, their length only 50% of the male's.

Geographic Variation It is possible that a small population of Mongalla Gazelles occurring north of the Sobat R. differs from the main population in the Sudd (Mefit-Babtie 1983). Because the latter appears to make a self-contained annual circuit on the eastern Sudd flood-plain, any possibility of a genetically distinct subpopulation around the Machar marshes merits further investigation.

Similar Species

Eudorcas rufifrons. A Sahelian species, occurring west of the Nile R. and absent in the Sudd ecosystem. Redder with face stripes buffy, if present at all, and black flank band very thin.

E. thomsonii. An East African species, present in S Kenya and N Tanzania. Smaller in size, with longer horns in ♂, forehead entirely red, black line running from the eyes to the nose and a black tuft on the tail contrasting with the buttocks.

Distribution Mongalla Gazelles inhabit the flood-plains and flat savanna grasslands in SE Sudan, east of the Nile R. (Hillman 1982, Hillman & Fryxell 1988, East 1999), but their normal range does not reach the Ugandan and Kenyan borders. The western margin of their

*Eudorcas albonotata*

range is close to Kongor and Ayod (about 31° E, 8° N), the eastern limits lying in the Anuak district of Ilubabor region, Ethiopia (34° E, 8° N). The current range is known to extend from Mongalla and Jebel Lafon in the south to the vicinity of Malakal between about 32° E, 5° N to 32° E, 10° N. There are gazelles north of the Sobat R., but these may belong to a distinct population that possibly ranges as far north as Renk. It is important to determine whether these gazelles belong to this species or not.

Habitat The Mongalla Gazelle lives mainly in open grassland (Hillman 1982, Hillman & Fryxell 1988). The dry-season range in Boma N. P. comprises open to light savanna woodland in which thatch grass *Hyparrhenia* spp. is associated with *Acacia zanzibarica*. The gazelles often aggregate in burnt areas with green flush (Hillman & Fryxell 1988). The wet-season range of the eastern Sudd flood-plains is savanna grassland with medium and tall grasses in low rainfall areas to the south of the National Park (Hillman & Fryxell 1988).

Abundance Using a crude sampling system, Watson *et al.* (1977) estimated the global population of Mongalla Gazelle at 300,000. A more intensive study conducted in the late dry season in Jonglei Canal area in S Sudan estimated 66,000 for about one-quarter of their total range (Mefit-Babtie 1983). Within this area the numbers of gazelles declined to about 1000 in the mid-wet season because of wholesale emigration out of the study area, to the east and south-east. In a still more limited sample, the Boma N. P. region hosted a little over 20,000 gazelles during peak periods (Hillman & Fryxell 1988). East (1999) suggested that the total population could number 100,000, but more recent survey work in S Sudan has shown this to be a significant underestimate, with nearly 300,000 animals estimated to occur, mainly in the southern section of the Jonglei and Boma N. P. (Fay *et al.* 2007).

Adaptations This gazelle is adapted to following a nomadic annual cycle over the eastern Sudd flood-plains, an ecologically peculiar region where extensive floods are followed by extreme aridity. A major reason why Mongalla Gazelles are able to inhabit a flood-plain that dries out during the dry season is that they do not need water for drinking and can withstand intense solar radiation (Hillman 1982). Their tolerance of insolation is tempered at the height of the dry season by most animals resting during the heat of the day, taking advantage of scanty shade under *Acacia drepanolobium* and occasional, scattered *Balanites* or *Piliostigma* trees (Mefit-Babtie 1983). Another major adaptive trait is that this species, like its close relative the Thomson's Gazelle, is a 'gleaner' (Vesey-Fitzgerald 1960, Brooks 1961). This is a strategy that relies on other, larger plains bovids, zebras, fires or cattle to flatten or remove rank (and for the gazelles, almost impassable) long grass and thus expose regrowth that they can eat. Which of these grass-removing agencies is most useful to the gazelles at any one time changes with the seasons (J. Kingdon pers. comm.).

In the eastern Sudd flood-plains there are two separate migration patterns, one being that of the White-eared Kob *Kobus kob leucotis*, the other that of the Tiang *Damaliscus lunatus tiang*. In both instances dense herds of these animals gather during the flood season and make localized movements on higher ground to the south and east of the flood-plains. In both instances the herds move north as the floods recede, only to return southwards as the waters rise again. The Tiang, as a flood-plain specialist, follows a westerly traverse, close behind the retreating waters and the largest herds often graze close to the Nile or to the deep, permanently flooded swamps that define the western and northern boundaries of the eastern Sudd flood-plain. A sizable proportion of the total gazelle population is known to follow the Tiangs for the earlier part of their migration and probably depends upon them even more during the height of the wet/flood season (Mefit-Babtie 1983). The White-eared Kob, on the other hand, favours very open, broad shallow valleys where fires and large numbers of grazers cut back the rankest of the grass. The White-eared Kobs follow a more easterly pattern of migration well away from the Sudd swamps, and Hillman & Fryxell (1988) documented a smaller number of gazelles associating with this eastern migration.

Mongalla Gazelles take advantage of both these larger species to process the sward for them but actively avoid getting caught up in dense herds of larger animals that are on the move. The gazelles are, therefore, 'camp followers', trailing a month or so behind the main herds, gleaned the regrowth that sprouts in their wake. However, as the dry season progresses the frequency and extent of fires increases and the gazelles' dependence on trampling and grazing to clear the long grass therefore declines. At this time, the gazelles, for the most part, cease to follow the Tiangs onto the 'Toic' (flooded grassland) pastures. By about Mar they can begin to spread out and drift north-eastwards (Mefit-Babtie 1983) and are probably at their most widely dispersed during Apr and May (see map opposite).

During the dry seasons of 1981 and 1982, between Dec and Apr, the movements of those Mongalla Gazelles that were following up the main body of migrating Tiang were recorded and mapped by means of aerial surveys, supplemented by observations on the ground. The gazelles were largely absent from the western part of their range between about May and Oct (Mefit-Babtie 1983).

and their occupation of distant eastern plain margins during the intervening months was confirmed by extensive questioning of local travellers. Because the wet, grass-growing season is the most problematic for the gazelles and assuming that they therefore intensify their 'gleaning' 'camp-follower' strategy throughout the wet season, their movements at this time can be tentatively extrapolated from the known wet/flood season ranges of the Tiang and White-eared Kobs (Mefit-Babtie 1983, Hillman & Fryxell 1988). How large a proportion of the entire population travels in the wake of the Tiangs has not been determined, but in 1981–82 it accounted for more than 60,000 animals. A reconstruction of this population's annual cycle of movement around a roughly circular traverse is shown here. It can be surmised that in the course of a year some individuals within these gleaning mobs of gazelle may travel close to the perimeters of virtually their entire flood-plain range. While the vast majority of Mongalla Gazelles follow some such circuit, a scatter of individuals and very small groups seem able to remain resident in proven favourable localities (J. Kingdon pers. obs.).

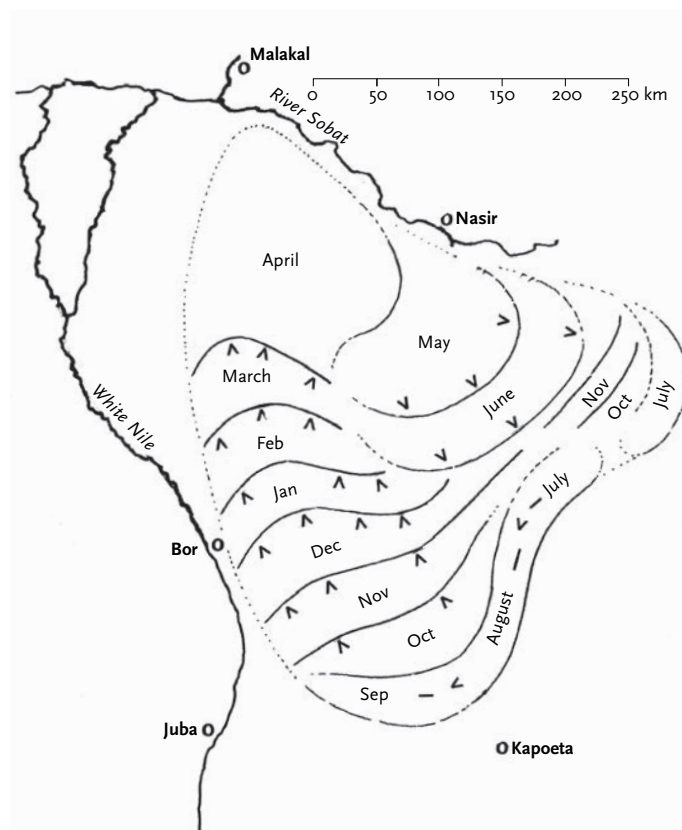

In summary, it would seem that Mongalla Gazelles are only able to survive the wet and flood seasons on the eastern Sudd flood-plain through their dependence on larger grazers. The adaptations to drought, which they share with other gazelles, only come into play during the dry season but, unlike water-dependent species, allow them to inhabit a large part of the flood-plain.

Foraging and Food The Mongalla Gazelle is mainly a grazer but also browses during the dry season when the nutritive value of herbaceous vegetation is very low; browsing comprises leaves and twigs of herbs and bushes (Hillman & Fryxell 1988). Very young *Hyparrhenia* regrowth appears to be an important part of the dry-season diet (Mefit-Babtie 1983).

Social and Reproductive Behaviour The Mongalla Gazelle is a social antelope. Groups of 10 to 50 are common (Hillman 1982) especially in prime feeding areas, i.e. burnt areas, where groups of more than 30 gazelles often occur (Hillman & Fryxell 1988). Females form groups of more than five individuals; young ♂♂ live in bachelor herds and adult ♂♂ are territorial (Hillman & Fryxell 1988). During the wet season, the Mongalla Gazelle aggregates in high population densities (several hundred per km²) with other migratory species such as White-eared Kobs, Tiangs and Plains Zebra *Equus quagga* (Hillman 1982, Hillman & Fryxell 1988).

Reproduction and Population Structure Besides the fact that most young are born in the early wet season from Apr to Jun (Hillman & Fryxell 1988), there is no information available.

Predators, Parasites and Diseases Mongalla Gazelles are taken by Lions *Panthera leo*, Cheetahs *Acinonyx jubatus* and hyaenas, but low numbers of these predators and large numbers of alternative prey buffer mortality to very small numbers. Eagles and the larger vultures may take the young. Diseases and parasites are a more significant factor. Prevalent parasites observed at post-mortem (Mefit-Babtie 1983) include nematodes (*Longistrongylus sabi*, *Trichuris glouloosa*, *Pneumostrongylus calcaratus*, *Skrjabinema tanganyikae*, *Setaria sculprum* and *S. boulengeri*), cestodes (*Cysticercus tenuicollis*, *Avitellina*

Mongalla Gazelle *Eudorcas albonotata* annual circuit over east bank of the Sudd flood-plain. Note dispersal over eastern portion of the flood-plain is less well known and might include a separate minor circuit by possible subpopulation(s) (from data gathered by Mefit-Babtie Srl wildlife studies team 1983).

centripunctata and *Taenia crocuta*) and pentastomid larvae. In the wet season a greater number of worms are found in the abdomen, small intestine and large intestine compared with the dry season. The species likely to be contributing to worm burdens are *Haemonchus contortus*, *Longistrongylus sabi*, *Oesophagostomum* or *Agriostomum* sp.

Mongalla Gazelle *Eudorcas albonotata* neonate.

Conservation IUCN Category: Least Concern. CITES: Not listed.

There are significant numbers in Boma N. P. (more than 20,000 animals; Fay *et al.* 2007) and in Mongalla G. R., but seasonal movements cause very large fluctuations in numbers. The population in the Boma ecosystem is apparently stable and not exposed to serious hunting pressure. The large population surviving in the Jonglei remains entirely unprotected. Part of the Mongalla Gazelle range is devoid of water in the non-flood season, making access to this part of their range by poachers difficult.

Measurements

Eudorcus albonotata

No reliable body measurements are available. Groves (1969, 1975) provides various skull measurements

Maximum recorded horn length is 35.6 cm for a pair of horns from Gemmeiza, Sudan (Rowland Ward)

GENUS *Nanger*

Greater Gazelles

Nanger Lataste, 1885. Actes Soc. Linn. Bordeaux 39: 183.

Grant's Gazelle *Nanger (granti) granti* rectilinear signal from rear.

Bright's Gazelle *Nanger (granti) notata* myology.

Externally, apart from the characteristic white haunch-wedge, *Nanger* gazelles are characterized at once by their very large size, and also by the fact that the rhinarium does not extend as far along the dorsal rim of the nostrils as in *Gazella* (although further than in *Eudorcas*). The pattern varies from contrastingly coloured in the gazelles of the Grant's Gazelle *N. (granti)* complex and in Soemmerring's Gazelle *N. soemmerringi* to almost completely white, with just a small pale reddish area on the head and neck, in some populations of the Dama Gazelle *N. dama*.

Like gazelles of the genus *Eudorcas*, the karyotype has both an X-autosome and a Y-autosome translocation (Effron *et al.* 1976, Vassart *et al.* 1995).

Unlike the two genera of small-bodied gazelles, which though they overlap in distribution have distinct ecological contexts, species of *Nanger* are very diverse in their ecological settings. Gazelles of the *Nanger (granti)* complex live in the East African savanna, and extend north-east into the southern part of the Somali Arid zone; in the northern part, they are replaced by Soemmerring's Gazelle, which extends north of the Ethiopian Highlands, including some fairly arid country; while Dama Gazelle is quite different, living in extremely arid environments in the southern Sahara, extending into more

Bright's Gazelle *Nanger (granti) notata* adult female.

mesic environments only in the north-westernmost part of its range, in S Morocco.

Colin Groves

Nanger (granti) GRANT'S GAZELLE SPECIES GROUP

Taxonomy In the current work Grant's Gazelles, traditionally classified as a single species, are treated as a species group comprising three distinct species, based on the level of genetic differentiation among them. This complex belongs, together with Soemmerring's Gazelle *N. soemmerringi* and the Dama Gazelle *N. dama*, in the genus *Nanger* (Haltenorth 1963, Lange 1971, Groves 2000).

Arctander *et al.* (1996) studied the structure of Kenyan populations of Grant's Gazelles. They sequenced 371 nucleotides of the maternally inherited mitochondrial d-loop from 44 individuals and found an extreme genetic divergence among three population groups. A broader study by Lorenzen *et al.* (2008) increased the sample size to 178 individuals from 17 locations in Kenya and Tanzania (constituting the main distribution range of the species). This extended study confirmed the existence of three distinct population groups and, except in one case, the three groups had DNA sequences that were not found in any of the other groups (see Geographic Variation). The genetic distance between *N. (g.) petersii* and each of the other two groups was 12%. This was as large as the distance to their closest relative, the Soemmerring's Gazelle. The genetic distance between *N. (g.) granti* and *N. (g.) notata* was 8%, suggesting a closer relationship. Of the total amount of genetic variability found in the samples, 74% was found between groups. This, together with allopatric or parapatric distributions, and an almost completely disjunct distribution of highly diverged DNA sequences, has confirmed the need to raise the three groups to species level. This had been mooted in some older literature for *N. petersii* (Heller 1913a), the group which shows the highest divergence morphologically as well as genetically. In spite of such acknowledged differences, most recent works, including Kingdon (1997), have treated them as allopatric subspecies.

Genetic variation within the three species also varies. *Nanger (g.) granti* and *N. (g.) notata* have nucleotide diversities of 3.2% and 4.1%,

respectively, which is comparable with the level observed in other bovids (Simonsen *et al.* 1998, Arctander *et al.* 1999, Nersting & Arctander 2001). On the other hand, *N. (g.) petersii* has a lower level of nucleotide diversity, 1.6%, which might reflect smaller long-term population sizes.

Gazelles are characterized by extensive rearrangements of chromosome arms through Robertsonian fusions. Diploid chromosome numbers range from 30 to 58 with a constant number of autosomal arms of 56–58 (Vassart *et al.* 1995). Fifty-eight autosomes and 2 sex chromosomes is considered to be the ancestral state in Bovidae (Gallagher & Womack 1992). As with many other African gazelles, an autosome/X-chromosome translocation has taken place, resulting in different chromosome numbers among the sexes. Effron *et al.* (1976) reported that a *N. (g.) granti* ♀ had a diploid number of 30, i.e. 28 metacentric autosomes and 2 large sub-metacentric X chromosomes. Males had 31 chromosomes, 28 autosomes, 1 X chromosome and 2 small acrocentric Y chromosomes, Y1 and Y2 (Effron *et al.* 1976, Gallagher & Womack 1992).

The different species in the complex are expected to differ in their karyotypes (as has been noted for the other species in the genus *Nanger*). In *N. dama* the subspecies *N. d. ruficollis* and *N. d. mhorri* differ in their diploid chromosome number having $2n = 38$ and $2n = 40$, respectively. *Nanger soemmerringi* is even more variable, with diploid chromosome numbers varying between 34 and 39 (Benirschke *et al.* 1984). In the latter the chromosome variability is accompanied by poor reproductive success, suggesting post-zygotic isolation mechanisms are important in the speciation within this group.

A number of subspecies have been described based on horn shape and colouration, nine of which were recognized by Haltenorth (1963) and Gentry (1972). Due to poorly known ranges, variability

of the traits within populations across species and lacking genetic evidence, we do not go into detail with them here. Synonyms: *N. (g.) granti*; *robertsi*, *roosevelti*; *N. (g.) notata*: *brighti*, *raineyi*, *lacuum*; *N. (g.) petersii*: *gelidjiensis*, *serengetae*

Description Tall, pale gazelles with long, upright horns above relatively small eyes, set in highly characteristic, black, leaf-shaped eye patches. They are characterized by having a substantial white rump patch. The rump patch matches the underside, which is white like the throat and inner sides of legs. The rump patch is accentuated by dark thigh-stripes. Flank-bands are common in young and ♀♀, often disappearing with age. In ♂♂ the flank-bands disappear earlier, except in the Laikipia region of Kenya (Bright's Gazelle) and perhaps other populations that are allopatric with Thomson's Gazelle *Eudorcas thomsonii* (R. Estes pers. comm.). Colouring of the upper side varies from pale, reddish-brown to dark brown. Tip and underside of the tail is dark, with a black tuft.

On the face, a white band extends from the horns, in front of the eye down to the small muzzle. The black mask that surrounds the eye extends tenuously down towards the mouth. The relatively long ears are lancet-shaped. Preorbital glands are vestigial. Glands are present between the hooves and on the knees; ♀♀ have a pair of inguinal nipples with a striking black and white pattern. Males have long horns with 20–30 rings; horns in ♀♀ are shorter, with 15–20 rings.

Geographic Variation Although it has long been regarded as a single species, we consider Grant's Gazelles as a species complex comprising three genetically distinct, broadly allopatric species. Past climatic fluctuations have influenced the isolation, diversification and distributions of the three species. In response to changes in vegetation and habitat, contact zones between the gazelles have shifted geographically over time.

Nanger (granti) granti GRANT'S GAZELLE

Fr. Gazelle de Grant; Ger. Grant-Gazelle

Nanger granti (Brooke, 1872). Proc. Zool. Soc. Lond. 1872: 601-602. Tanzania, 'Western Kinyenye, in Ugogo'.

Grant's Gazelle *Nanger (granti) granti*.

Lateral view of skull of Grant's Gazelle *Nanger (granti) granti*.

The species is named for Colonel James Grant, the Scottish naturalist and explorer.

N. (g.) granti species: distributed from the north bank of the Ruaha R. in C Tanzania to Kenya south of L. Baringo and Mt Kenya, and from L. Victoria in the west to Voi R. in Tsavo in the east. Has a dark, triangular patch on the nose and an undivided white rump patch, leaving the upperside of the tail white. Horn shape is highly variable, and horn spans range from 26 to 66 cm (Grubb 2000).

The genetic profiles of populations from Masai Mara and Serengeti revealed a genetic distance of ~1% between these and populations further east. This could support the validity of two previously described subspecies *N. (g.) g. granti* and *N. (g.) g. robertsi*. However, as the genetic data were inconclusive we do not consider the subspecies well authenticated.

N. (g.) g. granti: distributed from the Ruaha R. through NE Tanzania to Kenya south of Mt Kenya, across the plateau west of Voi in Tsavo and up the Rift Valley as far as L. Baringo. The horns are lyrate, spreading evenly with the tips approaching each other. The horn span is about 36 cm, with a range from 26 to 48 cm (Grubb 2000).

N. (g.) g. robertsi: limited to NW Tanzania and SW Kenya, immediately east of L. Victoria. Horns are very distinct; their spread is wide and they curve outward with the tips turning backwards. The horn span has an average of about 50 cm, with a range from 34 to 66 cm (Grubb 2000).

Nanger (granti) notata BRIGHT'S GAZELLE

Fr. Gazelle de Bright; Ger. Bright-Gazelle

Nanger notata (Thomas, 1897). Proc. Zool. Soc. Lond. 1897: 53-54. West slope of Lorogi Mts, Kenya Colony.

Bright's Gazelle *Nanger (granti) notata* female.

Lateral view of skull of female Bright's Gazelle *Nanger (granti) notata*.

Nanger (g.) notata species: distributed from NE Uganda to S Somalia with a range that surrounds L. Turkana and extends across the very arid regions of N Kenya. A belt of uplands and forest is thought to have separated Grant's Gazelle from Bright's Gazelle (Simon 1962, Stewart & Stewart 1963). It differs from Grant's Gazelle in having more parallel horns, but is otherwise similar in rump pattern and nasal spot. Horn span is ~24 cm with a range of 18–32 cm that overlaps with Grant's Gazelle. It is, therefore, not possible to allocate individuals to the correct species based on horn shape alone (Grubb 2000). There is variation in the tonal contrast of flank- and pygal-bands within the species. Individuals from the Lorogi plateau in the southern part of the range (the type locality for this species) are at the darkest end of the colour spectrum. They have longer pelage and both pygal- and flank-stripes are often present in mature animals of both sexes.

The vernacular name Bright's Gazelle derives from a supposedly smaller subspecies *brighti* (named for Colonel R. G. T. Bright who collected the first specimen), which was thought to be distributed west of L. Turkana as far as NE Uganda and SE Sudan. Another previously recognized subspecies, *raineyi* – locally known as Rainey's Gazelle – was thought to range east of L. Turkana in very arid country. Yet another named subspecies, *lacuum*, was described from Ethiopia and was supposedly distinguished by the absence of side stripes. Populations distributed east of L. Turkana are genetically differentiated from the remaining populations, but due to small sample size, the data are judged as insufficient to warrant their classification into distinct subspecies (Lorenzen *et al.* 2008).

***Nanger (granti) petersii* PETERS'S GAZELLE (TANA GAZELLE)**

Fr. Gazelle de Peters; Ger. Peters-Gazelle

Nanger petersii (Günther, 1884). Ann. Mag. Nat. Hist., ser. 5, 14: 425–429. Gelidja near mouth of Osi and Tana Rivers, Kenya Colony.

Nanger (g.) petersii species: the most distinctive species within the *Nanger (granti)* species complex. Two characteristics distinguish it from the others: the fawn-brown body colouring extends back onto the tail – a feature that links it with non-*Nanger* gazelles and is presumably conservative – and the lack of a triangular nose patch (indeed, the facial colouring is altogether somewhat bleached). The relatively short and straight horns are not easily distinguished from those of Grant's Gazelle, but Grubb (1994) regarded them as less developed than in the other two species. Peters's Gazelle is distributed in E Kenya from the lower Tana Valley to west of the Juba R. in Somalia (Kingdon 1997). This species has recently extended its range to most of Tsavo East N. P. in Kenya.

LEFT: Peters's Gazelle *Nanger (granti) petersii*.ABOVE: Lateral view of skull of Peters's Gazelle *Nanger (granti) petersii*.

The border between Bright's Gazelle and Peters's Gazelle is primarily defined by elevation and also by differences in vegetation, with Bright's Gazelle preferring higher, more wooded country than Peters's Gazelle. Within Tsavo N. P. in Kenya, the former comes into close contact with the latter (Leuthold 1981). This contact is recent and is the result of range expansion, possibly by both species.

The *Acacia–Commiphora* woodlands formerly acted as a barrier between Peters's Gazelle and Grant's Gazelle. A relatively small and scattered Peters's Gazelle population was reported to be virtually surrounded by dense vegetation barriers to the south and west of their range during the nineteenth century (Leuthold 1981, I. Parker pers. comm.). The transformation of the *Acacia–Commiphora* woodland to more suitable open grassland (under the influence of elephants, fire and charcoal burning), expanded the distribution of Grant's Gazelle and increased the relative abundance of Peters's Gazelle; road counts on the Galana Ranch from 1963 and 1981 recorded a fourfold increase in the proportion of Peters's Gazelles prior to and after the destruction of *Acacia–Commiphora* (Parker 1983).

In the extended genetic study that confirmed the existence of three species within Grant's Gazelles, one mitochondrial DNA sequence from an individual Grant's Gazelle from Mkomazi G. R., Tanzania, grouped with the sequences from Peters's Gazelle. This horizontal

transfer of the maternally inherited genome between the two species suggested hybridization had taken place. If the *Acacia–Commiphora* woodland had presented a barrier to gene flow, Peters's Gazelle and Grant's Gazelle had come into contact following the thinning of the woodland.

That the Peters's Gazelle genotype may have extended to the south is further implied by the existence of an additional form *serengetae* (Heller 1913a) (from Taveta, on the eastern foothills of Mt Kilimanjaro, not the Serengeti N. P. area). Characterized by the back colour extending dorsally in a narrow stripe onto the tail, Grubb (1994) noted that this characteristic might have been the result of hybridization between Grant's Gazelle and Peters's Gazelle (in the individual's immediate, or earlier ancestry) as both locality and morphology suggested an intermediate condition between the two species.

Similar Species

Nanger soemmerringi. Allopatric, but ranges are close in Ethiopia.

Smaller, paler and with a characteristic horn form: short, lyrate, back-swept and with tips curling out and then sharply inwards.

Eudorcas thomsonii. Sympatric, with ranges overlapping in Tanzania and C and SW Kenya. Smaller, shorter-legged gazelle with brighter, redder back and bold black flank-stripe. Estes (2000) considers the

colouration of Grant's and Thomson's Gazelles as an example of character displacement, serving to distinguish sympatric populations and discourage interbreeding.

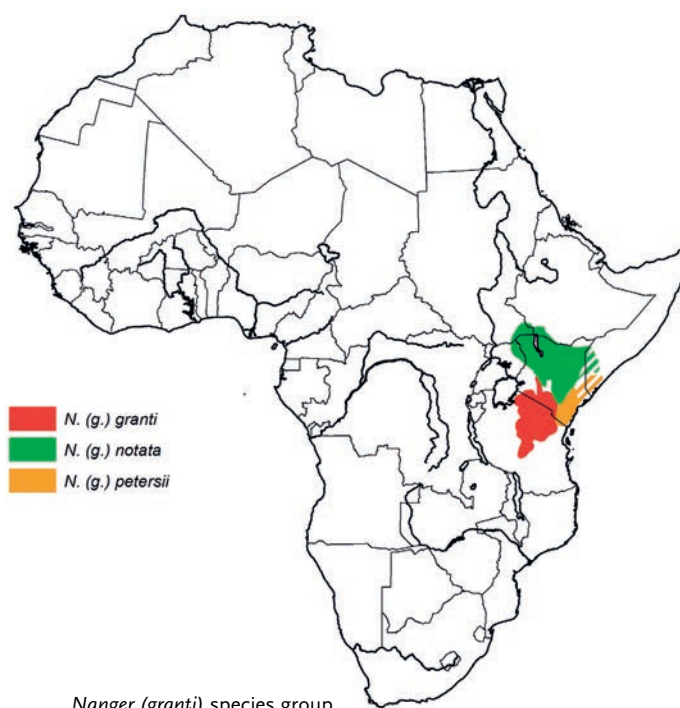

Distribution Endemic to Africa. The Grant's Gazelle species complex ranges from NE Uganda to Somalia and from S Ethiopia and SE Sudan to C Tanzania. The details of each species' distribution are discussed in the previous and following sections.

Habitat The habitat of all species encompasses open savannas and extends into the hot, arid semi-desert regions (Taylor 1970a). In more densely bushy country the gazelles are restricted to glades or open, scrubby valleys. They do not tolerate soft soils but inhabit, if only seasonally, longer grass than most other gazelles. Their distribution coincides with rain shadows and with an arid corridor of unstable climate across the East African plateau that is known to have been much more arid in the past (Kingdon 1997). Grant's Gazelle inhabits open, dry plains and open savannas, including some high, cool uplands. Its habitat is typified by the plains and savannas of Serengeti. N. P. Peters's Gazelle is essentially a lowland species and in the Tana R. delta lives on very flat plains that are periodically flooded. A large part of the range of Bright's Gazelle is very dry, but it periodically inhabits cool upland savannas and semi-deserts. In more south-eastern parts it tolerates more wooded country than the other species.

Adaptations These gazelles are adapted to life in a hot, semi-arid environment and can survive without drinking. Taylor (1968a) followed a herd of Bright's Gazelles for four days during which they apparently did not drink. They eat predominantly at night, and the water available in their food renders them nearly independent of surface water. In the course of nearly four decades of work in the Ngorongoro Conservation Area, R. D. Estes (pers. comm.) has only once seen a Grant's Gazelle drink. The gazelles tolerate very high body temperatures, and let their body temperature increase and exceed air temperature when water is in short supply. If body temperature exceeds that of the air, heat flows from the body to that of the surroundings, thereby avoiding evaporative cooling (such as panting) and dehydration (Taylor 1970a). At 45 °C dehydrated animals had rectal temperatures exceeding the air temperature by 0.5–2 °C. Such high temperatures would be lethal in most mammals, but result in large water-savings in this species (Taylor 1970b).

Abundance Kenya and C and N Tanzania are the core areas of the *Nanger (granti)* species complex. Kenya supports the largest number of individuals, around 100,000, although the country has lost >50% since the 1970s. Although numbers have been diminished due to poaching and competition from livestock and most of the larger populations are in gradual decline, the species complex remains widespread within and outside protected areas. Correcting for undercounting bias in aerial surveys, East (1999) estimated the total population size of the entire species group at about 350,000, of which one-third are found in protected areas.

The largest population of Grant's Gazelles occupies the Serengeti ecosystem and the Tarangire area, with estimates of 26,020 and 8060, respectively (TWCW *et al.* 1997). Smaller populations have been recorded from Mkomazi G. R., unprotected rangelands of Narok and Kajiado, and the Masai Mara region. Although a number of the

populations have experienced declines (e.g. the Mara; Ogotu *et al.* 2011), the population size of this species probably exceeds 75,000.

In Uganda and Sudan, Bright's Gazelle has been reported to have decreased considerably. The latest survey in Uganda, in 1995, found it only in the southern part of Karamoja, with an estimated population of 150 (Von Richter *et al.* 1997). Surveys in S Sudan in the 1970s and 1980s estimated the population at 15,000 (including 3000 in Boma N. P.). Recent surveys in S Sudan estimated the total population in Boma N. P. at ca. 2500 (Fay *et al.* 2007). In Ethiopia, the species is mainly confined to the extreme south-west and the estimate of 6340 was considered stable (Schloeder *et al.* 1997, East 1999). The largest populations of this species are found in Kenya's rangeland districts: Turkana (8750), Marsabit (21,160), Samburu (2490) and Isiolo (9740) (Butynski *et al.* 1997a). Total population size is in the order of about 50,000 animals.

The total population size of Peters's Gazelle in the rangelands of Wajir, Garissa and Tana R. has been estimated at 12,120 (Butynski *et al.* 1997a). In Tsavo, south Kitui, Ngai-Ndeithia and protected areas, some 3300 animals have been recorded. These numbers probably include Bright's Gazelle in the northern part and Grant's Gazelle to the south. The population size of Peters's Gazelle is probably less than 15,000.

Recorded population densities for the species group estimated from aerial surveys range from 0.04 to 3.8/km² in Amboseli N. P., while estimates obtained by ground counts in areas where the species is common range from 1.0 to 3.7/km² (East 1999, and references therein).

Foraging and Food These gazelles are mainly browsers, borne out both by direct observations and analysis of stomach contents, as well as studies involving stable carbon isotope analysis (Cerling *et al.* 2003). Averaged over a year, 69% of the analysed rumen content of ♀♀ (n = 51) from Longido G. R., Tanzania, was categorized as browse and 27% was considered graze (Spinage *et al.* 1980);

male stomachs ($n = 18$) had a higher fraction of browse (86%). The amount of browse was correlated with the amount of rainfall (Spinage *et al.* 1980).

Hofmann (1973) has characterized Grant's Gazelle as a seasonally adapted, intermediate feeder, preferring herbs and shrub foliage. During the dry season, and while grass is tall and rank, *Solanum*, *Indigofera*, *Sida* and *Disperma* have been recorded as common foods. Fruits of *Balanites*, *Solanum* and *Calotropis* have also been recorded. Among grasses, *Cynodon* and *Harpachne schimperi* are taken in the early rains as is the early growth of *Hyparrhenia* and *Themeda*, although these are generally avoided at later stages of their growth (Kingdon 1982).

Talbot (1962) drew attention to some preferred foods that were typical of abused, overgrazed ranges. Sinclair & Norton-Griffiths (1979), noting an increase of these gazelles in Serengeti N.P. from 30,000 in 1967 to 52,000 in 1978, attributed this increase to the expansion of Common Wildebeest *Connochaetes taurinus* that had reduced competition from grasses and therefore benefited herbs, thereby increasing the food supply for Grant's Gazelles.

In Serengeti N. P., some Grant's Gazelles make seasonal movements, while others remain behind (Walther 1972b). Sometimes movements reverse those of other species and the gazelles are found in drier areas; this possibly reduces competition for food (Estes 1991a). A major part of the population probably joins other migrants back onto the open plains during the wet season (Estes 1991a) and move to bushier areas in the dry season. Grant's Gazelles are the last to leave the plains in the dry season (Walther 1972b).

Social and Reproductive Behaviour Studies on social structure have been carried out on Grant's Gazelle in Serengeti N. P. and the Ngorongoro Conservation Area (Walther 1965, 1972b, Estes 1967, 1973) and have been summarized by Estes (1991a). Group sizes and composition varied with habitat and season. In Serengeti N. P., mixed herds of ♂♂ and ♀♀ constituted a large fraction of groups on the open plains (49%), but a much smaller fraction in the woodland (12%). The proportion of solitary ♂♂ was similar in the two habitats (14%) whereas single ♂♂ with female groups comprised 16% in the open plains and 34% in the woodlands. Herds of ♀♀ alone made up 8% on the plains, 7% in the woodland and ♂♂ alone constituted 20% on the plains, 15% in woodland. Herd size differed in the two habitats. The largest herds are found out on the open plains. In bush areas the largest size recorded was 40, whereas 26% of all herds on the plains exceeded that number, with an upper limit of more than 400 individuals. Large associations were not stable; they broke up into smaller units within a couple of hours. The latter author attributed the differences in group size between habitats to the difficulty of maintaining visual contact in the bush area. The size of other social groups averaged 4.6 for bachelor ♂♂, 6.1 for ♀♀ and 9.6 for harem herds (Walther 1972b).

Sexually mature ♂♂ of Grant's Gazelle form territories in Serengeti N. P., on which they stay from Dec/Jan to Jun/Jul. During this time they acquire harems of 10–25 ♀♀, mostly in open areas surrounded by woodland. Below a minimum of 10 ♀♀, they tend to leave and search for larger groups. An upper limit of about 20–25 may be determined by the ability of a ♂ to keep the ♀♀ on his territory. Harems are 'half open' groups in which ♀♀ can move into, but less easily out of, a male's territory (Walther 1972b). Females do not maintain territories, but may be restricted to an area by territorial

Grant's Gazelle *Nanger (granti) granti*.

♂♂. Sizes of territories range from a diameter of 300 m (Walther 1965) to 600 m (Estes 1967) in the Ngorongoro Crater, but a diameter of 1–2 km in Serengeti N. P. (Walther 1972b).

The territorial behaviour of Grant's Gazelles differs from that of Thomson's Gazelles: Grant's Gazelles regularly horn long grass and rely on linked urination–defecation for scent-marking, whereas Thompson's Gazelles mark with their preorbital glands. Grant's Gazelles pursue ♀♀ far less vigorously than Thompson's Gazelles, probably due to their much larger territories. A conspicuous trait of Grant's Gazelles is lying alone where their presence is obvious, visually advertising their territorial status. Grant's Gazelles use head-flagging in their dominance display, whereby the head is abruptly turned from side to side, perhaps to advertise the neck development characteristic of adult ♂♂. This behaviour is not found elsewhere in the Antilopini (Estes 1967, 1991a).

On the open plains of Serengeti N. P., mixed herds are typical of Grant's Gazelle. They have home-ranges of up to 5 km in diameter, in which they move in daily circuits. The home-ranges of different groups may overlap and individuals may switch from one to another. During daily circuits herds may enter male territories in which they may remain for some hours. Male territory holders show dominance displays toward other ♂♂ and monopolize all copulations (Walther 1972b).

Less is known about the social structure in the other species of the species complex. Peters's Gazelle has been studied by Leuthold (1981) in Tsavo East N. P., both north and south of the Voi R. Group sizes scarcely differed between the two areas, but those in the south averaged 4.7, those in the north 3.7. Group sizes did not vary between rainy and dry seasons. For the ♂♂, about one-quarter to

one-third were found in all-male groups, the rest in groups consisting of one ♂ with several ♀♀ or in mixed groups with several individuals of each sex. All-female groups were less than 20% of the individuals and groups with a single ♂ were more common (Leuthold & Leuthold 1975a).

Females indicate receptiveness by straightening the tail horizontally. The ♂ follows or approaches with his tail in a similar position, neck vertical and nose lifted. He walks in a stiff-legged manner and performs low-amplitude goose-stepping, kicking with his forelegs (cf. Thomson's Gazelle). Having been followed for a while, the ♀ also slows to a walk and may then toss her head back and to the side, indicating receptivity. Shortly after this the ♂ mounts, standing and walking on two legs in an almost vertical position (Walther 1972b), because the ♀ keeps walking, a gazelle trait.

Reproduction and Population Structure Females start breeding at 1.5 years of age, whereas ♂♂ mature at three years (Estes 1991a). Gestation in captive ♀♀ has been reported at 198–199 days ($n = 3$) (Furley 1986). Grant's Gazelles give birth to offspring throughout the year with a peak in Dec–Feb and another in Aug and Sep. The first peak is within or after the short rains, the second in the dry season (Estes 1991a). In Karamoja, Bright's Gazelle ♀♀ gave birth in Nov/Dec and in Jun (Kingdon 1982). Twin births have not been recorded. Grant's Gazelles in captivity have been reported to live to 19 years (Weigl 2005).

Predators, Parasites and Diseases In Serengeti N. P., larger predators, such as Lions *Panthera leo*, Leopards *P. pardus*, Cheetahs *Acinonyx jubatus* and African Wild Dogs *Lycaon pictus* regularly prey on these gazelles although the gazelles only make up a minor fraction of the prey species. This is in contrast with Thomson's Gazelles, which are the main prey of Cheetahs and African Wild Dogs (Estes 1991a, Caro 1994). Because they drink infrequently this may help protect them from some of the larger predators, which tend to hunt closer to watering places. Golden Jackals *Canis aureus* and Black-backed Jackals *C. mesomelas* are major predators of gazelle young. These may be defended by the mother, often successfully when a single jackal attacks. Quite often, particularly in maternal groups, a second ♀ may join the defence (Estes 1991a, Walther 1995).

Conservation IUCN Category: Least Concern. CITES: Not listed.

Considering that some populations have decreased substantially over the last 30 years and that this has affected the three species differently, the conservation status for each of the three species requires re-evaluation. Grant's Gazelle seems to be relatively well protected and secure since a substantial fraction of its population is found in protected areas, such as Serengeti N. P., Tarangire N. P., Mkomazi G. R. (Tanzania), and Masai Mara National Reserve, and Lake Nakuru, Amboseli and Nairobi National Parks (Kenya). Bright's Gazelle has a lower fraction of its population in protected areas. Peters's Gazelle has the lowest population size, probably below 15,000, and since Tsavo N. P. (where numbers were declining in the 1990s) and Tana River National Reserve are the only protected areas within its range, this species might be more vulnerable than the other two species.

Measurements

Nanger (granti) species group

N. (g.) granti

TL (♂♂): 1646 (1580–1750) mm, $n = 9$

TL (♀♀): 1575 (1507–1635) mm, $n = 7$

T (♂♂): 310 (280–350) mm, $n = 9$

T (♀♀): 289 (267–305) mm, $n = 7$

HF c.u. (♂♂): 444 (433–455) mm, $n = 9$

HF c.u. (♀♀): 409 (400–425) mm, $n = 7$

E (♂♂): 153 (150–158) mm, $n = 9$

E (♀♀): 154 (150–157) mm, $n = 7$

Sh. ht (♂♂): 888 (865–915) mm, $n = 9$

Sh. ht (♀♀): 803 (745–835) mm, $n = 7$

WT (♂♂): 61.7 (53.2–70.1) kg, $n = 9$

WT (♀♀): 42.5 (40.0–45.9) kg, $n = 7$

Serengeti N. P., Tanzania (Sachs 1967)

Maximum recorded horn length for the three forms are as follows:

N. (g.) granti, 80.6 cm for a pair of horns from Kimali, Tanzania; *N. (g.)*

notata, 74.6 cm for a pair of horns from Kameube, Kenya; and *N. (g.)*

petersii, 69.5 cm for a pair from Voi, Kenya

Nanger soemmerringi SOEMMERRING'S GAZELLE

Fr. Gazelle de Soemmerring; Ger. Sömmerring-Gazelle

Nanger soemmerringi (Cretzschmar, 1828). Rüppell, Atlas Reise Nordl. Afr. Zool., Saugeth., p. 49, pl. 19. 'an dem östlichen Abhange Abyssiniens' (E Ethiopia); since restricted to 'Tal E'Sabb, Abyssinia' (Ethiopia, El Shab Valley).

Soemmerring's Gazelle *Nanger soemmerringi*.

The species is named after Samuel Thomas von Soemmerring (1755–1830), a Polish scientist skilled as an electrician and in anatomical work.

Taxonomy Soemmerring's Gazelle is here included in the genus *Nanger*, together with the Grant's Gazelle *N. (granti)* species group and Dama Gazelle *N. dama* (Groves 2000). Gentry (1972) listed six subspecies, noting that two subspecific names would probably suffice, namely *soemmerringi* and *berberana*. Currently, there are three recognized subspecies (Groves 1985a, Kingdon 1997, Grubb 2005). Synonyms: *berberana*, *butteri*, *casanovae*, *erlangeri*, *sibyllae*, *typical*. A study of the chromosomes of seven male and 20 female Soemmerring's Gazelle found 12 different karyotypes with chromosome numbers varying between $2n = 34$ and $2n = 39$. The variability is due to a Robertsonian chromosome system of fusions operating to make three metacentric pairs from six acrocentric pairs. The reason for this karyotypic variability is likely not due to hybridization and it is not yet known whether the poor reproductive success of the species is related to this chromosomal polymorphism (Benirschke *et al.* 1984; and see Vassart *et al.* 1995). There is no evidence as to whether the karyotypic variability might be related to geography or subspecies (C. Groves pers. comm.).

Description One of the larger gazelles, uniformly pale fawn in colour on its upper side, and bright white on the entire underside

Lateral view of skull of Soemmerring's Gazelle *Nanger soemmerringi*.

of the body, inside of legs, back of hindlegs and tail. The transition from fawn to white occurs abruptly along the flanks and upper edges of the rump. The face has several distinctive markings including a dark muzzle, a dark stripe running down the nose to the muzzle, a white stripe parallel to the dark nose-stripe, and a black stripe passing through each eye and ending at the muzzle. The tail is short and tapered, and tipped with black.

Both sexes have backwards-bent lyrate horns with inward-facing tips, and strongly ringed bases. The horns of the ♂♂ are larger, more strongly bent, and more heavily ringed than those of the ♀♀. The skull resembles that of other *Nanger* species, with large basioccipital tuberosities (C. Groves pers. comm.).

Geographic Variation

N. s. butteri: S Ethiopia. Faint dark band along its flank and adjacent to the rump patch; mid-face black; horns longer and more slender.

N. s. berberana: Somalia and NE Ethiopia. Entirely black face and longer horns.

N. s. soemmerringi: Sudan, Eritrea. Smallest subspecies; brown face and shorter horns; no dark flank.

There is an unnamed population of Soemmerring's Gazelle found on Dahlak Kebir I., Eritrea (Yalden *et al.* 1996). This form varies from its mainland counterparts in that it is considerably smaller in size.

Similar Species

Nanger granti. Allopatric, but ranges were formerly very close in Ethiopia/Kenya borderlands. Longer, straighter horns and less extensive white on rump.

Gazella spekei. Observed in mixed herds with Soemmerring's Gazelle on the coastal grasslands in Ceel Dhere District, Somalia, in the late 1980s; however, there is no recent information to confirm whether Soemmerring's Gazelle still occurs in this area (Laurent & Laurent 2002). Smaller, with shorter horns, swollen nose, and black side-stripe.

Gazella dorcas. Pelzeln's Gazelle *G. d. pelzelni* overlaps in range in Djibouti (Künzel *et al.* 2000). Smaller, more gracile, with long pointed ears.

Eudorcas tilonura. Largely allopatric, but ranges overlap in SW Eritrea (and formerly in NE Sudan, although Soemmerring's are now probably eliminated from their historical range in this country). Small gazelle, redder in colouration, with horns bowed outwards and hooked inwards at the tips.

Distribution Endemic to the Horn of Africa region.

Historical Distribution Formerly widely distributed throughout most of Djibouti, N Somalia and the central coastal plain and locally between the Shebelle and Juba Rivers; NE and EC Sudan; the lowland areas of Eritrea and the eastern lowland areas of Ethiopia (East 1999). At one time this gazelle may have occasionally ventured as far south as extreme NE Kenya, though it is unclear whether they still sporadically occur there today (Kingdon 1982, East 1999). A population on Dahlak Kebir I. was probably introduced over 100 years ago (Yalden *et al.* 1996).

Current Distribution Still occupies substantial parts of its historical range, mainly in Djibouti, Eritrea and Ethiopia, but at lower densities and as isolated populations, primarily due to a long history of uncontrolled hunting, habitat destruction and livestock grazing, which have most probably eliminated this species from its historic range in Sudan (East 1999, I. Hashim pers. comm.). Funaioli & Simonetta (1966) mentioned that the species was almost exterminated in the southern region of Dafet in Somalia, and East (1999) states that by the early 1980s it had been eliminated from most of its former range in this country, but was still present in reasonable numbers in parts of the central coastal hinterland and occurred seasonally in mixed herds with Speke's Gazelle *Gazella spekei* on the coastal grasslands in Ceel Dhere District.

In addition to the Dahlak Kebir population, there is a resident herd on Dahlak Norah I. following the introduction of this species in the late 1980s (J. C. Hillman pers. comm.).

Habitat Occupies a wide range of habitats ranging from arid coastal plains and mudflats, to arid and semi-arid *Acacia* savannas, and semi-arid grassland plains. Tends to favour rough hilly country, but may also be found in open short-grass plains (Spinage 1986, Kingdon 1997), open bush savannas, and thinly wooded grass steppes (Haltenorth & Diller 1980), thornbush and open grassland plains in hilly country (Estes 1991a, Künzel *et al.* 2000), and open bushland areas with an abundance of forbs (Jacobs & Schloeder 1993, Laurent & Laurent 2002). Recorded to 1500 m in Ethiopia (Yalden *et al.* 1996).

Abundance There is no detailed information on abundance throughout their current range. However, reports from Eritrea, Somalia and Sudan, and population estimates from Ethiopia and Djibouti, suggest that there are less than 15,000 gazelles remaining today (East 1999). Ethiopia is still considered the stronghold for this species. Several stable populations can be found throughout the middle and lower Awash River Basin and parts of the Ogaden region, with an estimated average density of 0.3 gazelles/km² (Jacobs & Schloeder 1993, Thouless 1995, Wilhelmi 1997, East 1999); Wilhelmi *et al.* (2006) noted that probably at least a few hundred to a few thousand Soemmerring's Gazelles may survive in the Ogaden region.

Adaptations Soemmerring's Gazelle can go for days without drinking, meeting its water requirements by selecting protein-rich forage and foraging when it is coolest. It is also known to seek out tall *Acacia* and evergreen trees and rest in the shade during the hottest times of the day during the dry season (M. Jacobs & C. Schloeder pers. obs.). Other water-conservation adaptations include concentrating its urine, adjusting its body temperature and evaporative cooling (Estes 1991a).

Foraging and Food Both a browser and a grazer (and classified as a browser-grazer intermediate by Gagnon & Chew [2000]), this gazelle is often found at lower elevation plains during the wet season, where it exhibits a preference for grasses and forbs (and, to a lesser extent, shrubs). Once the dry season is under way and the availability of herbaceous forage declines, it tends to move to higher elevations with moderate to rough relief, and switches to a diet that includes a variety of *Acacia* shrubs and woody herbs. The behaviour of the subspecies found on Dahlak Kebir I. differs somewhat from those on the mainland. The island subspecies tends to move from the interior open-shrubland areas at the onset of the dry season, to forage on the mudflats and on algae growing in the shallow coastal waters (J. C. Hillman pers. comm.). Disturbed areas such as abandoned settlements and grazing arenas are considered important foraging sites because a variety of annual forbs and grasses typically colonize these sites following abandonment (Barker *et al.* 1990, Jacobs & Schloeder 1993, Laurent & Laurent 2002). In addition, salt, mineral licks and the soil in abandoned domestic livestock compounds are sought out by this gazelle, particularly when ♀♀ are lactating (Laurent & Laurent 2002, M. Jacobs & C. Schloeder pers. obs.).

Social and Reproductive Behaviour Herd size varies seasonally, with animals tending to congregate during the wet season in large groups (up to 150); the dry season is characterized by smaller group sizes (1–9), as a result of dispersal. Most herds comprise primarily adult ♀♀ and their young (both subadults and calves). The

exception is those rare occasions when ♂♂ form small, male-only groups (1–3 ♂♂), and when ♂♂ join the female groups during the breeding season. Males attempt to keep the female groups within their own territory for breeding (Jacobs & Schloeder 1993). They may occur in mixed herds with other gazelle species. For example, they have been seen in mixed herds with Speke's Gazelles on the coastal grasslands in Ceel Dhere District, Somalia (East 1999), and in mixed herds with Pelzen's Gazelles in most areas in Djibouti (Künzel *et al.* 2000).

Reproduction and Population Structure Breeding generally occurs between Sep and Dec (Djibouti), with birthing tending to coincide with the onset of the wet season (Kingdon 1982, A. Laurent pers. comm.). The appearance of new offspring as late as Sep in Awash N. P., Ethiopia, indicates that this species also breeds as late as Jan (Jacobs & Schloeder 1993).

One young is born after a gestation period of about 198 days (Walther 1990). The young are usually kept hidden until they are at least one month old. Weaning takes place after six months and sexual maturity typically occurs after 1.5 years. The species has been known to live as long as 15 years in captivity (Weigl 2005).

There is little information about the population structure of this species with the exception of one study from Ethiopia. This study indicated that the population in Awash N. P. was comprised of 84% adults, 10% subadults and 5% calves; the estimated proportion of ♀♀ and ♂♂ was 63% and 37%, respectively (Jacobs & Schloeder 1993).

Predators, Parasites and Diseases Predators include most large carnivores, although large predators are now absent from many, if not most, of the regions in which the species now occurs. Yearlings are most vulnerable to predation (Walther 1990). There is little information about this species' susceptibility to parasites and diseases, but it is probably vulnerable to the helminths and ticks common to other gazelles (Graber *et al.* 1980, W. Karesh pers. comm.).

Conservation IUCN Category: Vulnerable A2cd; C1. CITES: Not listed.

Soemmerring's Gazelle *Nanger soemmerringi* head.

In general, this species is in decline throughout its historic range with the exception of certain areas in Eritrea, Ethiopia and Djibouti, and the Dahlak Islands, largely as a result of uncontrolled hunting, in combination with a loss of habitat and livestock grazing (East 1999, Künzel *et al.* 2000). The largest protected population occurs in the Awash N. P. (about 200 animals).

Measurements

Nanger soemmerringi

HB: 1250–1500 mm

Sh. ht: 800–920 mm

T: 180–280 mm

WT: 30.0–55.0 kg

Throughout the geographic range (Kingdon 1982, Laurent & Laurent 2002)

Maximum recorded horn length is 58.4 cm for a pair of horns from Somalia (Rowland Ward)

Nanger dama DAMA GAZELLE (ADDRA GAZELLE)

Fr. Gazelle Dama (Biche-Robert); Ger. Damagazelle

Nanger dama (Pallas, 1766). Misc. Zool., p. 5. No locality cited; based on 'Le Nanguer' of Buffon from 'Sénégal'.

Taxonomy The Dama Gazelle belongs, together with Soemmerring's Gazelle *N. soemmerringi* and the Grant's Gazelle *N. (granti)* complex, in the genus *Nanger* (Groves 2000).

In the type description of Pallas (1766), based on Buffon (1764), no reference to a type specimen is made. Buffon's illustration clearly corresponds to *N. dama*, showing a square-cut transition from dark back to white rump, with no rufous colouring extending onto the hindleg, not unlike the *N. d. dama* colour type (although a transition toward *N. d. mhorh* can be debated). Information on location in Buffon (1764) is limited to the observation that 'this is an animal which according to M. Adanson, is called Nanguer or Nanguer au Sénégal'. Buffon (1764) also reports Adanson's

observation 'qu'il y a trois espèces ou variétés de ces nanguers, qui ne diffèrent entr'eux que par les couleurs du poils, mais qui tous ont les cornes plus ou moins courbées en avant'. Malbrant (1952) and Grubb (1993c) suggest that the Dama Gazelle's type location is L. Chad. However, it is curious that specimens of three different types were already identified in 1764, some 60 years before the first recorded European expedition entered central parts of the range near L. Chad (and shot two Damas) (Denham *et al.* 1826). Cretzschmar (1826) reported the first specimen from Sudan and noted that only one juvenile specimen from elsewhere, 'Senegal', was known. Other reports (Bennett 1833, 1835, Sclater & Thomas 1899) report specimens from Morocco or Western Sahara from

Dama Gazelle *Nanger dama dama*.

Lateral view of skull of Dama Gazelle *Nanger dama*.

where two live specimens and one damaged skin arrived in London (ZSL) in 1833.

There is a wide variation in colour pattern, which has led to the description of numerous subspecies (see Gentry 1972). Cano (1984) distinguished three morphologically defined subspecies (*N. d. mhorr*, *N. d. ruficollis* and *N. d. dama*), each with a light and dark variant. Preliminary biochemical and cladistic analyses support this distinction (E. Handrus pers. comm.), possibly reflecting the limited genetic base of the sampled captive populations. However, Vassart *et al.* (1995) concluded that the morphological cline of these subspecies could not be related to a chromosomal one ($2n = 38, 39$ or 40 being found in the same cline). Further, thousands of animals in Chad, from one area and even in the same herd, could be attributed to either *ruficollis* or *dama*, without expressing any geographic gradient (Malbrant 1952). Sclater & Thomas (1899) earlier questioned the distinction between *N. d. mhorr* and *N. d. dama* (as did Groves 1985a and Kingdon 1997). With the small and isolated wild populations, few specimens collected and the limited genetic stock of captive

populations, it will be difficult to clarify the subspecies status. For pragmatic reasons we provisionally retain the distinction of the three subspecies of Cano (1984) as colour forms; *permista* from Senegal may also represent a distinct form (C. Groves pers. comm.). Synonyms: *addra*, *damergouensis*, *lazoni*, *lozanoi*, *mhoks*, *mhorr*, *mohr*, *nanguer*, *occidentalis*, *orientalis*, *permista*, *reducta*, *ruficollis*, *weidholzi*. Chromosome number: $2n = 38-40$ (Effron *et al.* 1976, Vassart *et al.* 1995). Vassart *et al.* (1993) published a karyotype with $2n = 34$, from a ♀ of unknown origin.

Description The tallest and largest of all gazelles, brightly marked and coloured in the west and centre of the range, with eastern forms often appearing almost white from a distance. The long-necked and long-limbed structure, with a slight shoulder hump, creates a characteristic profile and running action. The upper and front part of the head is white, regularly with a dark stripe through the eye (especially pronounced in *N. d. mhorr*). The neck is rufous with a conspicuous white spot visible half-way up the neck. Body with decreasing red-brown colouration on the upper half, from (north-) west (*N. d. mhorr*), which shows solid rufous back sharply delineated from a large bright white rump area, through forms showing varying and intermediate reduction in the rufous back colouring through the central range (*N. d. dama*), to eastern forms (*N. d. ruficollis*) in which the rufous cape on the back and upperparts fades out rapidly through a grizzled roan area starting anywhere from the base of the neck, shoulder or mid-back. Legs white, with a variably prominent rufous stripe down the front of the lower forelegs. Rufous extension of back colouring onto white outer thigh is broad, well delineated and prominent in *N. d. mhorr*, narrower, or faded or absent in *dama*, and absent in *ruficollis*. Flank- or pygal-bands are absent. Underside of tail darkish, upperside white. Preorbital glands are small.

Young are uniform apricot-tan colour for first month of life, and noticeably more bulky than young of other gazelles, with coarser features. Adult body colouration develops rapidly except for the face, which is initially strongly patterned with a very dark-brown nose-spot, near-black flashes below the horn bases separated from pale bands around the eyes, a narrow dark eye-stripe, pale-brown cheeks and a tawny central muzzle, reminiscent of the face pattern in Soemmerring's Gazelle. Nose-spot and central muzzle to the level of the narrow eye-stripe replaced with pure white by around 18 months, but dark marks above eyes and across forehead may persist (T. Wachter pers. comm.). Many subadults retain variably prominent dark forehead marks, which continue to grizzle and whiten into full adulthood, the white colouring in many eventually spreading around the horn bases to the nape to create the near fully white head of older animals.

Horns are comparatively short relative to other large gazelles, and lyrate and sharply backswept, before curling forward. They are heavily built with pronounced annulations and swollen bases in ♂; much lighter and weaker in ♀.

Geographic Variation

N. d. mhorr (Mhorr or Mohor Gazelle) (including *lozanoi*): North Africa. The range between this colour form and the Sahelian populations of *N. d. dama* in SE Mauritania may have been in contact (Sclater & Thomas 1899), although historical observations gathered by Trotignon (1975) suggest the existence of a gap. In

this colour form the upperparts have the full extent of reddish colouration from the head to the rump and down the hindlegs to at least the hock.

N. d. dama. Senegal to Aïr – L. Chad. Upperparts fawn to reddish in colour, extending along the back to the rump and down the hindleg to the hock; stripes on the face.

N. d. ruficollis (Red-necked Gazelle). Aïr – L. Chad to Sudan. Upperparts red-brown, but restricted to the neck or only part way along the back, the rest of the body being white; legs usually white, at most suffused with reddish; face-stripes obliterated.

Similar Species At close proximity, this species is unlikely to be confused with any other species, although at greater distances especially *N. d. ruficollis* may appear similar to other 'large white' antelopes such as the Scimitar-horned Oryx *Oryx dammah* and possibly the Addax *Addax nasomaculatus*. Although the body shape is distinctive, colour pattern of *N. d. mhor* is reminiscent of related, but allopatric, Soemmerring's Gazelle in the lack of a flank-band, large white rump area and the face pattern of young.

Distribution Endemic to Africa.

Historical Distribution The range of the Dama Gazelle resembles that of the Scimitar-horned Oryx. North of the Sahara, the former Atlantic distribution of the Dama Gazelle encompassed a 200–300 km-wide band of oceanic and sub-oceanic desert from the Oued Noun in S Morocco to NW Mauritania (Valverde 1957, Trotignon 1975, Loggers *et al.* 1992). Dama Gazelles also used to occur in NW Algeria (Heim de Balsac 1936, Kowalski & Rzebik-Kowalska 1991, De Smet & Smith 2001) and extreme S Libya (Hufnagl 1972, Essghaier 1980, Khattabi & Mallon 2001), from where it extended into the central Saharan massifs. In Tunisia they are believed to have occurred in the south and to have disappeared before the twentieth century (Kacem *et al.* 1994, Smith *et al.* 2001). That they formerly

Nanger dama ruficollis.

Nanger dama dama.

Nanger dama mhor.

Nanger dama

ranged into Egypt is evidenced by fossilized remains from the upper Pleistocene in the south-western part of the Western Desert (Osborn & Osbornová 1998).

South of the Sahara, Dama Gazelles formerly occurred in N Senegal during the dry season, or periods of drought, only (Bourlière *et al.* 1976). Also formerly present in SE Mauritania, SE Algeria, Mali, Niger, Chad and NW Sudan (Wilson 1980, East 1999), but not extending east of the Nile R. (East 1999, Devillers *et al.* 2005b). They have also been recorded, albeit rarely, from the Sahel zone of NE Nigeria (in the region of L. Chad and the Jawa) and N Burkina Faso (East 1999). There may still be a potential link between populations north and south of the Sahara across the Hoggar (where they were recorded in the central ranges until 1964; Kowalski & Rzebik-Kowalska 1991), and Air–Tassili N'Ajjer–Plateau du Djado–Tibesti (C. Magin pers. comm.).

Current Distribution Numbers of Dama Gazelles have declined drastically since the 1940s in the Atlantic Sahara and central Saharan massifs, and since the 1960s from the Sahelian part of its range. In North Africa, Dama Gazelles (*N.d.mhorr*) are probably extinct, though they may survive in the Drâa Basin (where the last observations were made by nomads in 1993) (Cuzin 1996, 2003, Aulagnier *et al.* 2001). They may survive in very small numbers along the border between Western Sahara and Mauritania (Cuzin *et al.* 2007), but this is not confirmed. Dama Gazelles are now extinct in the Hoggar in S Algeria (Kowalski & Rzebik-Kowalska 1991; Wachter *et al.* 2005), but they may survive in the Tassili de Tin Rehror in S Algeria (K. De Smet pers. comm.). They have been reintroduced in Bou-Hedma N. P. in Tunisia (mapped).

South of the Sahara, Dama Gazelles are reported to still be present in the Tamesna region in E Mali (Lamarque 2005, Lamarque *et al.* 2007), the Aïr and Termit/Tin Toumma in Niger (Newby *et al.* 2004, Wachter *et al.* 2004a, b), and in the Chadian Manga and Ouadi Rimé–Ouadi Achim Faunal Reserve between 13°N and 18°N in C Chad (Monfort *et al.* 2004, Wachter *et al.* 2004b, Wachter & Newby 2010, Wachter *et al.* 2011) (see Conservation). Aerial and ground surveys conducted in the Termit and a contiguous block of the Tin Toumma dune system in 2007 failed to record any Dama Gazelles (Wachter *et al.* 2008), but surveys in December 2008 recorded the presence of gazelles in both the northern and central parts of the Termit massif (Wachter *et al.* 2009).

Dama Gazelles are now thought to be extinct in Mauritania (F. Lamarque pers. comm.), despite reports that they may still survive in the remote south-east and in the vicinity of Tidjika in the west (East 1999). They also are probably extinct in Nigeria, Burkina Faso (Heringa [1990] reported they could have survived in the Seno-Manga area) and Libya (although a relict population could survive in the Tibesti region near the Chadian border; Essghaier 1980). There are no recent confirmed records from the Sudan, although East (1999) mentioned anecdotal information from local people who suggested that they still occurred at low densities in northern Darfur and northern Kordofan. Dama Gazelles have been (re-)introduced in Senegal where they went extinct (not mapped; see Conservation).

Habitat Contrary to what its present distribution suggests, the Dama Gazelle prefers sparsely wooded savanna rather than open desert and is more Sahelian than Saharan. The early travellers

Denham *et al.* (1826) and Nachtigal (1879–89) reported Dama Gazelles from dense woodlands around L. Chad in the late dry and early wet season, contrasting to its present habitat such as the scarcely vegetated Manga area north of L. Chad (Scholte 2012). Early travellers also observed Dama Gazelles in the wadis between the massifs of the Aïr Mts (Barth 1857–1859) but not from the extensive deserts they crossed. Compared with the Dorcas Gazelle *G. dorcas*, Dama Gazelles used to be less abundant and confined to large dry river beds with (sparse) woodland with short migration into the desert zone in times of abundant (high-quality) forage. In Chad, the area east of the Bahr al Ghazal used to be particularly suitable, with wadi habitat of flood-plains with woody vegetation (Ouadi Rimé, Ouadi Haddad, Ouadi Kharma and others), with Dama Gazelles together with the Red-fronted Gazelle *Eudorcas rufifrons*, whereas the Scimitar-horned Oryx and the Dorcas Gazelle used to be dispersed in the inter-wadi areas (J.E. Newby pers. comm.). Occasionally, Dama Gazelles can be found far out in sandy seas or ergs and they have been observed with Addaxes near Fachi and to the south-east of the Erg du Ténéré (Dragesco-Joffé 1993). Habitat north of the Sahara is said to be treeless (Cuzin 1996), likely the result of human pressure.

Abundance The Dama Gazelle was formerly widespread and abundant, but numbers have declined drastically since the 1950s and 1960s. For example, the population in Ouadi Rimé–Ouadi Achim Faunal Reserve in C Chad, one of the strongholds of the species, was estimated at 10,000–12,000 individuals in the early 1970s or 0.14/km². These figures are from a population that had already been reduced since the 1950s. Surveys undertaken in early 2011 in Ouadi Rimé–Ouadi Achim provided the first formal records of Dama Gazelle persisting in this region for many years (Newby & Wachter 2011, Wachter *et al.* 2011). In the mid-1980s, the other main surviving population, in the Aïr–Ténéré reserve in Niger, was estimated at 150–250 individuals (Grettenberger & Newby 1986); by the late 1980s it was estimated at approximately 170 (Magin 1990). Numbers have dropped dramatically there as well, and observations in March 2002 were limited to a few animals and tracks in the eastern Aïr, especially on the Takoloukouzet plateau (Newby *et al.* 2004). However, there are reports of others further north and to the west; a population was reported to still exist in the Termit Massif (Wachter *et al.* 2004a, b), although more recent surveys recorded no signs of them (Wachter *et al.* 2008).

In summary, in the last decade, only scattered observations of Dama Gazelles have been made (Scholte 2001, Claro 2004, Monfort *et al.* 2004, Newby *et al.* 2004, Wachter *et al.* 2004a, b, Wachter & Newby 2010, Wachter *et al.* 2011), including one survey which confirmed the existence of the species in the south Tamesna region of E Mali (Lamarque *et al.* 2007). In all areas surveyed, numbers were very low and the size of observed gazelle groups very small (range 1–5 individuals), and the number of gazelles observed was less than 0.05/km² (Lamarque *et al.* 2007). The total current wild population is almost certainly less than 500 individuals (J. Newby pers. comm.).

Adaptations The current distribution of this species in more arid areas largely reflects marginalization due to hunting pressure and is not an adaptive preference (Scholte 2012). This, and its

seasonal migrations north into the Sahara during the wet season (retreating again into the Sahel during the dry season), explains why some authors considered the Dama Gazelle as more Saharan than the Dorcas Gazelle. The Dama Gazelle is reputed to be more water-dependent than the Dorcas Gazelle, but compensates for this by browsing. Light pelage is an additional physiological adaptation (Wilson 1989). With their long legs, Dama Gazelles are one of the fastest mammals, although reported speeds of up to 100 km/h (Dragesco-Joffé 1993) seem exaggerated. Dama Gazelles are able to reach tree branches by standing on their hindlegs, but probably only do this in periods of food scarcity.

Foraging and Food During the dry season, Dama Gazelles browse leaves, flowers and pods of *Acacia ehrenbergiana*, *A. tortilis*, *Maerua crassifolia* and *Balanites aegyptiaca*, obtaining a crude protein content above 12% (Le Houérou 1989). Dama Gazelles also browse the abundant coarse shrubs *Capparis decidua*, *Leptadenia pyrotechnica* and *Salvadora persica* (Grettenberger & Newby 1986). Dama Gazelles were recorded browsing on *C. decidua*, *S. persica*, *A. tortilis* and on a mixed sward green flush of short herbs and grasses. Freshly chewed bark of *Maerua crassifolia* was found while inspecting a recently vacated feeding site in E Chad in mid-Sep (Monfort *et al.* 2004). Bark chewing on *Acacia gummifera* and browsing of *A. gummifera* and *Ziziphus lotus* has also been observed in the extralimital enclosed population at R'Mila in Morocco. During the dry season moisture is obtained through browse and, additionally, consumption of the wild melon *Citrullus colocynthis* (Dragesco-Joffé 1993). Abundant grass species such as *Panicum turgidum* (perennial grass) and various annual grasses and sedges are only selectively consumed during the rainy and early dry season, after which their feed value drops dramatically. During the early wet season, temporarily available high-quality forbs such as *Tribulus terrestris* and *Indigofera aspera* may constitute an important part of the diet (Dragesco-Joffé 1993).

Social and Reproductive Behaviour The only reliable studies on social behaviour are from the Aïr area (Niger) in the late 1980s. Dama Gazelles probably used to live mainly in harem herds, comprising a single dominant adult ♂ and many ♀♀, but human pressure has led to the disintegration of this system. Based on a data set collected from 1979 to 1990 (J. Newby pers. comm., incorporating Grettenberger & Newby [1986] and Magin [1990]), Dama Gazelle group composition (n = 229 individuals) consists of pairs with young (11+ 8%), single ♂♂ (17%), harems (17%), mixed groups (13%), single ♀♀ (11%), females with young (11%), ♀♀ (5%), bachelor groups (3%) and single immatures (2%); average herd size was 2.1. Observations in relatively undisturbed populations indicate the presence of groups up to 200 individuals (Lavauden 1926b), uniting in the late dry season (Dragesco-Joffé 1993) or early wet season (J. E. Newby pers. comm.), probably because of the concentration of (nutritious) pastures. There are occasional observations of large assemblages during the dry season, such as 500–600 in the Aïr (Brouin 1950).

Limited field observations suggest that the social behaviour of Dama Gazelles resembles that of members of the Grant's Gazelle complex (Walther 1995). Frequent male fighting has been a major constraint in reintroduced populations, mainly due to confined space (Cassinello & Pieters 2000). Mungall (1980) studied courtship

behaviour in captive *N. d. ruficollis* and concluded that general behaviour follows that observed in other gazelle species (Walther 1995). Striking was the Dama Gazelle's frequent use of foreleg kicking (laufs Schlag), without pronounced nose-up display, whereas foreleg kicking of Grants' and Soemmerring's Gazelles was reduced to special steps with nose-up display (Mungall 1980). It remains speculative whether this can be related to the need by the latter species to minimize horn-threat profile, whereas Dama Gazelle horns are smaller and less conspicuous.

Reproduction and Population Structure Births are highly seasonal, and probably influenced by food availability. In Chad, Newby (1978a) recorded births and young from Jul to Dec, corresponding largely with the onset of rains in Jun; in Niger, Dragesco-Joffé (1993) noted births from Oct to Mar; and in Western Sahara births occur from Feb to Mar (Cuzin 1996). A captive population in Senegal (which had a supplemented diet) showed continuous breeding throughout the year (unpublished birth log, from Guembeul N. P. 1984–2000). Based on observations from captive animals, the mean duration of the oestrous cycle is 18.6 ± 0.3 days (range 16–22; Pickard *et al.* 2001).

Gestation length has been given as about 6.5 months (Drüwa 1985, Furley 1986, D. Noble pers. comm.). Females have a single young weighing 4–6 kg. In captivity, ♀♀ breed when they reach two years of age; fecundity ranged from 0 to 1.86 (mean 0.91) offspring annually (Alados & Escos 1991). One captive lived to 19 years (Weigl 2005). The ♂ : ♀ sex ratio in Aïr was 0.89 : 1 (Poilecot 1996).

Predators, Parasites and Diseases No observations reported, but Cheetahs *Acinonyx jubatus* and especially African Wild Dogs *Lycaon pictus* might have been important predators when they were in greater abundance. In the wooded areas where the early European travellers found Dama Gazelles, Lions *Panthera leo* and Leopards *P. pardus* were mentioned as common. Not necessarily confined to heavily wooded areas, these predators may have been present until the early 1960s. Newborns and young are potentially taken by Striped Hyaenas *Hyaena hyaena* and Golden Jackals *Canis aureus*, as well as eagles *Aquila* spp., Ratels *Mellivora capensis* and Rüppell's Foxes *Vulpes rueppellii*. There is no information on parasites or diseases.

Conservation IUCN: Critically Endangered A2cd; C2a(i). CITES: Appendix I. CMS: Appendix I.

The decline of the Dama Gazelle, as with other Sahelo-Saharan antelopes, can be attributed to the combination of habitat degradation, particularly due to the increase in grazing pressure from domestic livestock, and direct exploitation (exacerbated by the introduction of modern firearms and 4×4 vehicles) (East 1999, Devillers *et al.* 2005b). Apart from hunting by military, hunting of Dama Gazelles by Arab hunting parties has been frequent in Sudan (Cloudsley-Thompson 1992) and in 1998 and again in 2001 in Chad, where it was, temporarily, halted after a local NGO made it public.

Ouadi Rimé—Ouadi Achim Faunal Reserve was designated in 1969, at least on paper, to protect, amongst others, Addaxes, Scimitar-horned Oryxes, Ostriches *Struthio camelus* and Dama Gazelles. Part of the Aïr Mts and Ténéré Desert in Niger also received protected area status in 1988 (Aïr—Ténéré N. P.), stimulated by the activities of a conservation-development project (Newby 1992). Both reserves still

harbour Dama Gazelle populations, but have suffered from military unrest resulting in the collapse of conservation infrastructure. International interest for arid-land species has remained low despite the largely improved security situation (Scholte 2001). In early 2012, Niger established the Termit and Tin Toumma National Nature Reserve, a 97,000 km² tract of desert and sub-desert specifically designed and managed to protect Addax, Dama Gazelle and other species.

Captive Dama Gazelles originate from two locations only: *N. d. mhor* from Rio de Oro, Western Sahara (Cano *et al.* 1993) and *N. d. ruficollis* from Ouadi Haouach, NE Chad (G. van den Brink pers. comm.), although some captive Dama Gazelles (Al Ain Zoo) could be *N. d. dama* (T. Smith pers. comm.), and small numbers of *N. d. dama* were present at Al Wabra (Qatar) in the 1990s (T. Wachter pers. comm.). The number of founders is limited with 2 ♂♂, 10 ♀♀ and 5 ♂♂, 20 ♀♀, respectively (Sausman 1998, Thuesen 1998). Animals from Almeria (Spain) – stock originating from Western Sahara – were introduced to an enclosure (R'mila) near Marrakech (130 present in 2007; Cuzin *et al.* 2007) and gazelles from Munich Zoo (originally bred at Almeria) were released into an enclosure in Souss-Massa N. P. (12 animals in 2006 HCEF Rabat); these semi-captives are intended to form part of a reintroduction programme in Morocco (see also Wiesner & Muller 1998, Cuzin *et al.* 2007).

Elsewhere, Dama Gazelles (*N. d. mhor*) were released into the 2000 ha Bou-Hedma N. P. in Tunisia in the early 1990s (Abáigar *et al.* 1997), where around 17 were present in 2006 (T. Wachter pers. comm.), and gazelles (*N. d. mhor*) were reintroduced to Guembeul Faunal Reserve in Senegal in 1984 (Cano *et al.* 1993), although they have not fared well of late (Moreno *et al.* 2012); a reintroduction programme in Ferlo-Nord Reserve is underway. *Nanger d. ruficollis* has not been reintroduced and priority should be given to the conservation of the remaining wild populations.

Paul Scholte

GENUS *Ammodorcas*

Dibatag

Ammodorcas Thomas, 1891. Proc. Zool. Soc. Lond. 1891: 207, pl. 21, 22.

Ammodorcas includes only the Dibatag *A. clarkei*, confined to dry wooded habitats in the Somali–Masai Bushland BZ of Somalia and E Ethiopia. The genus was originally thought to be related to *Redunca* only because of the course of the horns, and was placed in the genus *Cervicapra* by Thomas (1891a); based on further samples, it was later amended by the same author to *Ammodorcas clarkei* (Thomas 1891b). Its affinities were later widely regarded as uncertain, and it was even placed in a distinct tribe, Ammodorcadini (see Ansell 1972, East 1999).

The Dibatag is very similar to the Gerenuk *Litocranius walleri* in facial pattern, proportions, brachyodonty and many cranial features; nevertheless, it differs significantly in the form of the horns, horn cores, tail, postorbital region of skull and basioccipital processes, as well as the absence of a two-tone flank-pattern and in lacking pedal glands (the latter feature unique among members of the Antilopini).

Peter Grubb

Ammodorcas clarkei DIBATAG (CLARKE'S GAZELLE)

Fr. Gazelle du Clarke; Ger. Lamagazelle (Stelzengazelle)

Ammodorcas clarkei (Thomas, 1891a). Ann. Mag. Nat. Hist., ser. 6, 7: 304. 'Northern Somali-land'; according to the collector Clarke (in Sclater and Thomas, 1898: 220), 'about three hours from "Bairwell" or about one day from "Buroa Well, Habbergerhagi's country"' (N Somalia, vicinity of Burao and Ber).

LEFT: Dibatag *Ammodorcas clarkei*.
 ABOVE: Lateral and palatal views of skull of
 Dibatag *Ammodorcas clarkei*.

The now widely used vernacular name 'Dibatag' derives from Somali *dabu* 'tail' and *tag* 'erect'.

Taxonomy Monotypic. Synonyms: none. Chromosome number: not known.

Description Medium-sized, graceful antelope similar in appearance to the Gerenuk *Litocranius walleri*, with slender body and elongated neck and legs. Head small, flat, wedge-shaped and pointed. Eyes large, ears medium-sized, broadly lancet-shaped with dark, rounded tips. Lips very mobile, with the upper lip slightly elongated, and mouth opening very small. Facial markings strongly marked and gazelle-like; there is a chestnut-brown streak from the crown along the bridge of the nose to the nostrils, on both sides paralleled by a distinctive white stripe, circling the eyes and running down to the nostrils (these are bordered by a narrow chestnut band from the preorbital glands to the muzzle). Pelage short, smooth and very soft. Dorsal pelage and flanks uniform cinnamon-brown to rufous, but may appear silver-grey depending on the incidence of sunlight. There is a white spot at the throat. No dark band on the

flanks or buttocks. The underparts and insides of the legs are white. The tail is rounded and long, dark in colour, reaching the hocks, and is well furred but with no distinct tassel. Insides of the ears have a branched black pattern, similar to other gazelles; the lower fringe of the ear, towards the tip, has an inward curved lobe (distinct from the Gerenuk). Lateral (false) hooves are small. Preorbital and carpal glands present, the latter with hair tufts; pedal and inguinal glands absent. Females are slightly smaller than ♂♂, and have two pairs of inguinal nipples.

Horns present in ♂ only, reedbuck-like, basal half with 6–10 large and well-spaced annuli, and angling back from forehead; terminal half smooth, curving around with pointed tips facing forward. Horn cores are grooved, with transverse ridges marking annuli of overlying horn sheath, not supported by pedicular extensions of the frontal bones. The skull is long and shallow; premaxillae long, tapering to very narrow tips, and extending back to reach (or almost reach) the long nasals. An ethmoid fissure is present. Preorbital fossa shallow without marginal ridges. There are prominent basioccipital processes. The median incisiform teeth are broad, the remaining pairs narrow with third incisors narrowest.

Geographic Variation None recorded.

Similar Species

Litocranius walleri. Sympatric in E and C Somalia and SE Ethiopia (Ogaden). Two-tone body colouration; horns in ♂ thick and strong and S-shaped; tail with distinct tassle. Generally flees headlong with tail never upright.

Distribution Endemic to the Ogaden region of SE Ethiopia and adjoining semi-arid to arid lowlands of C Somalia.

Historical Distribution Southern parts of N Somalia throughout SE Ethiopia and C Somalia between coastline of the Indian Ocean and Fafan R. in the west and the Shebelle R. in the south-west (Funaioli 1958, Schomber 1966). Rock drawings of two Dibatags on the west bank of the Nile, north of Aswan, suggest a southwards retreat of this species in the Ite Predynastic period of Egypt (Osborn & Osbornová 1998).

Current Distribution The Dibatag has disappeared from substantial parts of its former range, and is reported in viable numbers only from the Ogaden south of Degeh Buur down to the northern foothills of the Shebelle R. (Wilhelmi 1997). Repeated sightings from Kebri Dehar and Warder District indicate an east- and southward distribution up to the Somali border and into the Hiiran region of S Somalia (H. Kaariye pers. comm.). In 1988, reported by pastoralists as present in Bay Region and west of the Juba R. in S Somalia (T. Thurow pers. comm.), but not verified by the author's own extensive ground and aerial survey in 1987 and 1988. Their possible persistence in the coastal hinterland of C Somalia has been discussed by several authors (Funaioli 1971, East 1999), and was confirmed in 2005 (N. Dougherty pers. comm.).

Habitat Dibatags inhabit semi-arid dense to scattered bush, low- to medium-height thornbush savanna and plains with thicket/grassland mosaics. They prefer sandy to moderately gravelled, ferrous oxide-rich

red soils, characterized by numerous termite mounds. Occasionally, Dibatags visit treeless grasslands (Meester 1960). Their occurrence is assumed to be correlated with the presence of *Commiphora* shrubland (Lawrie 1953) and probably associated with areas very far from any form of present and historical shifting cultivation (T. Thurow pers. comm.). They have an altitudinal range of approximately 200–1200 m (Yalden *et al.* 1984, 1996). No significant seasonal changes in habitat preference are evident.

Abundance Based on the results of Scott's expedition in 1959, the population size was estimated at approximately 12,000 individuals with an average density of 1 animal/km² (Schomber 1966). After three decades of political unrest and armed conflicts, East (1999) cautiously estimated a total population in the low thousands (East 1999). The current author estimates the population in the C Ogaden (about 46,000 km²) to be a maximum of about 4000 individuals. If security in the area improves, standardized counting methods or even aerial surveys may allow for more reliable estimates. Since Dibatags are very secretive, it is likely that actual population numbers are higher than currently believed.

Adaptations Dibatags are well adapted to their semi-arid environment. They probably obtain their water requirements from food alone, and indeed there are no records of them drinking water in the wild. The long neck and the ability to stand like Gerenuks on their hindlegs, with forefeet in the branches of a tree, enable them to reach a considerable height when browsing. The long upper lip facilitates browsing in thorny vegetation. The body shape and colouration of Dibatags render them practically invisible as they hide behind vegetation, remaining motionless while keeping track of potential threats. Once discovered, they bound away in an ambling gait with upright neck and tail erect like an antenna – hence the Somali name; galloping is reserved for true emergencies. Pronking is performed when alarmed, but is more often seen in a playful burst of motion.

Foraging and Food Primarily browsers (Gagnon & Chew 2000), Dibatags feed on foliage and young shoots of trees and shrubs using their flexible lips and front teeth to pluck or bite off leafy material. The diet includes species such as *Commiphora* (myrrh trees), *Acacia*, *Boscia*, *Dichrostachys* and *Maerua* spp. (Meester 1960). Animals most likely congregate seasonally in areas with foliated *Commiphora* stands due to the high water content of leaves and shoots (Maydon 1957). Young, soft grass is taken following the onset of the rains (Swayne 1895). In the dry season various fruits, flowers and buds of trees, shrubs and tall herbs are preferred. More than 60 browse species have been identified in the diet; the lack of any clear dietary specialization does not help explain the species' restricted distribution.

Social and Reproductive Behaviour Very little information is available regarding social and reproductive behaviour in the wild (Meester 1960). Dibatags are vagrants throughout most of the year, foraging within a confined area. They probably maintain temporary defended territories at favourite sites demarcated by secretions from the preorbital glands, urine and faeces (Walther *et al.* 1983). They defecate at regular points forming dung piles (Wilhelmi 1997). Fighting techniques to defend territories have not been described and not yet observed by the author. Dibatags move in family parties

of 3–6 individuals, comprising only one adult ♂, in pairs, or solitarily; groups of more than four individuals are now very rare. N. Dougherty (pers. comm.) observed three sightings of larger mixed groups of 20, 15 and 8 individuals on the Somali coastal plain just north of the town of Jariban; these probably comprised an amalgam of several loosely associated smaller groups. Loose associations with Gerenuks and Soemmerring's Gazelle *Nanger soemmerringi* have been reported (Schomber 1966), although there are other reports of Dibatags actively avoiding Gerenuks (F. Wilhelmi pers. obs.).

Courtship and mating behaviour has only been observed in detail with a captive pair at the Zoo of Naples, and parts of the 'mating march' have been observed in the field by the author. Behaviour appears to be similar to that of the Gerenuk (Walther 1963). The ♂ marches behind the ♀ in erect posture with the nose lifted. Laufsclag (leg tapping) is exceptionally ritualized and pronounced. Standing close behind the ♀, the ♂ slowly raises a straightened foreleg between her hindlegs until contact is made. Prior to any mating attempt, the ♂ marks the ♀ on her chest, back and rump with the preorbital glands. This behaviour is, with the exception of the Gerenuk, otherwise unrecorded in the Antilopini (Walther 1958, Estes 1991a). Flehmen, nosing of female genitalia and mutual urine testing are part of courtship behaviour. Copulation takes place with the ♂ walking upright behind the moving ♀, with his forelegs dangling. Following parturition, young lie out concealed for one to two weeks and the nursing ♀ remains close to it during dependence.

Reproduction and Population Structure Females are thought to give birth from Sep to Nov to a single young after a gestation period of 6–7 months (Dittrich 1972, Walther 1990). Young are also reported in Jun and Jul (Meester 1960), thus rutting seems to be correlated with the onset of rain in different parts of the distribution range. Further details on reproduction, longevity and population structure not known.

Predators, Parasites and Diseases Large cats and Spotted Hyenas *Crocuta crocuta*, still present in the Ogaden, are probably

the most important predators. Black-backed Jackals *Canis mesomelas*, Caracals *Caracal caracal* and large eagles probably prey on young. Ticks (*Rhipicephalus parvus*, *R. pulchellus* and *Hyalomma detritum*) and filarial worms (*Artionema* spp.) have been reported from hunted Dibatags (Meester 1960). Nothing is known concerning other diseases. Captive individuals suffered from pneumonia (Schomber 1966).

Conservation IUCN Category: Vulnerable A2cd. CITES: Not listed.

Numbers of Dibatags have been severely affected by habitat degradation (due to excessive numbers of livestock), drought and overhunting. While their status appears to be precarious, its alertness, flight distance and the difficulty of hunting it in dense bush have enabled it to survive locally in viable numbers. In Ethiopia the species is legally protected from hunting, yet it does not occur in any protected areas, and enforcement of protective measures is needed. Given that this species is not known to occur in any formal protected areas in any part of its range, initiation of action to conserve this species is a very high international priority in antelope conservation. No Dibatags are known to be held in captivity.

GENUS *Litocranius*

Gerenuk

Litocranius Kohl, 1886. Ann. K. K. Naturhist. Hofmus. Wien 1: 79.

Litocranius includes only the Gerenuk *Litocranius walleri*, confined to the Somali–Masai Bushland BZ in dry wooded habitats. The species was mistakenly described as 'a new species of Gazelle from Western [sic] Africa'. There is some controversy about the spelling of the generic name: '*Lithocranius*' (= stony skull) is said to relate to the hard braincase. The original (and probably correct) spelling *Lito-* refers to the small size and relative flatness of the skull, compared with that of other Gazelles (cf. discussion in Schomber 1966).

Gerenuks are medium-sized antelopes (with a shoulder height up to about 100 cm, and mass of up to about 50 kg) similar in proportions to the Dibatag *Ammodorcas clarkei*. However, *Litocranius* differs from *Ammodorcas* in the more extreme specialization of skull, shorter

premaxilla, different horns and horn cores, presence of pedal glands, and a tufted tail. The Gerenuk differs from gazelles in its elongated body proportions, great elongation of the skull (gazelles being characterized by the shape of the cranium that does not narrow to form a projection, but is more rounded and the depression in front of the orbit is not fenestrated), low-crowned cheekteeth, close annulation of the horns, lack of inguinal glands, presence of two pairs of inguinal nipples, and colour pattern. Gerenuk regularly adopt a markedly upright bipedal feeding position that, together with their long limbs and neck, allow access to forage otherwise unavailable to a ruminant of its mass.

Peter Grubb

Litocranius walleri GERENUK (WALLER'S GAZELLE)

Fr. Gazelle-Girafe (Gazelle de Waller); Ger. Giraffengazelle (Gerenuk)

Litocranius walleri (Brooke, 1879). Proc. Zool. Soc. Lond. 1879: 929, pl. 56. '... mainland of Africa, north of the island of Zanzibar, about lat. 3° and long. 38°'. This was originally assumed to be in SE Kenya, but first specimens were later shown to have come from S Somalia, 'coast near Juba River' (Sclater & Thomas 1899). Type locality now accepted as 'the vicinity of Chisimaio' in S Somalia (Grubb 2002).

Gerenuk *Litocranius walleri* female (left) and male (right).

Gerenuk *Litocranius walleri* male myology.

The common name is derived from Somali (or other local) language, meaning 'giraffe-necked' (Simon 1962).

Taxonomy The first specimens (three skulls) of this animal were brought to England by one Gerald Waller, who obtained them from his brother (deceased in East Africa), hence the species name. Two subspecies have been named, the southern *L. w. walleri* and the northern *L. w. sclateri*, but their geographic separation has been unclear. Schomber (1966) called the Gerenuk a good example of a species with a discontinuous distribution and hence two clearly separable subspecies, but this was erroneous. The data available to him fortuitously included no records of Gerenuks from the area between the Galana and the Tana Rivers in Kenya, where the species is actually quite common. According to Schomber, the northern subspecies was somewhat larger than the southern one, which is confirmed by Grubb (2002) in his revision of the subspecies of the Gerenuk. Synonyms: *sclateri*. Chromosome number: $2n = 60$ ($FN = 60$) (Wurster & Benirschke 1968).

Description Extremely slender antelope with very long legs and an exceptionally long neck; head small with pointed, hairy muzzle and highly mobile lips. Eyes large, and surrounded by a whitish eye-ring. Ears fairly large with dark tips and black leaf-shaped markings on the inside. Facial pattern is indistinct: two whitish stripes separated by dark stripe from eye to muzzle; adult ♂♂ have a pronounced black spot around the orifice of the anteorbital gland. The centre of the

Lateral and palatal views of skull of Gerenuk *Litocranius walleri*.

face is fairly dark, and crown of ♀♀ blackish. Throat pale, tending to white. General body colour reddish-brown with a cinnamon tinge; back darker and sharply delimited against the flanks. No dark stripe along the sides. Underparts, inside of legs and buttocks white, clearly separated from brown parts. As a curiosity, an all-white adult male Gerenuk was observed in three consecutive years (1964–66) in the then Marsabit National Reserve in N Kenya (Kayser 1970). There are dark hair tufts on the 'knees'. Lateral (false) hoofs are minute. Tail of medium length with tapering terminal tuft of dark hair. Anteorbital

(functional probably in ♂♂ only), pedal and carpal ('knee') glands are present, but there are no inguinal glands. The neck in adult ♂♂ is considerably thicker than in ♀♀ and does not taper toward the head; the back in adult ♂♂ is often somewhat slanting.

Horns are found in ♂ only, and are blackish, rather thickset, lyrate, with tips curved forward; the spread is quite variable. The anterior surface of the horns is heavily ringed. Horn cores are smooth, with no ridges, and grooves only on the posterior surface; horns are not raised on pedicular extensions of the frontal bones. Skull is elongated and shallow with long slender jaws. Basicranium is very broad. Occiput is relatively flat on top, and sharply angled posteriorly compared with the more rounded cranium of other gazelle species; this appears to have been the principal basis for the separate generic name. The angle is even visible in living animals, particularly adult ♂♂, in lateral view (e.g. Fig. 15 in Schomber 1966). The premaxilla does not reach the long nasals. Preorbital fossae are shallow without marginal ridges. Median incisiform teeth are broad, remainder narrower but with both second incisors and canines somewhat broader than the third incisors; cheekteeth are low crowned.

Geographic Variation

L. w. walleri: NE Tanzania, Kenya, S Somalia and S Ethiopia. Smaller, with shorter cranial measurements (see Grubb 2002).

L. w. sclateri: restricted to the northernmost parts of the species' range (Djibouti, N Somalia, adjacent parts of Ethiopia). Larger (see Grubb 2002).

The subspecies have been said to differ in colouration (Neumann 1899), but this was not confirmed in the study by Grubb (2002), although the latter author did draw attention to a band of reversed hairs directed towards the head on the dorsal mid-line of the neck present in seven skins from Tanzania, Kenya and S Somalia (but absent in 12 skins from N Somalia) and that may have potential systematic significance.

Similar Species

Ammodorcas clarkei. Range overlaps entirely with that of the Gerenuk, but found only in E and C Somalia and SE Ethiopia (Ogaden) with a preference for more open habitat. Very similar in general appearance, especially ♀, but smaller, colouration more greyish (and lacking the two-tone body colouration), uniform on flanks, turning to reddish on legs and parts of head; tail blackish, carried upright in flight; horns (in ♂ only) shorter and sharply curved forward, as in reedbuck (*Redunca* spp.).

Aepyceros melampus. Sympatric only in East Africa. Similar colouring, but lacks the elongated legs and neck and has prominent dark thigh stripes; horns in ♂♂ noticeably longer.

Distribution Endemic to Africa. The Gerenuk is confined to the Somali–Masai Bushland BZ, mainly the 'Horn of Africa'. Its range extends from ca. 11° 30' N in S Djibouti (Künzel *et al.* 2000, Laurent & Laurent 2002) through E and S Ethiopia, much of Somalia, most of Kenya (except W and SW) to NE Tanzania. The southern limit lies in or near Tarangire N. P. in Tanzania, at ca. 05° 30' S. In the west the range extends to the east slope of the Great Rift Valley, and locally into it, to ca. 36° E. Information on occurrence of Gerenuk west of L. Turkana is conflicting, with some recent affirmative reports (Grunblatt *et al.* 1996, M. Dioli pers. comm.); in SW Ethiopia it

Litocranius walleri

is not recorded from west of the Omo R. (Yalden *et al.* 1996). In E Kenya, the Gerenuk's range is continuous, as far as habitat conditions are suitable.

Within recent history the Gerenuk's range has probably not changed much, except locally. In Kenya, the Gerenuk apparently disappeared from the vicinity of L. Baringo in the Rift Valley around the end of the nineteenth century (Stewart & Stewart 1963). More recently, local populations have decreased or even been eradicated in various areas through human encroachment (see Conservation).

Rock paintings and engravings of animals resembling the Gerenuk, found in Egypt, have been interpreted as indicating a much wider distribution in prehistoric and Predynastic times (e.g. Fig. 2 in Schomber 1966, Kingdon 1982, Osborn & Osbornová 1998; and see Manlius 2002).

Habitat The Gerenuk inhabits a variety of habitats that can all be characterized as semi-arid to arid, with some degree of woody cover. Colloquially called 'thorn bush', these habitats range from almost semi-desert to fairly dense woodlands and patchy thickets, notably of the *Acacia–Commiphora* type widespread in the Gerenuk's range. A certain proportion of shrubs, rather than trees only, are essential, and this is closely tied to the species' feeding habits (see below). Dense woodlands, for example, near rivers, are generally avoided, as are very open grass-dominated habitats, particularly areas with long grass (Leuthold 1978b). Reduction of woody cover through fire, elephants (as in Tsavo N. P., Kenya) or human activities may have led to a decline of Gerenuk populations locally (see Conservation). On the other hand, the species may benefit from encroachment of trees and shrubs due to overgrazing in some areas (Simon 1962).

The Gerenuk is largely confined to relatively flat areas and does not usually enter hilly country. It inhabits lowland areas up to an altitude of 1200–1600 m (Stewart & Stewart 1963, Yalden *et al.* 1996), except for coastal regions with unsuitable habitats. Water is not an essential requirement for the Gerenuk.

Abundance Because of its preferred habitat, small group size and somewhat cryptic colouration, the Gerenuk is difficult to census, both from the ground and – even more so – from the air. Figures on density and abundance thus have to be evaluated with some caution. Aerial surveys have suggested an estimated mean density of ca. 0.05 animals/km² (e.g. East 1999), a substantial underestimate for reasonably favourable habitats. Aerial counts near Amboseli N. P., Kenya, resulted in density figures of 0.2 ind/km² as a maximum (Grunblatt *et al.* 1995). In Tsavo N. P., mean density derived from road counts was 0.5–1 ind/km², with considerable variation between habitat types, but only minor seasonal differences (Leuthold 1978b). Densities may be considerably higher in areas with particularly favourable habitats, for example, up to 8 ind/km² in Samburu G. R., Kenya (Räder 1982, 1989).

Recent population estimates, derived mainly from aerial counts, add up to a total of 24,000 animals (East 1999), which is probably a substantial underestimate of actual numbers. Using correction factors for undercounting in aerial surveys, East (1999) revised the total population estimate to 95,000 animals over the species' entire range. The largest surviving populations occur in SW Ethiopia and the northern and eastern rangelands of Kenya, although East (1999) noted that the estimated total Kenyan Gerenuk population had decreased by about 50% since the 1970s.

Gerenuk *Litocranius walleri* female and male in bipedal posture.

Adaptations The most striking features of the Gerenuk are its very long neck and legs, which are similarly developed only in the Dibatag *Ammodorcas clarkei*. The skeletal basis consists of an elongation of the cervical vertebrae and the metacarpal and metatarsal bones (Richter 1970). In addition, the Gerenuk shows a phenomenal ability to rise up on its hindlegs and feed at up to 2 m above ground level. Basically, all ungulates can rise onto their hindlegs (they do it when mounting), but the Gerenuk is extreme in reaching a very erect bipedal posture that it can maintain for a considerable time. This erect stance is facilitated by some modification of the lumbar vertebral spines (Richter 1970). While feeding bipedally a Gerenuk may, but does not need to, rest its forelegs on the tree/bush being browsed, and it can even do several steps sideways on its hindlegs only. The Gerenuk uses this ability much more frequently than a few other ungulates that possess it, too (e.g. dik-diks of the Kirk's Dik-dik *Madoqua kirkii* complex), and several individuals may feed side by side in a bipedal stance. Occasionally, they may even pull down a branch with a foreleg for better reach (Räder

Gerenuk *Litocranius walleri* head myology.

1982). The ecological advantage of all this is to permit the Gerenuk to gather food at higher levels than animals of similar weight with more 'normal' proportions, an important aspect of ecological separation (Leuthold 1978a). As further adaptations to feeding from trees and shrubs, particularly thorny ones, the Gerenuk's muzzle is rather narrow and pointed, and the lips and tongue are highly mobile, enabling the animals to pluck small leaves from among thorns of, for example, *Acacia* trees. These characters, coupled with the long and pliable neck, make possible the Gerenuk's highly selective feeding style. Sensory hairs on various parts of the head may help avoid injuries to the eyes from thorns or twigs.

Gerenuk *Litocranius walleri* frontal view of head.

As in some other browsers, the stomach of the Gerenuk is characterized by a small rumen, omasum and abomasum, but a large reticulum. These features are related to its food choice (see following section), implying a quick turnover and a high fermentation rate, in contrast to the situation in grazers (Hofmann & Stewart 1972). In structure (and function) the Gerenuk's stomach is very similar to that of the Giraffe *Giraffa camelopardalis*, providing a good example of convergent evolution (Hofmann 1973). Also related to the Gerenuk's feeding habits are the relatively low crowns of the molar teeth, compared with the much higher ones of grass-eating relatives, and the spoon-shaped, sharp-edged incisors.

The Gerenuk appears to be entirely independent of free water. There are no well-documented observations of a Gerenuk drinking, not even in captivity (Schomber 1966). Evidently, the animals can satisfy their water requirements entirely from their food. The 'capacious, heavily papillated ruminoreticulum [forms] ... an ideal substrate for water absorption' (Hofmann 1973).

While undisturbed, a Gerenuk walks slowly, with fairly long steps; when alarmed it uses a somewhat slinking pace, which quickens into a bouncing gallop in full flight. The latter is reminiscent of the 'stotting' of Thomson's Gazelle *Eudorcas thomsonii*, but not as pronounced. Sometimes the hair of the perineal area is spread in flight, forming a white rump patch.

In the relatively hot climate of the Gerenuk's range, regulation of body temperature may be a potential problem. Daytime activity patterns vary widely from day to day and between seasons. In Tsavo N. P., the mean proportions of foraging time are 47% (range 32–64%) in adult ♂♂ and 60% (range 51–68%) in adult ♀♀, the latter probably being higher because of additional requirements for pregnancy and/or lactation. Conversely, ♂♂ spend more time (25%) ruminating than ♀♀ (15%). An alternation between foraging and ruminating bouts is apparent but not very pronounced. Movements and foraging time are reduced in very hot weather, when the animals may remain in the shade of trees or bushes. In cool conditions, and especially during rain, a Gerenuk may lie down. This reduces the surface exposed to heat loss (Leuthold & Leuthold 1978b). Nocturnal activities vary with light conditions, being lower in very dark nights. In Samburu G. R., the

animals usually move to areas of more open vegetation for the night, which presumably facilitates detection of predators (Räder 1982, 1989).

A behavioural adaptation related to the great length of the neck entails a slight modification of fighting technique in the Gerenuk, compared with that of other antelopes (see Social and Reproductive Behaviour). The elongation and relative flatness of the cranium can also be seen in this context (Kingdon 1982).

Foraging and Food The Gerenuk is one of the most exclusive browsers among bovids, i.e. eating leaves, flowers and occasionally fruits of broad-leaved (dicotyledonous) plants only. No grass was recorded among over 5000 food items identified in Tsavo East N. P. (Leuthold 1978b) or in stomach contents examined by Hofmann & Stewart (1972). Indeed, in their review of the dietary preferences of African bovids, Gagnon & Chew (2000) classified Gerenuk as browsers, with a diet comprising as much as 95% dicotyledons and 5% fruit; this is largely mirrored by studies involving stable carbon isotope analysis (Cerling *et al.* 2003).

Gerenuks utilize a wide range of food plants, with over 80 plant species recorded as being eaten in Tsavo East N. P. The great bulk of the food consists of leaves of trees and shrubs, with considerable seasonal variation. Many of the woody plants typical of the Gerenuk's habitat are deciduous, shedding their leaves during the – often very long – dry seasons. In the wet season a considerable number of climbers and vines grow leaves, which in Tsavo East N. P. may constitute up to 25% of the Gerenuk's diet (e.g. *Thunbergia guerkeana* and several species of Cucurbitaceae). Woody plants commonly eaten at that time include *Premna resinosa*, *Bauhinia taitensis* and several species of *Acacia* and *Commiphora*. In the dry season leaves of trees and shrubs make up 95% or more of the diet, including mainly evergreen species, such as *Thylachium thomasi*, *Boscia coriacea* and *Salvadora persica*. The extent of seasonal variations depends on the composition of the available vegetation and the local and temporal distribution of rainfall. In Samburu G. R., where *Acacia* species are much more abundant, these constituted the bulk of the Gerenuk's food, and no climbing plants were recorded as being eaten (Räder 1982).

Particularly in the dry season, the Gerenuk appears to be highly selective with respect to plant parts eaten. The evergreen species mentioned above have rather coriaceous leaves, and a Gerenuk often 'sniffs over' the plants at some length before accepting anything. Conversely, some of the climbers taken in the wet season clearly appeared to be 'sought-after'. Presumably, this behaviour serves to optimize protein – and perhaps water – intake. When available, the fruits of *Solanum incanum* ('Sodom Apple') are also consumed in some quantity, constituting up to 30% of solid stomach contents (Hofmann 1973). As they are round and fairly hard, they have to be chewed at some length, which makes feeding on them very obvious to the observer. This is also a situation in which a Gerenuk may collect food items extensively at or near ground level. Leaves of the trees *Melia volkensii*, *Sterculia* spp. and the slightly succulent shrub *Euphorbia scheffleri* seem to be rejected entirely (although eaten by Lesser Kudu *Tragelaphus imberbis* and Giraffe). The seasonal changes in plant condition and availability are the probable reason for at least small-scale seasonal movements related to vegetation type and stratification (Figs 3 & 4 in Leuthold 1978b; and see Räder 1982).

Gerenuk *Litocranius walleri* skeleton.

Young animals appear to develop their specific feeding habits by closely following their mothers and consuming plant material eaten by those. A young Gerenuk raised in captivity together with a young Lesser Kudu ate several plant species not recorded as being eaten by free-ranging Gerenuk, evidently as a result of imitating its companion (Leuthold 1971a).

Social and Reproductive Behaviour The Gerenuk lives singly or in small groups rarely exceeding 5–6 animals. Groups of 25–30 animals (Schomber 1966) appear to be highly exceptional and may be temporary aggregations caused by favourable feeding conditions. Group size, composition and stability vary between populations of different densities. In Tsavo East N. P. (low density), mean group size was ca. 2.5, with a maximum of 13 and did not vary seasonally (Leuthold 1978c). Animals of different sex/age classes associate in various combinations. Apart from the mother–young bond, there appear to be few stable associations. Subadult ♂♂ tend to join up with ‘peers’ to form loose groupings that may persist for some time. Adult ♂♂ occur singly more often than expected on the basis of their proportion in the population, suggesting territoriality. In Samburu G. R. (high density), groups of both ♀♀ and subadult ♂♂ are somewhat larger, more stable and tend to develop a rank order based mainly on age (Räder 1982, 1989, 1998).

Home-ranges of individually known animals measured 1.5–3.5 km² and were occupied year round. Those of six adult ♂♂ in one area averaged 2.5 km² and showed little or no overlap. Behaviour associated with territoriality includes intolerance of other adult ♂♂, a striking defecation posture and scent-marking with anteorbital glands. Only adult ♂♂ adopt a strongly crouched posture for defecation, which is usually preceded by sniffing the ground and/or scraping it with a forefoot. Often old dung is present at a defecation site, suggesting the formation of dung heaps with a possible olfactory significance (Leuthold 1978c). However, large amounts of dung, as in some other species, do not accumulate.

Adult ♂♂ mark protruding stems and twigs of trees and shrubs with a tar-like secretion of their anteorbital glands (Fig. 21 in Leuthold 1977). The sites are sniffed at before marking and are often used repeatedly, so that small ‘tar balls’ accumulate. The marking sites are concentrated at a height of 105–125 cm above ground and occur

almost exclusively on plant species that are eaten by the Gerenuk. In one case examined in detail, scent-marks were arranged in an oval-shaped polygon, measuring 30 and 12 ha in consecutive years, with additional ones ‘radiating outward’ (Gosling 1981). All these characteristics may ensure a high probability of the markings being detected, irrespective of their function, which remains unclear.

Thus, adult ♂♂ are territorial, whereas ♀♀ have individual home-ranges that may overlap with those of other ♀♀ and the territories of one or several ♂♂. In Samburu G. R., several ♀♀ share the same home-range, which is essentially congruent with the territory of one ♂♂. Subadult ♂♂, individually or in small groups, also occupy home-ranges overlapping those of other individuals. As they grow older, they are increasingly harassed by territorial ♂♂. Overall, the social organization of the Gerenuk resembles that of several other small antelope species (SO-type 4 of Leuthold 1977). Apart from olfactory marking with urine, faeces and the secretion of anteorbital glands, territories may be advertised visually by ♂♂ standing upright on elevated spots such as termite mounds (Fig. 9 in Leuthold 1978c).

In mixed groups adult ♂♂ are clearly the most dominant individuals, from which other animals withdraw in situations of possible conflict. However, they do not usually initiate or lead a group’s movements but

tend to trail behind. Agonistic behaviour includes shrub-horning, i.e. thrashing branches of shrubs or small trees with the horns, and possibly horning the ground, though the latter has been observed only in captivity (Walther 1968). Serious fighting is observed rarely in the wild because of the rarity of encounters between adult ♂♂. Subadult ♂♂ often engage in sparring or play-fighting, and this is accompanied by other playful elements (e.g. cavorting, feinting). These behaviours look particularly 'graceful' in the Gerenuk because of its long limbs and neck. They are accompanied by much head-jerking, head-low threats, and occasional 'facing away' (head upright, turned sideways), as well as vigorous tail-swishing. Actual fighting among adult ♂♂ differs somewhat from that of other bovids in that heavy head-to-head clashes are avoided, the long and slender neck not being suited to withstand them. Instead, male Gerenuks clash horns by vigorous nods or jerks of the head, with necks held low. The power for the nods is developed by the heavy muscles near the top of the neck, while the elongated cranium provides additional leverage (Kingdon 1982). When pressed hard, young ♂♂, and sometimes ♀♀ too, lift the tail and curl it over the back in what appears to be a submissive gesture (Fig. 9 in Leuthold 1971b). Lying down as a submissive behaviour, described from captive animals (Fig. 28 in Walther 1968), was not observed in the field.

Courtship behaviour resembles that of other gazelles, with prolonged attempts of the ♂ to approach the ♀ from behind, but no special posture is adopted in this context as, for example, in Thomson's Gazelle (Walther 1968). Particularly striking on account of the Gerenuk's

long legs is lauschlag, in which an outstretched foreleg is raised slowly into a near-horizontal position, usually from behind the ♀. This may induce the ♀ to urinate; in response, the ♂ commonly shows flehmen, as most bovids do. The mating posture is very upright, as in other gazelles (perhaps even more so), with forelegs dangling and not touching the ♀; copulation may be achieved while the ♂ walks bipedally. A feature characteristic of the Gerenuk – also shown by the Dibatag – is marking of the female's shoulders or rump by the ♂ with his anteorbital glands (Backhaus 1958, Walther 1958; Fig. 10 in Leuthold 1978c). In captivity, the ♂ produced a 'humming' sound during courtship; this may be too low to be audible in the field.

In two cases observed in captivity, the ♀♀ gave birth while standing. The young was able to stand within about an hour and uttered low-pitched calls that were answered by the mother. The latter consumed amniotic fluids and the entire afterbirth, which appeared 2–3 hours postpartum (Kirchshofer 1963). Behavioural interactions between mother and young correspond to those of other gazelles (Walther 1968). Females lick their offspring frequently, particularly in the perineal area, and the young lie out for extended periods of time while their mothers move up to 1 km away. The young animals use hiding places with different characteristics for day and night, respectively (Reif & Klingel 1991). The ♀ returns to the young's hiding place periodically, mainly in the morning and evening (no data for the night). Suckling takes place in a few bouts lasting about 2 min each, timing and duration being determined mainly by the mother. The latter consumes her offspring's urine and faeces. The young animal often runs and cavorts about playfully after being suckled (Leuthold 1978c). When about 4–6 weeks old the young gradually change their activity pattern, start feeding on plants and begin to follow their mothers. They attempt to rise onto the hindlegs from two weeks of age, but become adept at it only at 2–3 months. The mother–young association lasts 8–9 months, i.e. until the following young is born. If the latter dies soon after birth, the previous young may rejoin its mother, particularly if it is a ♀. Otherwise it will leave its mother's group and attempt to join another female group. The fate of a young ♂ depends to a large extent on the tolerance of the territorial ♂. But at one year of age, at most, young ♂♂ leave their original home-range and join a bachelor group.

Captive animals observed by Walther (1958) showed much mutual licking and nibbling but in the wild such behaviour was rather rare; the main contact behaviour observed consisted of mutual head rubbing while standing close together (Fig. 11 in Leuthold 1978c). Also, vocalizations were rarely noticed in the wild, perhaps because they were too low to be audible. Young animals utter a short bleating call before being suckled, which was also noticed in a young ♂ raised in captivity. When alarmed, as by a predator, a Gerenuk may utter a short snorting sound, apparently by forcing air through the nostrils, with abdominal contractions being visible.

Reproduction and Population Structure Reliable data on reproductive parameters are difficult to obtain in the wild. Births are distributed throughout the year, though not quite evenly, and one young is born at a time. Inter-birth intervals are 7.2–9 months (Leuthold 1978b, Räder 1982).

The Gerenuk has been bred successfully in zoos, particularly in North America, where information on over 430 births since 1977 is

available (R. Barnes pers. comm.). Females attain sexual maturity at about one year of age and, with an estimated gestation period of 28–29 weeks, can give birth at less than two years of age (Backhaus 1958). With a postpartum interval of 3–4 weeks (or even less), a ♀ can produce four young within three years (Kirchshofer 1963, Ditttrich 1970, Leuthold 1978b). Mean birth-weight of 90 young born at Los Angeles Zoo was 3.4 kg, ♂♂ being slightly heavier than ♀♀ (R. Barnes pers. comm.). Detailed parameters of reproductive physiology and artificial insemination studies are discussed by Penfold *et al.* (2005).

For ♂♂ the situation differs in that, in the wild, reproduction is usually contingent upon holding a territory. Whereas physical maturity may occur earlier, a ♂ will reach social maturity towards three years of age. Horns begin to grow at 6–8 months and reach the full double curve at ca. 2.5 years. It takes some additional time for the neck to attain the thickness typical of adult ♂♂ (Leuthold 1978b). Little is known on longevity. Animals observed in Tsavo East N. P. were estimated to be 7–8 years old. Weigl (2005) reports a captive specimen living to 17 years.

In view of the low density, data on population structure are difficult to obtain. In Tsavo East N. P., a sex ratio of 65 ♂♂ to 100 ♀♀ over about one year of age suggests that ♂♂ suffer higher mortality during adolescence than ♀♀, a phenomenon well known in other ungulate species.

Predators, Parasites and Diseases There is no quantitative information on predation and its possible influence on Gerenuks. Adult animals may fall prey to any of the larger predators in their range, such as Leopards *Panthera pardus*, Cheetahs *Acinonyx jubatus* and African Wild Dogs *Lycaon pictus*, whereas many smaller predators, including large birds of prey, could be dangerous for young animals. Because of its small size, remains of a Gerenuk killed by predators are unlikely to be found. Neither is there much information on parasites or diseases in the Gerenuk. Like other artiodactyls the species is said to be susceptible to rinderpest, which occurs in periodic outbreaks in Africa, and apparently contributed to the decline of the population in Tsavo N. P. (East 1999). In captivity, a considerable proportion of young died at an early age, but causes of death were usually unknown (in addition, there were several stillbirths at Frankfurt Zoo; Kirchshofer 1963).

Conservation IUCN Category: Near Threatened. CITES: Not listed.

Living in semi-arid to arid areas, in which agriculture and other human activities mostly remain at a low level, the Gerenuk is not immediately threatened. Expanding human populations and concomitant intensification of land use (such as pastoralism, collection of firewood, illegal hunting) have led to a substantial decrease of Gerenuk numbers in some areas and to minor reductions in the species' range locally (East 1999, F. Wilhelmi pers. comm.; see also Distribution). Some of these adverse influences of human activities will doubtless continue and may even increase locally. Serious problems are created by the recurrent political unrest and warlike situations in parts of the Gerenuk's range (particularly Somalia and Ethiopia). These cause law enforcement and supervision of conservation areas to subside, so that illegal hunting may become prevalent. Such conditions also make it difficult to obtain reliable information on the situation in the

areas affected. The exact status and the degree of potential threats thus cannot be assessed accurately, nor can possible conservation measures be devised and implemented.

Fairly large areas within the range of the Gerenuk are under some kind of protection, particularly in its southern parts, e.g. Tsavo East, Sibiloi, Meru and Amboseli National Parks, Samburu and neighbouring Game Reserves in Kenya, and Mkomazi G. R. and Tarangire N. P. in Tanzania. In Ethiopia, the species occurs in Mago and Yangudi-Rassa National Parks and several Wildlife Reserves, and in Somalia in Bush Bush N. P. About 10% of the total population are estimated to live in protected areas (East 1999). Provided that protection of the areas mentioned remains effective, the survival of the Gerenuk is likely to be assured. However, this statement applies only to the southern subspecies *L. w. walleri*; the range of *L. w. sclateri*, as defined by Grubb (2002), includes few well-protected areas at present. Actions are necessary to remedy this situation.

Measurements

Litocranius walleri

HB (♂♂): 1550–1600 mm

HB (♀♀): 1400–1550 mm

T: 250–350 mm

GENUS *Antidorcas*

Springbok

Antidorcas Sundevall, 1847. Kongl. Svenska Vet.-Akad. Handl. Stockholm 1845: 271 [1847].

Antidorcas includes only the Springbok *A. marsupialis*, a small- to medium-sized antelope of slender proportions limited to South Africa, Namibia and SE Angola. The genus was assigned to its own tribe by Haltenorth (1963; Antidorcatini) and Kingdon (1997; Antidorcini), though correctly this should be Antidorcadini (see Grubb 2001a). In this work, the genus is included in the tribe Antilopini, which is consistent with current molecular (Hassanin & Douzery 1999, Matthee & Robinson 1999a, Matthee & Davis 2001; Hassanin *et al.* 2012 and see Hernández Fernández & Vrba 2005) and morphological (Groves 2000) studies.

Fossils belonging to the genus *Antidorcas* occur in Pliocene and Pleistocene deposits in East and southern Africa, and more doubtfully in North Africa. This antilopine type often predominates among the Antilopini of Pleistocene faunas (*A. Gentry pers. comm.*). The entirely southern distribution of the single species today contrasts starkly with the abundance of several fossil species in deposits over several million years, and their wide distribution in Africa is indicative of the ecological range and success of this genus in the past. The antilopine niche is one of foragers living in arid to semi-arid biomes with unreliable rainfall and, as a result, dispersed resources.

Few palaeontological studies of *Antidorcas* have been undertaken. However, Vrba (1973) suggested that fossil species *A. recki* and *A. bondi*, and to a lesser extent *A. australis*, are closer to the ancestral antidorcine condition than is the extant *A. marsupialis*. She hypothesized, based on cranial and dental morphology, that *Antidorcas* arose in East Africa from the ancestral *Gazella* more than 3 mya during the Pliocene, giving rise to the three fossil species mentioned. Moreover, there is good evidence that *A. bondi* and *A. recki* occurred in South Africa, and that *A. bondi* was present during the late Pleistocene (Brain 1981).

Brink & Lee-Thorp (1992), examining the feeding niche of the extinct, and extremely hypsodont, *A. bondi*, suggest that a small- to medium-sized grazing antelope had a high fibre diet. *Antidorcas bondi* disappeared quite suddenly 7000 years ago at the end of the last glacial when the environment became significantly drier (Scott 1992). Following this aridification, *A. marsupialis* arose from *A. recki* (Vrba 1973, Brain 1981). *Antidorcas marsupialis* is recorded in Herold's Bay Cave deposits that are at least 80,000 years old (Brink & Deacon 1982), and it is possible that the Florisbad *A. marsupialis* is more than 100,000 years old (Brink 1987, 1988).

The specific name of the species '*marsupialis*' derives from *marsupium*, a pouch (derived from the dorsal fan of long white hairs, which, when not erected, lie flat) hidden by the brown hair on the back, a characteristic unique to this species. Springbok stand ca. 75 cm at the shoulder and body mass varies geographically. Their slim sleek appearance gives the impression of speed and grace. Their distinctive cinnamon-brown colouration contains a reddish-brown band running from the upper region of the foreleg to the hip. This band separates the dark dorsal areas from the pure white ventral surfaces. The skull, which is typical of the family Bovidae, can be distinguished from other mixed dicotyledenous feeders by the exceptionally short premolar row (Spencer 1995). The anatomy of the postcranial skeleton is also typically that of a cursorial bovid, but sufficiently different from that of the extinct *A. bondi* to allow separation of fragmented skeletal remains of the two species (Plug & Peters 1991). A thorough and detailed review of the Springbok is provided by Skinner & Louw (1996).

John D. Skinner

Antidorcas marsupialis SPRINGBOK (SPRINGBUCK)

Fr. Springbok; Ger. Springbok

Antidorcas marsupialis (Zimmermann, 1780). Geogr. Gesch. Mensch. Vierf. Thiere 2: 427. South Africa, 'die Lander am Cap der guten Hoffnung', since restricted to 'Cape Colony [Cape Prov.]' (Lydekker 1914: 111).

Taxonomy Three subspecies have been recognized (Ansell 1972, Groves 1981c, Meester *et al.* 1986), although Robinson (1979) concluded that there was little support for their continued recognition and that those advocating subspeciation ignored the interaction between heredity and the environment on certain traits. Subsequently, Peters & Brink (1992), examining skulls from specimens of Kalahari Springboks and from the South African interior, concluded that size differences were indeed apparent between animals north and south of the lower Orange and Vaal Rivers, and that these differences might well result from subspeciation (see also Geographic Variation). Synonyms: *angolensis*, *centralis*, *dorsata*, *euchore*, *hofmeyri*, *pygargus*, *saccata*, *saliens*, *saltans*. The species has a monomorphic karyotype, with chromosomes $2n = 56$; the X chromosome is large and acrocentric, while the Y chromosome is small and metacentric (Robinson & Skinner 1976).

Springbok *Antidorcas marsupialis*.

Springbok *Antidorcas marsupialis*.

Description Medium-sized antelope similar in appearance to Thomson's Gazelle *Eudorcas thomsonii*, and standing about 750 mm at the shoulder. Males reach their asymptotic mass of 34 kg and length of 1400 mm at three years cf. 28 kg and 1340 mm for ♀♀ at 2.5 years in the Eastern Cape (Penzhorn 1974). The back appears to slope forward because the hindquarters appear higher than the forequarters. Face white with reddish-brown line running from anterior margin of eye to corner of mouth. Ears long, narrow and pointed. Back is bright cinnamon-brown with a distinct reddish-brown band running from the upper region of the foreleg to the hip, separating dark dorsal areas from white ventral surfaces that continue onto the flanks and marginally onto the anterior of the thighs. The medial surface of the rump is also white, narrowing into the dorsal crest of long (100–120 mm) white hairs, usually not apparent unless the crest in the pouch is erected (see Adaptations). Unlike hairs on the rest of the body, these are implanted at right-angles on the body (Findlay 1989). 'Black' and 'white' colour variations are rare, but exist, although the latter are not albinos (Kruger *et al.* 1979). Both black and white, and variations thereof, occur in herds with normally coloured individuals (Skinner & Louw 1996). Visual differences in the pelage are due to differing quantities of melanin and the translucency thereof, as well as to pale yellow horny cells in white hairs, and to the medulla, rather than due to colour as such (Findlay 1989). The hairs are concavo-convex in cross-section with gutters and an irregular waved scale pattern, two or three scales across the width (Keogh 1983). Tail white, with a terminal tuft of black hair. Legs long and slender. Preorbital and pedal glands are present, but there are no glandular knee-tufts as in other Antilopini and no inguinal glands. Adult ♀♀ are similar to ♂♂, but smaller. Females typically have a single pair of inguinal nipples, though individuals with two pairs are known.

Males possess heavily ridged horns that slope backwards, then diverge outwards and, in mature ♂♂, curve sharply inwards in a hook at their tips (lyrate). Female horns are more lightly ridged, distinctly smaller and more gracile. The skull is typically bovid, with well-developed mandibles and zygomatic arches. The supraorbital

Lateral and palatal views of skull of Springbok *Antidorcas marsupialis*.

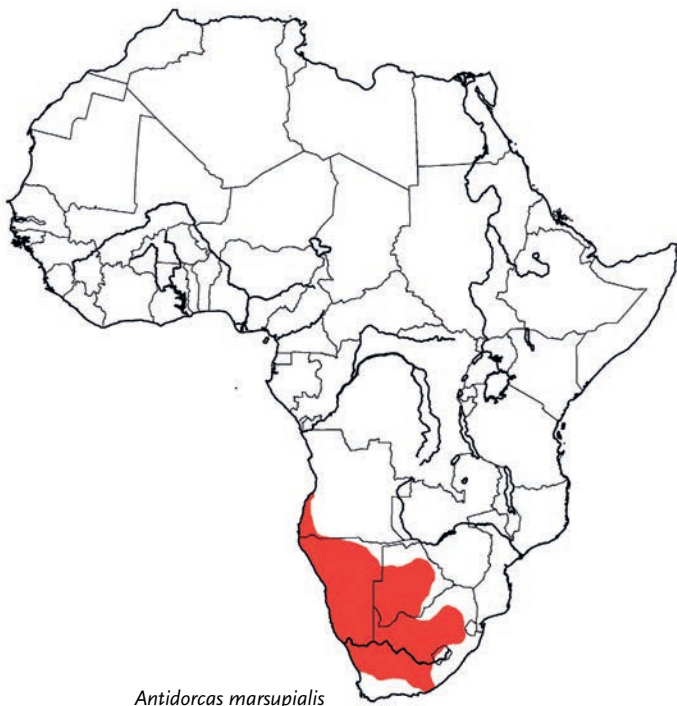

foramina is large, and the auditory bullae are small. Both anteorbital fossae and preorbital fossae are present. The premaxillae are wide aposteriorly, narrowing anteriorly. The dental formula, in contrast to the normal bovid dentition, is $I^{0/3}, C^{0/1}, P^{2/2}, M^{3/3} = 28$. The premolar tooththrow is short, with upper and lower first premolars lost and upper and lower second premolars, if present, small and non-functional. Adult dentition is reached at 22 months of age (Skinner & Louw 1996).

Geographic Variation Springboks vary in size, as mentioned earlier, and colour, which has given rise to former claims of subspeciation, but as these are both traits affected by environmental differences, there has been little consensus on the recognition of subspecies. In the eastern Highveld, where nutritional levels are low, Springbok mass is low, increasing south-west to the Karoo where, although body mass is heavier, this is further confounded by large ♂♂ having been consistently hunted for centuries. In Kgalagadi Transfrontier Park (South Africa/Botswana), Springboks are heavier, giving rise to a demand for rams to be imported, especially into the Karoo. However, there are no results from 'crossing' these rams with Karoo ewes in controlled experiments, to prove any beneficial effects. Kgalagadi Springboks are paler in colour, probably due to evolution through millennia in response to a duneveld environment. The largest Springboks occur in the Namibian Kaokoland where the soils are the most alkaline and herbage more protein-rich, in contrast to the situation in the north-west Highveld. Springbok in the Namib Desert in Angola are smaller with variable horn shape, although the sample taken there was small.

Similar Species Within their current range, Springboks cannot be confused with any other species, being the only 'gazelle' occurring in southern Africa.

Distribution Almost entirely confined to southern Africa, south of the Cunene and Zambezi Rivers, with the exception of a marginal intrusion into SW Angola in the Namib Desert west of the Escarpment.

Historical Distribution Rookmaker (1989) provides evidence of the abundance and widespread distribution of Springbok in the former

Cape Province, throughout the eastern, western and northern regions, where they were especially common on the arid plains. However, after 1870 the commercial demand for skins and the advent of the breech-loading rifle markedly reduced their numbers. Millais (1919) reported that nearly two million Springbok, Blesbok *Damaliscus pygargus* and Black Wildebeest *Connochaetes gnou* skins were exported between 1878 and 1880. One feature of Springbok distribution was migration or treks, which rarely, if ever, now take place. These were invariably triggered by a lack of pasture, with Springboks moving from an arid to a more mesic region (Skinner 1993). The impact of rinderpest, which killed thousands of antelopes, and reached the Cape in 1896, was another important factor affecting the frequency of Springbok treks. The last major treks occurred at the end of the nineteenth century, but, when numbers in the pristine Kgalagadi again increased, Sir Laurens van der Post, then Native Commissioner in Botswana, witnessed mass aggregations and trekking in the south-west (Skinner & Moss 2004). Today, this is an extremely rare occurrence due to a decline in numbers in the Kgalagadi and stock fences in the Karoo.

Current Distribution In Angola, restricted to coastal Namib Desert, from the Cunene R. north to Benguela. They remain widespread in Namibia, apart from the north-east, particularly on private farmland. In Botswana they occur in the south and west, north to 20° S on the Namibian border. In South Africa they have been widely reintroduced throughout their former distribution range, and also introduced to regions outside of their historical range (e.g. southern and central KwaZulu-Natal) (Skinner & Louw 1996, East 1999, Skinner & Chimimba 2005). There is no evidence that Springboks ever occurred in Swaziland (Monadjem 1998), although they ranged into the western lowlands of Lesotho (Lynch 1994).

Habitat Typically a species of arid regions and open grassland, Springboks are partial to the wide, short grass fringes of pans and

to fossil river beds and valley terraces. They occur from sea level to 2000 m on the Highveld. They do not occur in woodland savanna almost certainly due to the presence of heartwater, spread by the tick *Amblyomma hebraeum*, and to which they show no resistance (Neitz 1944). Springboks tend to occur in areas where surface drinking water is unavailable or only available seasonally.

Abundance East (1999) estimated the total population in southern Africa at more than 670,000, noting that it was probably an underestimate. Indeed, recent estimates for Namibia alone put the population at 730,000, itself an underestimate (P. Lindeque pers. comm.). Elsewhere in the range, numbers are probably in the order of 10,000 for Angola, 40,000 in the Botswana side of Kgalagadi Transfrontier Park (and an additional 60,000 at least in the rest of the country), 75,000 in the Free State, 75,000 in Gauteng and North West, 1,000,000 in the Karoo and about 100,000 in the Cape provinces outside of the Karoo. Numbers are extremely hard to estimate, but based on these figures the total population size in southern Africa is estimated at ca. 2,000,000 to 2,500,000 animals and increasing.

Springboks are a commercially important game species and, while numbers in the Kgalagadi have plunged in the past decade (the reasons for which are unknown), estimates in the Karoo show an opposite trend and are currently some 1,000,000 animals despite an annual cropping rate (for meat and skins) of 200,000 (Skinner & Moss 2004).

Adaptations Springboks have a thinner pelage and higher conductance than would be predicted for their body mass (Hofmeyr & Louw 1987). Advantages include the ability to off-load excessive heat rapidly without resorting to evaporative cooling, if ambient temperature is lower than body temperature, e.g. after sprinting away from predators. The white belly fur and long hairs of the dorsal crest reflect 72% of the sun's radiation, including that reflected from the desert surface. Disadvantages of the pelage are that the animals lose heat rapidly and begin shivering at moderately low temperatures and gain heat rapidly when ambient temperatures high. These are offset by behavioural adaptations, with Springboks seeking cooler areas and shade, orienting the long axis of the body towards the sun, and foraging mainly in the post-dawn and pre-dusk hours (and often at night), so that in free-ranging Springboks, extreme responses were never exhibited (Hofmeyr & Louw 1987).

Hetem *et al.* (2009) measured core body temperature in ♀♀ of three colour morphs of Springbok (normal, black, and white), free-living in the Karoo. During winter, white Springbok displayed lower daily minimum body temperatures ($37.4 \pm 0.5^\circ\text{C}$), than both black ($38.1 \pm 0.3^\circ\text{C}$) and normal ($38.0 \pm 0.6^\circ\text{C}$) Springbok; during spring, black Springbok displayed higher daily maximum body temperatures ($40.7 \pm 0.1^\circ\text{C}$) than both white ($40.2 \pm 0.2^\circ\text{C}$) and normal ($40.2 \pm 0.2^\circ\text{C}$) Springbok. Black Springbok had lower diurnal activity in winter, explained by their having to forage less because their metabolic cost of homeothermy was lower, but were disadvantaged in hot periods. White Springbok, by contrast, were more protected from solar radiation, but potentially less able to meet the energy cost of homeothermy in winter. Consequently, energy considerations may underlie the rarity of the various colour morphs.

Mitchell *et al.* (1997), in their studies on wild Springboks, found no evidence for adaptive heterothermy. Although selective brain

cooling is activated at high body temperatures, this is absent during vigorous exercise even when body temperatures are high. Fuller *et al.* (2005) found that mean monthly body temperatures are strongly positively correlated with photoperiod and that annual and daily variations in body temperature reflect an endogenous rhythm, entrained by the light:dark cycle, but largely independent of fluctuations in the environmental thermal load. Springboks exhibit remarkable homeothermy and Fuller *et al.* (2005) confirm that Springbok do not employ adaptive heterothermy to survive in their natural environment.

Springbok *Antidorcas marsupialis*.

The anatomy of the digestive system is well adapted to a diet of mixed forage, but the ability to digest highly fibrous food is limited (Hofmann *et al.* 1996). During droughts, even when sufficient lignified monocotyledons are available and consumed by, for example, sheep *Ovis aries*, Springboks starve to death (Davies *et al.* 1986).

Springboks have a *marsupium* or pouch extending along two-thirds of the back, which gave rise to its specific name. This fold encloses a dorsal fan of long white hairs, which, when not erected, lie flat as in a pouch and hidden by the brown hair of the back. The sebaceous glands within the pouch secrete an exudate with a strong, sweet odour, which most probably functions as a specific alarm signal when the back is arched, legs stiffened and the fan of white hair fully erected as the Springbok stotts or pronks (Burger *et al.* 1981a, Skinner & Louw 1996). Stotting comes into play when Springboks are alarmed, and particularly in response to sighting coursing predators.

Foraging and Food Primarily a browser, but taking also grass, the Springbok belongs to the intermediate group of feeders (Hofmann *et al.* 1996), a classification supported also by a detailed review of dietary preferences in bovids (Gagnon & Chew 2000) and by stable carbon isotope analysis (Sponheimer *et al.* 2003b). Springboks graze young succulent grass before it begins to lignify, and select succulent browse plant parts with a high ratio of leaf to stem. They have been found to browse a large number of species in the Karoo (Davies *et al.* 1986); in the latter study, the diet of adult ♂♂ and ♀♀ differed, rams preferring more palatable shrubs, especially *Salsola* spp. and *Eriocephalus ericoides*. Ewes preferred *Delosperma* spp.,

Plinthus karoocicus and significantly more *Eberlanzia spinosa*. The larger body size of Springbok rams and their larger fermentation capacity in their digestive system, enable them to use more fibrous material than ewes and juveniles. Bigalke (1972) found that karroid shrubs *Pentzia incana*, *P. tenuifolia*, *P. globosa*, *P. lantana*, the shrub *Rhus ciliata* and *Acacia tortilis* were important in the Springbok's diet.

In Kgalagadi Transfrontier Park, Leistner (1967) listed 57 species eaten, including grasses, shrubs and ephemerals. Grasses *Stipagrostis obtusa* and *Schmidtia kalahariensis*, shrubs *Monechma australe* and *Rhigozum trichotomum* and the legume *Psoralea obtusifolia* were preferred food plants and another 14 plant species of shrubs and ephemerals were eaten frequently. In the transition zone between the Karoo and Kgalagadi, Liversidge (1970) noted that, of 33 species eaten, monocotyledons predominated in rumen samples in the wet season and dicotyledons in mid-winter. On the other hand, van Zyl (1965) listed 68 species of plants eaten on the north-west grassland Highveld, of which 20 were the main food plants, including nine grasses and 11 shrubs. Important grasses were *Themeda triandra*, *Cynodon* spp., *Panicum* spp., *Eragrostis* spp. and *Sporobolus* spp. Nagy & Knight (1994) estimated that an adult ♂ consumes ca. 504 kg of dry matter a year, cf. 409 kg for an adult ♀.

Possibly as a result of the high mineral content of their diet, Springboks use mineral licks to a much lesser extent than other species (Leistner 1967). Where freshwater is available in Kgalagadi Transfrontier Park, Springboks drink 2.63 ± 0.45 litres per individual every second day (Dreyer 1987). They make use of heavily mineralized water in the Kgalagadi where this is available in the dry season (J. D. Skinner pers. obs.), but otherwise they satisfy their moisture requirements by browsing on succulent vegetation, such as the leaflets of blackthorn *Acacia mellifera* and candle thorn *Acacia hebeclada*. Springboks are able to maintain body water balance feeding on plant food containing 67% water (Nagy & Knight 1994). As such, they supplement their diet by digging for succulent roots such as *Acanthocycios naudinianus*, *Brachystelma* spp., *Cucumela cinerea* and *Talinum tenuissimum*, all of which have a moisture content exceeding 62% (Williamson 1987), or eating fruits such as wild cucumbers *Cucumis africanus* (83% moisture) and Tsama Melons *Citrullus lanatus* (90% moisture) (Cooper 1993) and the fruits of the snake berry *Solanum* spp.

Social and Reproductive Behaviour Springboks are gregarious, congregating and moving in small herds during the dry months of the year (Apr–Sep), although the sporadic occurrence of larger aggregations numbering hundreds of thousands (treks; see Distribution) has been documented (Skinner 1993). Larger summer concentrations usually result when there has been patchy rainfall and Springboks congregate on resultant greenery; however, such aggregations now seldom number more than a few thousand individuals (Bigalke 1972). On the other hand, as only territorial ♂♂ mate, they are sedentary and remain on their territories for as long as there is an adequate nutritional supply, abandoning them only at the end of the dry season when resources are exhausted. Territorial ♂♂ show great fidelity to these territories, returning to them after the first summer rains (Jackson & Skinner 1998).

Territorial ♂♂ take up conspicuous positions in open areas to advertise their presence to other rams; this also serves as an anti-predator mechanism (Jackson 1995). Territory size in Kgalagadi is variable, being roughly 0.2 km² during optimum times but five

Springbok *Antidorcas marsupialis* male (left) and female (right).

times that during periods of drought. There is no evidence to show that ♂♂ use preorbital glands in marking. Instead, territorial ♂♂ have a unique urination–defecation ritual (very occasionally used by bachelors): spreading the hindlegs far back and widely spaced, belly close to the ground, they urinate, then bring the legs forward and squat to defecate on the same place (Jackson 1995). This may be preceded by scratching the ground and concluded by tail wagging (Novellie 1975). Territorial ♂♂ also indulge in horn sweeping, which tends to make them more conspicuous. Non-territorial ♂♂ occur in groups ranging from two to 50 or more individuals. Bachelor herds sometimes associate with female herds but are usually easily distinguishable as they position themselves on the fringes of the latter.

The mating system is one of resource-defence polygyny, whereby ♂♂ defend their territory and endeavour to retain transient ♀♀ by herding them with head stretched forward, the horns laid back and the tail held stiffly horizontal, lifted vertically or curved forward. Defence of the territory is by advertising and fighting. Males rut infrequently, the rut occurring at any time of the year and lasting from five to 23 days (Skinner & Louw 1996, Skinner *et al.* 1996). At these times they vocalize loudly with grunting bellows and are very active chasing off rams intruding onto their territories. Only territorial ♂♂ mate, other ♂♂ being to all intents and purposes emasculated, and the presence of the ♂ has a marked influence on inducing oestrus in anoestrous ewes and synchronizing oestrus in cycling ewes (Skinner *et al.* 2002). This results in clumping of births for predator swamping, an advantage in an arid-adapted aseasonal breeder (Skinner & Louw 1996). Flehmen in the ram, nostril wrinkling following urine or vaginal smelling of the ewe and lauschlag by the ram (tapping of the ewe's hindleg with his stiff foreleg), occur particularly when ♀♀ are in pro-oestrus. Females usually mate once, but occasionally may mate several times, sometimes with more than one ♂ (Jackson & Skinner 1998). There may be up to eight false mounts until the ♀ finally stands, when penetration, followed immediately by ejaculation, takes place with a violent thrust forwards and upwards, the ram only being held upright by the inserted penis. There is no thrusting when penetrated and the ram withdraws the penis immediately, the whole procedure lasting less than a minute. Afterwards, there is no mate guarding.

Following parturition, the ♀ eats the afterbirth and hides her young in tall vegetation or underbrush for a day or two, during which

the neonate is immobile. Juveniles tend to congregate in nursery herds together, while their mothers browse in the vicinity (Skinner & Chimimba 2005). Young are weaned ca. four months, depending on food availability as they grow faster in optimum seasons. They continue to associate with their mothers for much longer; ♀♀ remain with the herd but ♂♂ join up with bachelor herds from 10 to 12 months of age.

Young ♂♂ indulge in playful sparring. Fighting among adult ♂♂ results in horn interlocking and side-to-side wrestling. Stabbing may result in mortality but usually one ♂ submits before either is seriously injured. Fighting is most common during the rut, when territorial ♂♂ no longer tolerate bachelors within the vicinity of female herds.

Springboks are vocal at particular times, the most common being a loud grunting bellow by ♀♀ in response to bleating by their young. When alarmed, Springboks emit a high-pitched whistling snort. Males are very vocal during the rut, emitting low-pitched grunt-like bellows when chasing intruders or rounding up ♀♀ (Novellie 1975, David 1978, Jackson 1995).

Springboks associate with other ungulate species at waterholes but rarely at other times, although they very occasionally migrate with species such as the Common Eland *Tragelaphus oryx* or Hartebeest *Alcelaphus buselaphus*. Individual vigilance decreases as herd size increases and Springboks on the periphery tend to be more vigilant than central animals. Springboks are also more vigilant at night and in woodland compared with walking in the open (Bednekoff & Ritter 1994; and see Burger *et al.* 2000).

Mutual grooming does not occur although self-grooming is important and this is facilitated by a dental grooming comb similar to that described in Impala *Aepyceros melampus* by McKenzie (1990).

Reproduction and Population Structure Springboks are aseasonal breeders and have the ability to multiply rapidly (Skinner & Louw 1996). Although ♂♂ are fertile throughout the year (Skinner & Van Zyl 1970), ♀♀ have been shown to have a clear endocrine anoestrus of between 4 and 5 months, the timing and duration of which is synchronized between some individuals but the time of onset and duration varies from year to year; the prevailing ambient temperature may influence the onset of ovarian activity (Skinner *et al.* 2001). The oestrous cycle is 16 days.

Single young, rarely twins, with a mass of 3.8–5.0 kg, are born after a gestation period of 25 weeks (Skinner & Louw 1996). Under optimum climatic conditions Springboks have a postpartum oestrus when the uterus involutes after about a fortnight, enabling ♀♀ to give birth twice a year (Skinner *et al.* 1971). Young are weaned at about four months of age (Liversidge & de Jager 1984); the composition of the mother's milk is discussed by Van Zyl & Wehmeyer (1970). Females are physiologically capable of conceiving at six months; ♂♂ produce sperm at one year, but probably are not able to breed until about two years (Skinner & Van Zyl 1970, Liversidge & de Jager 1984). Longevity has been given as 19.8 years in captivity (Weigl 2005), but is probably around ten years in the wild.

Foetal sex ratios are normally 1 : 1, but can change in response to climatic conditions (Liversidge 1993). Male-biased fetal sex ratios occur during periods with successive years of high rainfall, and female-biased foetal sex ratios following drought conditions. Liversidge (1993) hypothesized this might be of selective advantage to ensure high

reproductive rates following population declines. Adult male to female sex ratios have been recorded at 43–57 : 100 in Etosha N. P., Namibia, and Kgalagadi Transfrontier Park and up to 130 : 100 in Mountain Zebra N. P., Eastern Cape, South Africa (Bigalke 1970, Penzhorn 1974). Female-biased adult sex ratios may result from misclassification of subadult ♀♀ as adults, or because of higher mortality rates for adult ♂♂.

Predators, Parasites and Diseases Apart from the coursing predators such as Black-backed Jackals *Canis mesomelas*, Spotted Hyenas *Crocuta crocuta* and African Wild Dogs *Lycaon pictus*, Springboks may be preyed upon by Cheetahs *Acinonyx jubatus*, Leopards *Panthera pardus*, Lions *P. leo* and Caracals *Caracal caracal*, while young are predated by Brown Hyenas *Hyaena brunnea*, Wildcats *Felis silvestris*, Ratels *Mellivora capensis* and eagles, particularly Martial Eagles *Polemaetus bellicosus*, Tawny Eagles *Aquila rapax* and Verreaux's Eagles *A. verreauxii* (Skinner & Louw 1996). In Kgalagadi Transfrontier Park, Springboks constituted 87% of Cheetah kills, 65% of Leopard kills, 13% of Lion kills and 12% of hyaena kills (Mills 1984). In Etosha N. P., 97% of Cheetah kills were Springboks (Berry 1981).

Springboks carry very low tick burdens, but large numbers of lice, while numbers of helminth parasites varied in different regions from nine to 18 (Young *et al.* 1973a, Horak *et al.* 1982c, 1991b, 1992a, De Villiers *et al.* 1985); *Sarcoptes scabiei*, an ectoparasite associated with mange, was isolated from a Springbok in the Kalahari (see Young *et al.* 1973a). Fourie & Horak (1987) investigated six Springboks that had died of tick paralysis, a form of tick toxicosis, which is caused by the adult female Karoo paralysis tick, *Ixodes rubicundus*. A neurotoxin causes paralysis and initial signs are lower motor-neurone paralysis with varying degrees of incoordination and ataxia, animals eventually succumbing to respiratory failure (Gothé 1984). Other than these, there are apparently no documented deaths from parasite infestation in Springboks, although heavy infestations of the nematode internal parasite *Bronchonema magana* may in time cause death (Boomker *et al.* 2000). The latter authors counted helminth parasite loads in nine Springboks shot in four different National Parks in the Western Cape and Eastern Cape Provinces of South Africa. The species differed marginally depending on locality. Of 11 species identified, *Trichostrongylus falculatus* was the most numerous nematode, contributing 72% to the mean adult nematode burden, followed by *Cooperioides antidorca* (8%), *Normatodirus spathiger* (8%) and *Paracooperia serrata* (8%), making up 96% of the total internal nematode parasite burden. The larvae of several oestrid or nasal bot flies parasitize the nasal passages and sinuses of Springboks, including *Rhinoestrus antidorcitis*, which is host specific (De Villiers *et al.* 1985, Horak 2005).

Records about susceptibility to disease are scanty. Springboks have long been known to be susceptible to heartwater (Spreull 1922, Neitz 1944) and anthrax (Ebedes 1976), which has limited its introduction to some regions.

Conservation IUCN Category: Least Concern. CITES: Not listed.

Special measures to conserve Springboks are unnecessary. They are amongst the most valued species in the expanding game ranching industry in southern Africa due to the excellent quality of their meat, and therefore are found not only in numerous protected areas (including Etosha N. P. and Kgalagadi Transfrontier Park), but also extensively on private land. Of four popular species examined, Springboks were superior in terms of muscle fibre diameter, flavour intensity and acceptability, their prolific reproductive potential and fast growth rate in arid regions, and the fact that they are ideally suited to multi-species farming systems, especially in combination with domestic livestock such as sheep *Ovis aries* (Von la Chevallerie 1972, Davies & Skinner 1986a, b, Skinner 1989). Springboks are no longer regarded as strictly feral on many ranches, because they can be confined by ordinary stock fences. However, they would be a most difficult species to domesticate due to their highly nervous disposition. Some advances have been made in establishing cues for triggering reproductive cycles, but ♂♂ use resource-defence polygyny as their breeding system and such ♂♂ are intolerant of intruding rams; in an enclosed ranching system this will result in frequent fighting and mortality. Moreover, Springboks are not disposed to herding.

Measurements

Antidorcas marsupialis

TL (♂♂): 1501 (1390–1623) mm, n = 30

TL (♀♀): 1484 (1375–1580) mm, n = 13

T (♂♂): 244 (146–286) mm, n = 30

T (♀♀): 256 (200–305) mm, n = 13

HF c.u. (♂♂): 427 (400–455) mm, n = 30

HF c.u. (♀♀): 416 (395–462) mm, n = 13

E (♂♂): 177 (153–195) mm, n = 30

E (♀♀): 173 (150–187) mm, n = 13

Sh. ht (♂♂): 730 mm (690–770 mm), n = 20*

Sh. ht (♀♀): 692 mm (640–730 mm), n = 20*

WT (♂♂): 41.0 (33.0–47.6) kg, n = 30

WT (♀♀): 37.1 (30.4–43.5) kg, n = 13

Botswana (Smithers 1971)

*Skinner *et al.* (1971)

Kruger *et al.* (1979) reported a mean shoulder height of 857 mm for ♂♂ (n = 21) and 714 mm for ♀♀ (n = 9) from Kgalagadi Transfrontier Park, South Africa, and 843 mm (n = 10) and 816 mm (n = 10) for ♂♂ and ♀♀, respectively, from the Kaokoland, Namibia, and Iona N. P., Angola.

Maximum recorded horn length is 49.2 cm for a pair of horns from Prospect, Namibia (Rowland Ward)

Tribe OUREBIINI

Oribi

Ourebiini (tribe nov.)

Oribi *Ourebia ourebi* head of adult male showing skin gland patch below ear.

The particular permutation of the Oribi's *Ourebia ourebi* adaptation to its environment is unlike that of any other antelope and its affinities have long been a puzzle. None the less, its possession of subauricular glands and several other anatomical and adaptive features that are very unlikely to be convergent suggest a distant but likely relationship with the very earliest proto-reduncines. None the less, Oribis are too different to merit inclusion in Reduncini. Emptying of the neotragine 'waste-paper basket' (wherein *Ourebia* was formerly placed along with *Oreotragus*, *Raphicerus*, *Neotragus*/*Nesotragus*, *Madoqua* and *Dorcatragus*) has made it impossible to allocate the Oribi to any other major antelope grouping (certainly not to the Antilopini), even though it shares individual features with more than one other acknowledged tribe. Haltenorth (1963), who was the first to dismember the Neotragini into several tribes, included *Ourebia* with *Raphicerus* in the tribe Raphicerini, but we consider Raphicerini to include only members of the genus *Raphicerus*, plus, tentatively, the Beira *Dorcatragus*. In the absence of any new evidence for an unambiguous genetic affiliation, we have therefore seen no alternative other than to erect a new tribe to accommodate this extraordinary antelope.

The Oribi is the smallest open-country grazing antelope; it is small to medium in size, but tall and slender with a sandy-yellowish or reddish tinted body colour, white undersides, upper throat, mouth and ear linings. Unlike the Steenbok *Raphicerus campestris* (with which it is sometimes confused), the eyes are not rimmed by intensely black lids and the ears are of moderate size. In addition to pedal and inguinal glands, the Oribi has scent brushes below the knees and ankles and complex black skin gland patches below the ears.

A dominant peculiarity of the Oribi head is super-development of the preorbital glands, which are exceptionally large and well developed. The sheer size and depth of these glands has caused an extreme

Diagrams of unique features of Oribi *Ourebia ourebi* skull. Top left: elongated nasals, narrow premaxilla, enlarged fossa for pre-orbital gland. Lower left: Voluminous pre-orbital glands on either side of narrowed nasal passage. Top right: outline of muzzle superimposed on hypothetical ancestral form (note deepening toothrow, enlargement of gland and elongation of snout appear to have resulted in progressive downward deflection of entire muzzle). Centre right: skull profile corroborates evolutionary deflection of muzzle. Lower right: deflection of a more vertical maxilla-frontal suture (beneath the pre-orbital gland) to a more horizontal angle conforms with downward deflection of muzzle in evolution of the Oribi.

narrowing of the nasal chamber. Massive enlargement of the preorbital glands has also demanded expansion and deepening of the bony linings of the huge preorbital fossa within which they are contained, forcing both maxilla and lachrymal bones to expand or extend in this part of the face. When the Oribi is compared with smaller, more conservative antelopes, a marked elongation of the muzzle is also evident. Elongation of the face and neck is typical of open-country herbivores that have long legs because it helps them maintain contact with the ground when grazing. It is this combination of muzzle lengthening and expansion of the bones lining the preorbital pit that has resulted in a sharp downwards deflection of the muzzle, effectively bending the skull's basicranial axis in a way that is unique to the Oribi.

The crisp, clear-cut border of the preorbital fossa delimits the forward margin of the masseter. Thus, the gland's spread over the lachrymal and maxilla bones has served to shorten the reach of the masseter in its superficial anterior part. Narrowing the area of bony attachment further reduces the efficiency of this muscle component so the Oribi has compensated for this by greatly increasing the prominence of a bony knob on which all anterior fibres of the superficial masseter converge. It seems significant for the evolution of Reduncini and

their supposed relationship with the Oribi that this knob is also well developed in many reduncine species and that some fossil and living reduncines exhibit vestiges of preorbital glands. In reduncines, atrophy or outright disappearance of this gland has allowed a thickened masseter to extend its purchase on the unhollowed sides of their faces. However, the Oribi, as a grazer, has also had to enlarge the bulk of its masseter and to achieve this the lower margins of the orbits jut out, making the eyes quite prominent. A very similar arrangement occurs in the skulls of Reduncini, further hinting at an ancient common ancestry.

It can be assumed that the ultimate ancestors of the Oribi were smaller, shorter-legged and folivorous and that they marked out their territories with glandular secretions. Furthermore, it can also be assumed that the Oribi lineage, like any other that moved out into open country, acquired its slender proportions as a direct result of selection by predators (with fleeing replacing hiding). They also needed to cover more ground in enlarged ranges. It is therefore reasonable to suppose that many of the multiple expressions of scent-signalling found in the Oribi are grossly exaggerated retentions from a system that was originally only adaptive for small bovids in closed habitats. It also seems likely that the Oribi has reached upper limits, both for body-size and for the utility of scent-labelling in the larger, more open ranges that it occupies. This helps explain some basic limits put on the Oribi lineage and hints at the sort of constraints that an earlier, proto-reduncine would have had to overcome in order to become larger in body-size, less dependent on broadcasting scent over the entire home-range and less tied to the limited land-holdings that such scenting imposed. Even so, all Reduncini are clearly very olfaction-oriented and they uniquely share the Oribi's subauricular scent signals as well as relying on trails and land-marks created by glands or defecation. The ecological and behavioural resemblances

between the Oribi and reduncines are not trivial and serve to differentiate both groups from all other antelopes.

Increased body size and proportional lengthening of a spike-like horn has made male Oribis exceptionally dangerous. The possession of lethal weaponry may help to explain why male Oribis have intensified and ritualized scent-marking behaviour to the degree to which they have: ♂♂ cannot afford to wound or scare the hornless ♀♀. Females are larger than ♂♂ and are independent in their movements, but by becoming the object of continuous attention from a single ♂ each adult ♀ determines the area in which the ♂ is intolerant of other ♂♂. This area becomes the shared territory in which each partner repels members of its own sex. Within a shared territory, both occupants (and their offspring) are bombarded with the males' olfactory signals and both sexes avoid trespassing on neighbouring territories. Oribis therefore seem to have replaced direct attacks with ostentatious scent-marking that deters or minimizes risks of lethal confrontation.

There are also striking contrasts between periodic, semi-social and self-advertising behaviour and their otherwise solitary, cautious and inconspicuous habits. These behavioural differences have some correspondence with seasonal changes in their habitat. For example, when the grass is long and dense during the rains and visibility is cut to a metre or less, Oribis, and many other animals, are primarily reliant on scent and hearing. After fires and heavy use by big herbivores the Oribis become very exposed and sight becomes their primary sense. It is at this time that they are particularly alert and shy and their piercing whistle is frequently uttered as they flee with a characteristic rocking-horse gait.

Jonathan Kingdon

GENUS *Ourebia*

Oribi

Ourebia Laurillard, 1842. In: d'Orbigny, Dict. Univ. d'Hist. Nat. 1: 622.

Ourebia includes only the Oribi, *O. ourebi*, a small antelope larger than *Raphicerus* species (shoulder height 65 cm, mass 15–21 kg). The Oribi differs from members of the genus *Raphicerus* in proportions of the head (notably in the downwards deflection of the muzzle from the basicranial axis), in the form of the dentition, jaws and preorbital fossa, and in the presence of inguinal and subauricular glands, carpal tufts, tail tuft and ringed horns (see species profile).

Ourebia combines characters typical of small antelopes (solitary or in pairs, territoriality, dung piles, marking with preorbital secretion) with features of much larger species (predominantly graminivorous diet and associated hypsodonty and other dental specializations). The

subauricular gland, if it is an apomorphic character shared with reduncine antelopes, could imply membership of the same clade (see Hofmann 1972, Kingdon 1982, Vrba *et al.* 1994). However, this relationship has not found support in some other studies (e.g. Matthee & Robinson 1999a, Vrba & Schaller 2000, Hernández Fernández & Vrba 2005), and the affinities of the genus remain uncertain. In this work, the genus has been provisionally allocated to its own tribe, the Ourebiini.

Peter Grubb

Ourebia ourebi ORIBI

Fr. Ourebie; Ger. Bleibbockchen

Ourebia ourebi (Zimmermann, 1783). Geogr. Gesch. Mensch. Vierf. Thiere 3: 268. 'Bewohnt die Cafferen' (South Africa, Eastern Cape Prov., Kaffraria); since restricted to one of the syntypical localities: South Africa, Eastern Cape Prov., Somerset East Dist., Bruintjieshoogte (Grubb 1999).

Oribi *Ourebia ourebi*.Lateral and palatal views of skull of Oribi *Ourebia ourebi*.Upper-right tooththrow of Oribi *Ourebia ourebi*.

Taxonomy As many as 13 subspecies of Oribi have been proposed to account for considerable variation in body size and colouration across the species' range (see Haltenorth 1963, Ansell 1972). Animals in East Africa appear larger and darker than western, northern and southern conspecifics, but this trend, and the validity of many proposed subspecies/race distinctions, has not been tested using molecular techniques. Variation in body size and colouration among populations is sufficiently large to confound past efforts to identify suites of morphological traits specific to regions, and the listing of subspecies here is provisional (and adapted from Ansell 1972). Synonyms: *aequatoria*, *brevicaudata*, *cottoni*, *dorcas*, *gallarum*, *goslingi*, *grayi*, *haggardi*, *hastata*, *kenyae*, *leucopus*, *masakensis*, *melanura*, *microdon*, *montana*, *nigricaudata*, *pitmani*, *quadriscopa*, *rutila*, *scoparia*, *smithii*, *splendida*, *ugandae*. Chromosome number: not known.

Description Slender, small to medium-sized antelope similar in appearance to Steenbok *Raphicerus campestris*, but taller and larger with markedly smaller and narrower ears, more pronounced preorbital glands, tail longer and darker, and with a naked patch of black skin beneath the ear (the subauricular gland, which is sometimes covered by hairs). Pelage sandy to rufous with white undersides, throat, chin, mouth, eyebrows and ear linings. Dark patch on crown present in both sexes, but more visible in ♀♀, often extending to a narrow peak on the forehead, and sometimes absent in older individuals.

Insides of legs white to sandy; udders, hooves, nostrils and eyes black. Body colour and size and shape of white patches and dark crown patch highly variable between individuals. Tail short but with a prominent tuft; tail colour variable from sandy or rufous with a black tip to mostly black. Carpal brush of long hairs present below knees. Lateral hooves small. Preorbital gland large, opening by a slit; inguinal and pedal glands present. Animals in southern Africa exhibit a marked difference between the summer coat, which is shorter and smoother, and the winter coat, which tends to be thicker and more shaggy (Skinner & Chimimba 2005). However, in East Africa, and probably other areas close to the Equator, the difference in coats between cool and warm seasons is not marked. Adult ♀♀ are similar to ♂♂ but ca. 15% larger (Jongejan *et al.* 1991). Females have two pairs of inguinal nipples.

Horns present in ♂♂ only, short, straight and sharp-tipped, Steenbok-like, but thicker and annulated in adults older than one year of age, and angled more to the anterior (ca. 60° angle from plane of crown); during early growth, horns are enveloped in a deciduous keratinous sheath, which is lost at the time the adult dentition is completed, revealing the annuli. Horns appear at ca. 4.5 months of age and grow rapidly up to ca. 20 months of age. Horn length and number of annulations can be used to estimate age of ♂♂ ≤20 months, but the technique awaits validation for older animals (Jongejan *et al.* 1991).

The rostrum is relatively long, more elongated than in *Raphicerus*, not tapering towards the tip, and unlike *Raphicerus* the ethmoid vacuity is narrow or closed. Deep sharply margined preorbital fossae (to accommodate the preorbital glands) compress the rostrum laterally; the margin forms a sharp ridge between the fossa and origins of the masseter muscle, running diagonally forward from the orbit down to the masseteric knob just above the cheekteeth, a diagnostic feature of the genus most prominent in ♂♂. The dentary is deep and sharply angled. The first incisors are considerably broadened at the tip (more so than in *Raphicerus*); other incisiform teeth are narrow, with the second incisors a little broader than the remainder. Cheekteeth are relatively hypsodont with large enamel islands. The enamel varies in thickness and forms prominent styles.

Geographic Variation

O. o. ourebi: South Africa and S Mozambique.

O. o. hastata: SE Tanzania, E Zambia, Malawi, Zimbabwe and N Mozambique.

O. o. rutila: Angola, N and NE Botswana, and W Zambia; perhaps also SE DR Congo.

O. o. cottoni: SW Kenya to C Tanzania.

O. o. masakensis: S Uganda, Rwanda and NW Tanzania.

O. o. aequatoria: N Uganda and S Sudan. Apparently intergrades with *montana* to the north and *cottoni* to the east.

O. o. kenya (Kenya Oribi): isolated on the lower slopes of Mt Kenya. Extinct (Hillman *et al.* 1988).

O. o. haggardi (Haggard's Oribi): coastal Kenya to S Somalia, entirely isolated from other forms.

O. o. gallarum: C Ethiopia.

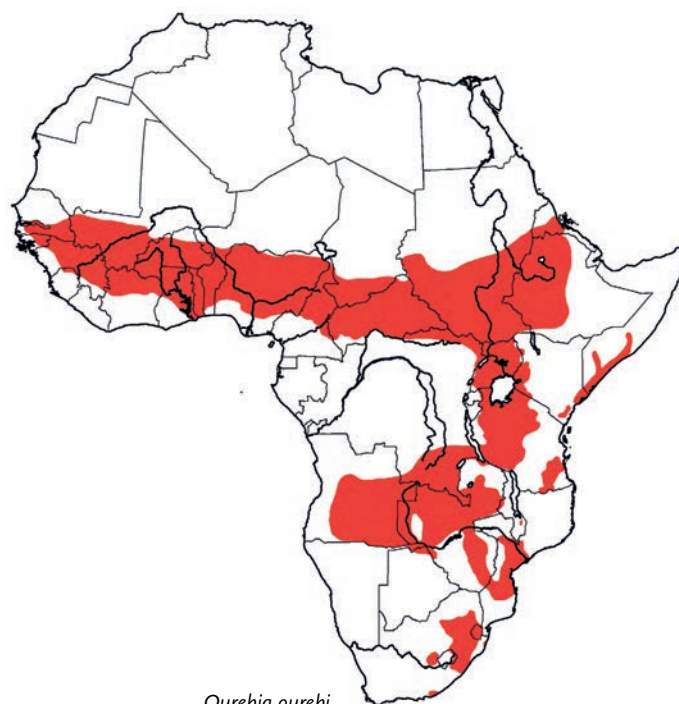

O. o. montana: SE Sudan to W Ethiopia.

O. o. goslingi: N DR Congo.

O. o. quadriscapa: Senegal to Nigeria.

Similar Species Similar sympatric species include the Steenbok *Raphicerus campestris*, Sharpe's Grysbok *Raphicerus sharpei*, Common Duiker *Sylvicapra grimmia* and Mountain Reedbuck *Redunca fulvorufula*. The Steenbok and Sharpe's Grysbok are smaller, stockier and more crouched in appearance than the Oribi; both lack the Oribi's striking black patch of skin beneath the ear and both have wider ears and a much shorter tail than the Oribi. Largest examples of the Common Duiker may come close to the Oribi in body mass, but this species is more crouched, shorter, lacks the black subauricular patch and has a much shorter neck than the Oribi. It is typically, but not always, darker in body colour than the Oribi and possesses a striking crest of hair between the horns. The Mountain Reedbuck is significantly heavier (ca. 30–50%) than the Oribi and typically greyer in body colour. It has a subauricular patch similar in appearance to that of the Oribi, but the horns of the Mountain Reedbuck are much thicker and noticeably curve forward at the ends. The Mountain Reedbuck's tail is much longer than the Oribi's and the tail's underside is white with no black markings.

Distribution Endemic to Africa. The distribution of the Oribi is extensive, but patchy, occurring in Guinea savanna habitat from Senegal, Gambia, Guinea-Bissau and N Guinea east to N Cameroon. In Sierra Leone, they were known to survive only in and around Outamba-Kilimi N. P. in the north, but there is no recent information

Ourebia ourebi

on the status of this population (East 1999). East of Cameroon, they range from S Chad and Central African Republic through S and E Sudan (where recent surveys in the dry season in the south have shown them surviving in much reduced numbers) and extreme NE DR Congo to C Ethiopia (within and to the west of the Rift Valley) and north to SW Eritrea. Their range extends in moist savannas and woodland mosaics from N Uganda and SW Kenya south through eastern and central-southern Africa to montane grasslands in SE South Africa. The only country in which they formerly occurred and are now considered extinct is Burundi, while in Rwanda they survive only in Akagera N. P. (East 1999, Apio & Wronski 2011). Shortridge (1934) recorded Oribis from N Namibia, and Smithers (1971) reported them from the eastern Caprivi, although the species was not reported during a questionnaire survey (Joubert & Mostert 1975); mention of the species in this country is oddly missing in Van der Walt (1989) and East (1999). In Botswana, they occur only in extreme north-east, from the eastern part of Chobe N. P. to the Zimbabwe border (East 1999). Their historical distribution is likely to have been more continuous across much of this range, whereas the current distribution is highly fragmented. An isolated and vulnerable population (*O. o. haggardi*) occurs in a coastal stretch from S Somalia into SE Kenya (East 1999).

Habitat Flat and gently sloping grasslands and mixed woodlands maintained by fire, grazing, or soil characteristics where mean annual rainfall is at least 500 mm. Altitude ranges from ca. 50 m (coastal Kenya) to over 2000 m (KwaZulu-Natal, South Africa and Mt Kenya). Proximity to open water (including dew) is essential in areas where rainfall is light or unevenly distributed through the year, although in many areas Oribis are considered to be water-independent, obtaining most of their moisture requirements from succulent herbage (Monfort & Monfort 1974, Oliver *et al.* 1978, Viljoen 1982). Vegetation varies from dry scrub, to mixed woodland, to treed savanna, to open grassland, to montane grassland, to moist

coastal savanna, to open flood-plain. Within each of these habitat types preferred micro-habitats are well-drained open pastures of short to medium grasses (100–1000 mm) with good visibility and cover for hiding and shade. Highest densities (i.e. 45 animals/km²) occur in moist tropical grasslands where annual rainfall is above 1100 mm and frequent (e.g. *Loudetia simplex* grassland in Rwanda). High densities (i.e. >30/km²) are also common on treeless flood-plain habitat (e.g. Kafue Flats, Zambia; Plewman & Dooley 1995).

Oribis often occur in close association with larger, less selective grazers such as the Plains Zebra *Equus quagga*, wildebeest *Connochaetes* spp., Common Hippopotamus *Hippopotamus amphibius*, African Buffalo *Syncerus caffer*, Topi *Damaliscus lunatus*, Thomson's Gazelle *Eudorcas thomsonii* and Hartbeest *Alcelaphus buselaphus*, which keep pastures short without diminishing greatly the Oribi's food supply (Estes 1991a), and which may enhance predator detection (Mduma & Sinclair 1994). Kingdon (1982) suggested that Oribi numbers decline where larger ungulates are extirpated and, thus, no longer serve to maintain short grasslands.

Abundance Oribis are locally common in suitable habitats at densities of 2–10 animals/km² (Mduma & Sinclair 1994, Arcese *et al.* 1995b, Adamczak 1999, Goldspink *et al.* 2002), but have been recorded at densities up to 45 animals/km² in exceptionally productive tropical grasslands and treeless flood-plains (Monfort & Monfort 1974, Plewman & Dooley 1995). In areas where it is uncommon or populations have been depleted, densities based on ground counts range from 0.1 to 0.4/km² (East 1999). Local densities are linked to abundance and evenness of rainfall and quality and quantity of preferred grasses (Brashares & Arcese 2002). Assuming an average density of 2/km² where common, and 0.2/km² elsewhere, East (1999) estimated a total population size of 750,000 animals. Numbers of Haggard's Oribi are probably in the low thousands.

Adaptations Oribis have several striking morphological and behavioural characteristics, including an enlarged digestive system adapted to processing grasses, an array of scent glands for olfactory communication and a highly variable social and mating system. This unique combination of 'primitive' and advanced traits has led to suggestions that the Oribi represents an evolutionary link between conservative thicket-dwelling antelopes and more recently derived grassland species (Kingdon 1982, Estes 1991a).

The Oribi is the only small bovid (<20 kg) that feeds primarily on grasses (Hofmann 1973, Gagnon & Chew 2000). The Oribi's use of foods that require slow fermentation and long passage times is possible because of a greatly enlarged forestomach (Hofmann 1973). Hofmann (1973) reports that a captive Oribi fed only browse gradually lost condition and died (see also Foraging and Food).

The Oribi possesses an arsenal of at least six sets of scent-glands including preorbital glands, subauricular glands, pedal and inguinal glands, and glands on the front and rear legs (Gosling 1985). Secretions from these glands are used in combination with urine and faeces to demarcate and maintain territory borders (Brashares & Arcese 1999a, b), in pair-bonding and group cohesion (Monfort & Monfort 1974), and most likely have many other functions that remain poorly understood. The most obvious scent gland to human observers is the preorbital gland, a trademark of Oribis, bulging prominently between the eye and mouth of the adult ♂.

As already noted, the architecture of the Oribi skull is modified to accommodate these considerable glands, most notably by the large fossae beneath the eyes in which the glandular tissue sits. Up to 45 times per hour, the ♂ tilts its head and inserts the distal portion of a plant stem into the vertical opening of the preorbital gland and deposits a black tar-like secretion (Brashares & Arcese 1999a). Mo *et al.* (1995) analysed the chemical constituents of the Oribi's preorbital gland secretions and identified 75 distinct chemical compounds that range widely in their volatility. It generally is assumed that the marks of each animal are chemically distinct and thereby serve as individual-specific olfactory signals, but this has yet to be demonstrated.

The Oribi displays flexibility in its mating system exceeding that seen in any other species of smaller antelope (Arcese *et al.* 1995b). Oribis are monogamous, polygynous and polygynandrous depending on habitat conditions (Rowe-Rowe *et al.* 1992). Oribis are dispersed in male–female pairs on overlapping home-ranges in drier and more seasonal habitats (e.g. KwaZulu–Natal, South Africa, Adamczak 1999, and N Ghana, Brashares & Arcese 2002). In wetter and less seasonal habitats, 1–4 ♂♂ assiduously defend a year-round territory and 1–8 adult ♀♀ (Arcese 1999, Brashares & Arcese 1999a). This variation in mating system is evident across and within populations. In Ghana, and likely elsewhere, Oribis display behavioural plasticity within subpopulations (Brashares & Arcese 2002). In micro-habitats characterized by abundant and high-quality green grasses (e.g. riverine habitats), adult ♀♀ form groups of 2–5 animals and ♂♂ defend a small territory encompassing the range of this group. In adjacent dry areas, ♀♀ are solitary and range widely and ♂♂ pair with a single ♀ and adopt a 'following' strategy throughout their large and non-exclusive home-range. 'Follower' ♂♂ quickly become polygynous and territorial after occupying a recently vacated territory in a high-quality habitat (Brashares & Arcese 2002).

Foraging and Food A selective grazer, the Oribi relies on fresh green grasses, but feeds also on forbs, legumes and tree foliage when fresh grass is unavailable. In their review of the feeding preferences of African bovids, Gagnon & Chew (2000) classed Oribis as 'variable grazers', taking as much as 90% grass in their diet; this is broadly supported by studies involving stable carbon isotope analyses of southern and East African bovids, which found that Oribis in these regions had 82% and 84% grass in their diet, respectively (Cerling *et al.* 2003, Sponheimer *et al.* 2003b).

When feeding, Oribis typically remove new leaves and seed heads of grasses and ignore older leaves and stems. Preferred grasses include *Themeda*, *Hyparrhenia*, *Loudetia*, *Eulalia*, *Andropogon* and *Pennisetum* (Kingdon 1982, Viljoen 1982, Awad 1985, Everett *et al.* 1992); the use of grass varies seasonally. In Ghana, Oribis in moist coastal savanna habitat feed year-round on green bunch-grasses (e.g. *Andropogon* sp.), while Oribis in dry Guinea savanna habitat to the north often (ca. 15% of time spent foraging) feed on forbs, tree leaves and nuts of the shea tree (*Butyrospermum parkii*) in the dry season (J. Brashares pers. obs.). Oribis in Serengeti N. P., Tanzania, occasionally eat flowers and large boletus mushrooms when available (J. Brashares & P. Arcese pers. obs.). Reilly *et al.* (1990) reported that Oribis in Golden Gate N. P., South Africa, would dig for corms of *Watsonia* sp.

Oribis regularly visit mineral licks and will travel across territory borders and gather in groups at preferred licks. Groups in Serengeti N. P. were observed on three occasions to break apart termitaria with their hooves and horns and consume the soil found within, presumably for its mineral content (J. Brashares pers. obs.). Oribis avoid planted croplands and plantations, but will use planted hayfields and occasionally may feed on field crops such as wheat, oats and new sprouts of sugarcane (Kingdon 1982, Perrin & Everett 1999, A. Marchant pers. obs.). In many areas, Oribis show a clear preference for sprouting grass in recently burnt areas (Oliver *et al.* 1978, Rowe-Rowe 1982a, Everett *et al.* 1991, Mduma & Sinclair 1994).

Foraging is most common during cool hours of early morning and late afternoon to early evening, often continuing into nightfall. During mid-day Oribis typically rest in tall grass or beneath a tree or shrub to escape the heat. Average time spent foraging varies between populations, ages and sexes. In Serengeti N. P., feeding comprised less than 10% of daytime activity for ♀♀ and juveniles and less than 5% for adult ♂♂ (J. Brashares & P. Arcese pers. obs.). In Red Volta F. R., Ghana, adults and juveniles spent ca. 20% of daytime actively feeding (J. Brashares pers. obs.). Oribis generally do not feed in heavy wind and rain.

Social and Reproductive Behaviour Group size, apparent mating system and territorial behaviour are extremely variable across the species' range and even within Serengeti N. P., where more than 500 individually identified Oribis were studied in detail over a period of seven years. Oribis are observed most often in male–female pairs, often with one (rarely two) young present; but also as single-male, single-female (0–82% of groups) or multimale, multifemale groups (0–39% of groups) (Arcese *et al.* 1995b). Sightings of lone animals in most instances are probably of ♂♂ patrolling the territory perimeter, young or old ♂♂ unable to secure or defend a territory, ♀♀ in the vicinity of young lying out, or other animals temporarily out of sight of a social group (J. Brashares & P. Arcese pers. obs.). Mean size of adult groups is 1.8 (Burkina Faso) to 3.92 (Murchison Falls, Uganda); group size is related positively to rate of apparent polygyny across populations in Africa ($r = 0.90$, $n = 9$) and years in Serengeti N. P. ($r = 0.88$, $n = 5$) (Arcese *et al.* 1995b). Apparent polygyny is also related positively to adult sex ratio and population density across years in Serengeti and populations in Africa (Arcese *et al.* 1995b). Group size including all ages in Serengeti N. P. is 3.1–4.3 (mean = 3.6, $n = 5$ yrs; Arcese *et al.* 1995b). Occasionally, Oribis occur in groups of up to 12 adults and young (Roosevelt & Heller 1915, Ansell 1960b, J. Brashares pers. obs.). Estimates of group size based on re-sightings of identified Oribis averaged 33% larger than estimates based on roadside counts of Oribis encountered at random (Arcese *et al.* 1995b).

Smaller groups (especially lone animals) are more common in drier, cooler and/or less productive habitats and where concealing cover reduces the detection of group members often resting or feeding at distances of up to ca. 100 m (Rowe-Rowe *et al.* 1992, Arcese *et al.* 1995b, Brashares & Arcese 2002). In Ghana, geographic variation in rainfall is related closely to forage quality and quantity, with each of these variables also related positively to group size (Brashares & Arcese 2002). In Serengeti N. P., experimental reduction of tall grass cover by cool-season patch burning resulted in a marked increase in group size relative to unburned controls (P. Arcese pers. obs.). Median inter-individual distance of identified

group members was 7 m in north-west Serengeti N. P. during the 'dry-season' (ca. Jul–Dec), when migratory grazers and/or intermittent fires reduce grass cover (Arcese *et al.* 1995b); inter-individual distance was greater, but unquantified, during the wet season (P. Arcese pers. obs.). Large groups in less productive habitats are probably aggregations of non-territorial groups at sites of local resource abundance, but groups of up to 11 (5 adult ♂♂, six ♀♀) occupied strongly defended territories in productive habitats of north-west Serengeti N. P. (Brashares & Arcese 1999a). Aggregations also form during border conflicts between territorial groups (Arcese *et al.* 1995b). Studies of group size in Ghana and Zambia suggest that predator abundance does not predict social group size (Brashares & Arcese 2002, Goldspink *et al.* 2002, respectively).

In Serengeti N. P., 25% of 32 adult ♂♂ and 27% of 26 adult ♀♀ were present after four years on the territory where they were first identified, but only 14% of 35 male–female dyads remained intact over this period; this indicates a moderate rate of year-to-year residency within groups, but a low rate of long-term pairing (Arcese *et al.* 1995b). Consistency of group membership requires study where territories are defended seasonally or not at all.

Over most of their range Oribis occupy seasonal to year-round territories 0.1–60 ha in size, with territories generally being larger and defended less assiduously where annual rainfall is less than ca. 800 mm and/or mean minimum temperatures less than 5°C. In north-west Serengeti N. P., territories defended year-round range from 10 to 90 ha in size (mean = 60; Brashares & Arcese 1999a), similar to those in Akagera N. P. (8–61 ha; Monfort & Monfort 1974). Territories are more or less seasonal in South Africa but generally similar in size; in KwaZulu–Natal, recorded territory sizes were 60.2 ha (Everett *et al.* 1991) and 59.4 ha (Adamczak 1999). Oribis may abandon territoriality entirely in driest, coolest and/or least productive parts of their range, for example, at high-altitude sites in South Africa and the driest sites in Ghana (Oliver *et al.* 1978, Rowe-Rowe *et al.* 1992, Adamczak 1999, Brashares & Arcese 2002). On the Kafue Flats, Zambia, Oribis defend territories seasonally in lowland flood-plains (T. H. Clutton-Brock pers. comm.), but important details concerning group membership, site fidelity and social behaviour during the wet season are unstudied.

Defence of territory is primarily by the ♂ via active border patrols, chasing intruders, sparring with neighbours, and regular scent-marking with secretions of the preorbital gland, dung and urine (Gosling 1972, Brashares & Arcese 1999a, b). Rate of scent-marking varies seasonally and with social status of the ♂; rates are higher among dominant versus subordinate ♂♂ and for singleton ♂♂ versus those in multimale groups (Arcese 1999, Brashares & Arcese 1999a, b). Territories defended by male groups are marked more thoroughly than others, and in these groups dominant ♂♂ remained on territories longer than ♂♂ that defended territories without the aid of subordinate 'auxiliary males' (Arcese 1999); about half of auxiliaries in Serengeti N. P. were probably the offspring of dominants, but others immigrated as adults or remained philopatric on the natal territory after the dominant and presumed sire was replaced by a challenger (Arcese 1999). In Serengeti N. P., territory borders are marked by dung middens, often located on flat, open soil of eroded termitaria at distances of 30–150 m (Brashares & Arcese 1999b). Middens typically have 3–12 identifiable pellet groups, depending on rainfall and activity of dung beetles.

Preorbital marks are almost exclusively made by ♂♂, though 2–3 instances of marking by ♀♀ were observed in >3000h of observation (Brashares & Arcese 1999a). Marks are placed on vertical grass stems (ca. 50–70 cm in height; rarely on lateral branches of shrubs where grasses are burnt or otherwise absent). Marks are more common near shared borders, particularly those of multimale groups (Brashares & Arcese 1999a). Males mark at rates up to 70/h while patrolling the territory, more often in Serengeti N. P. during seven months prior to the main birth period.

Agonistic behaviour is observed often among ♂♂, especially at shared territory boundaries, but less often in ♀♀ (Arcese *et al.* 1995b, Arcese 1999, Brashares & Arcese 1999a, b, 2002). Monfort & Monfort (1974) described each sex as territorial towards same-sex intruders. In Serengeti N. P., individually identified adult ♀♀ sometimes moved 1–5 territory-widths without notable aggression in groups involved. One radio-collared ♀ dispersed in late gestation, then left her subadult female offspring several months later to rejoin her former group (P. Arcese pers. obs.; see below). On two occasions, established female group members attempted at first to smell and then to chase from their territory a newly arrived subadult ♀. In one case, two resident ♀♀ avoided a territorial ♂ that used his body and horns to maintain a 2–6 m distance between the residents and the newcomer. Upon avoiding the ♂, each of the residents chased the subadult ♀, who settled subsequently with two bachelors defending an adjacent territory. Other obvious signs of agonistic behaviour in ♀♀ were not observed (P. Arcese & J. Brashares pers. obs.), suggesting that female agonistic interactions may occur mainly when young female dispersers attempt to settle. Allogrooming has not been reported.

Agonistic encounters among ♂♂ have been described in detail (Monfort & Montfort 1974, Estes 1991a, Arcese 1999). Briefly, dominance interactions among group-living ♂♂ are generally subdued, with subtle threats observed most often. In this case a dominant ♂, with a slightly lower head and extended neck, may tip his horns towards a subordinate as they pass within a metre of one another. Subordinates may respond by veering slightly from their current path, jumping sideways or, occasionally, by lowering their head, neck and chest towards the ground (subadults). More obvious agonistic interactions are common among ♂♂ on adjacent territories and between a territorial ♂ and challenger. In rare cases, one can observe short distance chases, interspersed with bouts of ‘air-cushion fighting’, as well as actual contact of one male’s horns with the flank or head of another. The most severe encounters result in severe injury and the loss of territory. More commonly, ♂♂ engage in short bouts of one or more of the behaviours above. Arcese (1999) used maps and time courses to depict the dynamics of territory turnover and use of aggression in Serengeti N. P.

Oribis more than three months old use 1–3 sharp, nasal whistles to note their alarm, usually upon detecting a potential threat (Estes 1991a, P. Arcese & G. Jongejan unpubl.). In Serengeti N. P., Oribis that whistled generally held their neck erect, aimed their head at the object of interest, and then either changed paths, fled or accustomed themselves to the situation (e.g. presence of human observers, passing baboon troop). Whistles were recorded more often from ♀♀ than ♂♂ and more often from adults than younger animals (P. Arcese & G. Jongejan unpubl.). Oribis may also stamp a front foot

when standing alert. Young Oribis, and occasionally oestrous ♀♀, ‘bleat’ when pursued (see also Estes 1991a).

Oribis avoid predators in open areas mainly by maintaining a distance of >60 m from potential threats. Oribis also take advantage of sparse cover in open areas, such as by sitting adjacent to a small shrub, in a small depression, or among scattered rocks. In these conditions, Oribis approached closely will often jump up and then flee in a stiff-legged gait with tail erect. Estes (1991a) notes that this ‘rocking horse’ run may also be employed by territorial ♂♂ to advertise ownership. Fleeing Oribis often travel 100–200 m before stopping to face the perceived threat, and then sometimes whistle. A different pattern of escape is observed in conditions of dense cover and tall grass. In this case, Oribis sometimes tolerate an approach to within 10 m, before scurrying away in a low zig-zag run reminiscent of duikers and the Steenbok.

Genetic evidence of a mating system is absent, but detailed observations of ♂♂ and oestrous behaviour of ♀♀ suggests one ♂ monopolizes matings by following receptive ♀♀ closely and defending against the advances of subordinates in multimale groups (J. Brashares & P. Arcese pers. obs.). However, in multimale, multifemale groups, overlap in oestrous periods of co-habiting ♀♀ may allow successful reproduction by subordinates, who are observed to mount ♀♀ on occasion (Arcese 1999).

In Serengeti N. P., oestrous behaviour was recorded in detail for several individually identified ♀♀ over one or more behavioural oestrus periods, and later verified via assay for steroid hormone products in faeces (P. Arcese pers. obs.). During oestrus ♂♂ maintained a close proximity to ♀♀, often lying or standing within 1 m. Among group-living male Oribis, one dominant ♂ usually isolated the ♀ from other group members, but in a few cases two or more ♂♂ engaged simultaneously in courtship. During courtship, ♂♂ habitually test female urine, and often lick the female’s side or hindquarters as she stands or sits. Males may perform repeated front leg lifts to the side or rear of a standing or sitting ♀, and they often follow closely even those ♀♀ that bleat or run short distances to avoid them. The intensity of courtship varies over the ca. 4–6 day behavioural oestrus, but reaches a plateau 1–2 days in duration. Several times during this plateau ♀♀ will stand to be mounted instead of running ahead and will allow the ♂ to ejaculate. Montfort & Montfort (1974) and Estes (1991a) also provide descriptions and drawings. In two ♀♀ in Serengeti N. P., two successive behavioural oestrous periods were observed via behavioural and hormonal assay to have been separated by about 14 days (P. Arcese pers. obs.). Mounting is rare among Oribis in Serengeti N. P. outside of the oestrous period, but tail marking by ♂♂, leg-lifts and testing of female urine are common outside of behavioural oestrus.

Young lie out for 2–10 weeks before joining the mother and the group during regular movements (J. Brashares & P. Arcese pers. obs.), but are much more precocious in captivity (Le Riche 1970). During this time, young are visited several times daily by the mother, who stands as the young sucks in bouts for up to 30 min. Hiding sites are located in areas with rocks, shrubs or grass that provide concealing cover and are visited occasionally by the entire social group. From the account of a captive birth, there is a suggestion that ♂♂ act as sentinels and engage in other parental behaviour (Le Riche 1970). These observations are supported in the field by observations of ♂♂ alarm-calling when predators are detected in

the vicinity of hiding young (J. Brashares & P. Arcese pers. obs.); more work is required to determine the extent of male parental care. Young 1–3 months old generally remain close to their mother, often lying within 1 m, occasionally straying to 30 m while foraging or frolicking. One-month-old young have been observed with the social group in 12% of 42 observations, compared with 73% of 51 sightings of groups with young ca. 3.5 months old. Oribi juveniles ca. five months old were observed with their social group as often as expected by adult re-sighting rate (81%; Jongejan *et al.* 1991). The proximity of the mother and young is often less than that between other group members less than 7–10 months of age (J. Brashares & P. Arcese unpubl.).

Frolicking is common in Oribis under four months of age, most often as kicking, jumping, dashing and head-butting. One young male twice butted his mother vigorously in the side in play, but was then rebuffed by the female's threatening head-down posture (J. Brashares & P. Arcese pers. obs.).

In Serengeti N. P., pregnant ♀♀ occasionally distanced themselves from the social group, or dispersed to another territory 1–2 weeks prior to giving birth. One radio-collared ♀ dispersed ca. 2 km (ca. four territories) to join a new social group occupying unburned savanna with tall, rank grasses. Her former territory encompassed an area wherein mature grasses had burned and cover was scarce, but where much regrowth was available as forage; this suggests that the motivation for the move was security cover for young. This ♀ returned to her former territory ca. 8 months later without her surviving daughter.

Reproduction and Population Structure Oribis breed year-round where climate allows (e.g. north-west Serengeti N. P.), but with peak breeding and birthing seasons evident (Jongejan *et al.* 1991, Sinclair *et al.* 2000); the former precedes the latter by a gestation of ca. 6.5–7 months. In Serengeti N. P., births are commonest from Mar to May, coinciding with long wet-season rains and resulting grass growth, but births have been observed in all months of the year (Jongejan *et al.* 1991, Sinclair *et al.* 2000). Here, vulnerability of young to depredation may select as strongly for seasonal breeding as forage volume (Jongejan *et al.* 1991). Peak birth period, generally lasting 3–4 months, varies regionally but coincides with or is restricted to the wettest months of the year (Montfort & Montfort 1974, Estes 1991a), especially in more arid, seasonal and cooler climates; in southern Africa, the main birthing season is from Oct to Dec (Oliver *et al.* 1978, Viljoen 1982). A single young is born, but many ♀♀ experience an immediate postpartum oestrus that facilitates a potential reproductive rate of more than 1.5 young per year (Le Riche 1970, Dittrich 1974, Jongejan *et al.* 1991). Data are unavailable to test whether inter-birth interval depends on survival of the young, climate or available forage, but some data suggest it is independent of the sex of the young (Jongejan *et al.* 1991).

Young Oribis grow rapidly, attaining near-adult size in about seven months. In Serengeti N. P., median age of young about one-third shoulder height of adult ♀ = 2.2 months; median age at half size = 3.6 months; at two-thirds size = 4.7 months; and at three-quarters size = 7.0 months (Jongejan *et al.* 1991). Various reports suggest age at maturity is 10–14 months in ♂♂, but ca. three months earlier in ♀♀ (Cade 1966, Kingdon 1982, Jongejan *et al.* 1991, Estes 1991a). The single estimate for ♂♂ is from a hand-reared Oribi

that inseminated captive ♀♀ at 14 months of age (Cade 1966); this precedes slightly the typical age at which ♂♂ first defend a territory (15 months: Estes 1991a; 17 months: Jongejan *et al.* 1991, Arcese 1999). Females in Serengeti N. P. typically elicited courtship interest from ♂♂ at more than seven months of age and occasionally stood to be mounted. One nine-month-old ♀ was mounted repeatedly and appeared via hormone assay of faecal progesterone concentration to have experienced normal oestrus (J. Brashares & P. Arcese pers. obs.).

In Serengeti N. P., about half of social groups contained a juvenile less than seven months old (range 0.3–0.8; Arcese *et al.* 1995b). Sex ratio is highly variable across the species' range, 0.83–3.55 ♀♀ per ♂; sex ratio is related positively to apparent rate of polygyny for populations in Africa and years of study in Serengeti N. P. (Arcese *et al.* 1995b). However, forage quality and quantity are a better predictor of adult sex ratio and apparent polygyny in Ghana (Brashares & Arcese 2002). Longevity in captivity is on the order of 14–16 years (Estes 1991a, Weigl 2005).

Predators, Parasites and Diseases Leopards *Panthera pardus* are the most important predator of adults in Serengeti N. P. (two of three radio-collars recovered), but Cheetahs *Acinonyx jubatus*, Lions *Panthera leo*, Spotted Hyaenas *Crocuta crocuta* and African Rock Pythons *Python sebae* probably kill adults opportunistically. Various anecdotal reports suggest that major predators elsewhere are similar to the Serengeti N. P., and that abundance is increased where these predators are extirpated. A freshly dead adult male Oribi in Serengeti N. P. that was found within 5 m of resting territorial group members showed no obvious signs of cause of death, but necropsy revealed free-flowing blood consistent with haemolytic snake venom; anthrax, common in the region and often associated with absence of coagulation, was ruled out by lack of inflammation in internal organs/lymph glands. Young are susceptible to a wide range of opportunistic predators due to small size, including large predatory birds and snakes and small felids and canids. Adult male baboons *Papio* spp. in Serengeti N. P. killed a young Oribi lying out, and regularly elicit the alarm calls of adult Oribis.

There is very little information on parasites and diseases. A single Oribi sampled in KwaZulu–Natal harboured the following parasites: *Trichostrongylus falculatus*, *T. colubriformis*, *Trichostrongylus* sp. and *Cooperia yoshidia* (Boomker *et al.* 1984). These were somewhat similar to those recorded from Oribis in Kruger N. P. (where Oribis no longer occur), although *Impalaia tuberculata*, *Cooperia fuelleborni* and *Oesophagostomum colombianum* were not present in Oribis from KwaZulu–Natal (Boomker *et al.* 1986). Other parasite records include *Setaria scalprum*, *Haemonchus contortus* and *Onchocerca* spp. (Ortlepp 1961, Round 1968).

Conservation IUCN Category: Least Concern (*O. o. haggardi* – Vulnerable C1; *O. o. kenya* – Extinct). CITES: Not listed.

The Oribi is now rare or absent in much of its former range, with hunting (both legal and illegal) the primary reason for declines of populations outside, and often inside, protected areas. The Oribi's poor stamina makes it vulnerable to hunting with dogs (Kingdon 1982, J. Brashares pers. obs.); in Kenya, a rancher related a case of her poodle running-down and killing an adult Oribi (sex unknown). Its tendency to whistle and approach potential predators also makes

it an easy target for hunters using firearms (J. Brashares pers. obs.). In Ghana, hunters report that the Oribi's reluctance to leave its territory makes it easy to follow and shoot, and that ♀♀ are shot first because a ♂ rarely abandons a fallen mate and, thus, can be taken easily with a second shot (J. Brashares pers. obs.). Oribi meat is much sought after in West Africa, where it is considered to be of high quality (J. Brashares pers. obs.). In Comoé N. P. in Côte d'Ivoire, Oribis experienced a decline of around 92% between 1978 and 1998 primarily due to poaching (Fischer & Linsenmair 2001a). Conversion of open grassland for agriculture and forestry has also resulted in declines and extirpation of Oribi populations throughout Africa (East 1999).

Populations of Oribis appear stable in areas where hunting is minimal or where snares rather than guns or dogs are the main tool used in hunting. When left unmolested Oribis can occur in close proximity to human settlement and often thrive on private ranches, as in South Africa (Van Teylingen & Kerley 1995, J. Brashares & P. Arcese pers. obs.). Large populations occur in a number of protected areas throughout their range, including Niokolo-Koba N. P. (Senegal), Comoé N. P. (Côte d'Ivoire), W N. P. (Niger), Arly-Singhou (Burkina-Faso), Pendjari N. P. (Benin), Bénoué, Bouba Ndjida and Faro National Parks (Cameroon), Omo N. P. (Ethiopia), Serengeti N. P. (Tanzania), Kafue and Liuwa Plains National Parks (Zambia), Liwonde and Kasungu National Parks (Malawi), and Golden Gate Highlands N. P. (South Africa) (East 1999). Recent surveys in the

dry season in S Sudan have shown Oribis to be surviving in much reduced numbers in Boma and Southern National Parks (Fay *et al.* 2007). Haggard's Oribi occurs in Boni-Dodori National Reserve in Kenya and Bush Bush N. P. in Somalia, but there is no information available on its status.

Tribe REDUNCINI

Reduncines

Reduncini Knottnerus-Meyer, 1907. Arch. Naturgesch. 73: 39.

The Reduncini comprises nine species arranged in three genera. *Redunca* is a unified group of three small- to medium-sized species. *Kobus* is a more diverse assemblage of five medium- to larger-sized species and this makes it harder to apportion morphological characters between the tribe and genera in a clear-cut manner. *Pelea*, containing only the Grey Rhebok *Pelea capreolus*, has sometimes been included in a separate tribe or subfamily of its own (e.g. Roberts 1951, Ansell 1972), but has been shown to cluster with the reduncines (Vrba & Schaller 2000, Birungi & Arctander 2001, Hernández Fernández & Vrba 2005) having diverged shortly before the separation between *Kobus* and *Redunca*. We therefore treat *Pelea* as a reduncine in this work. There are cranial similarities between *Pelea* and the Mountain Reedbuck *Redunca fulvorufula*, but the bullae are smaller and the cheekteeth differ. *Pelea* also differs from other Reduncini in lacking inguinal and subauricular glands (but possessing pedal glands and a preputial gland), while the horns are short, straight spikes instead of curved hooks.

Reduncini, even the smaller species, are more heavily built than Antilopini. Reduncines have slender to stocky legs, a long, well-muscled body and a relatively thick neck, especially in ♂♂. Pelages of the larger species are shaggy while smaller ones are sleek or slightly fleecy. Coat colours are usually brown, greyish or tan, sometimes with leg and throat markings. More striking colours and sexual dimorphism of colour and body weight can be seen in kobs and lechwes, particularly the White-eared Kob *Kobus kob leucotis* and

Myology of the neck in male Kob *Kobus kob* showing enlarged *longus capitis* muscle compared with same, slender muscle in Oribi *Ourebia ourebi*.

Skull architecture in (above) Grey Rhebok *Pelea capreolus* and (below) Mountain Reedbuck *Redunca fulvorufula* showing fine, straight horn and narrow, elongated muzzle in former. Deeper mandibles, enlarged masseter and thicker curved horn in latter.

the Nile Lechwe *Kobus megaceros*, both in the Sudan and both coloured dark brown or even black, with pale or white markings.

Female reduncines, with very rare exceptions, do not possess horns. The horns of ♂♂ are annulated and curve forward at the tip to a greater or lesser degree (this is pronounced in reedbuck, but less so in the Kob, Southern Lechwe *Kobus leche* and Waterbuck *Kobus ellipsiprymnus*), and corresponds with forward striking with the head, powered by muscles that help shape the characteristic bulging neck of ♂♂. The ontogenetic growth sequences in antelope horns have phyletic significance and are discussed in Kingdon (1982); thus, an upright, vertical base section is not typical for reduncines, is only seen in the Kob and Puku *Kobus vardonii*, and appears last in their ontogenetic developmental sequence. Horns of the Nile Lechwe have more of a low backward sweep, and those of adults of the Southern Lechwe a slightly sigmoid curve at the very base. Consequently, much of the length in lechwe horns and all of the length in the Waterbuck and reedbucks curves upwards from a nearly horizontal inclination and has a concave profile of the anterior edge.

Preorbital glands are absent, except in the Puku (which has active facial glands) and in the Kob (and then only vestigial), and as such there are no preorbital fossae. Pedal glands are also absent or vestigial, although pedal glands are present on all four feet in *Pelea*.

TOP: Superficial myology of Waterbuck *Kobus ellipsiprymnus* adult male.

ABOVE: Waterbuck *Kobus ellipsiprymnus* adult male skeleton.

All members, except *Pelea* and the Waterbuck, have well-developed inguinal glands in the groin. All have a pungent overall odour that emanates from sebaceous glands and films the entire body. This provides a seal against water-loss and possibly some insulation against temperature extremes but is also likely to carry socio-sexual signals (as must their musky urine). Reduncines, again with the exception

Invaginated inguinal glands in groin of Bohor Reedbuck *Redunca redunca*.

of *Pelea*, have black, glandular patches below the ears, which, among other messages, advertise the females' breeding condition. The smaller species whistle and make ritualized 'rocking-horse' displays, which apparently signify subordination. These might be the long-grass equivalent of the stotting or pronking of antelopes from more open habitats. Females of all species have two pairs of inguinal nipples.

In understanding the evolutionary history of Reduncini, we need to take account of their fossil record in the Asian Siwaliks deposits, which has been known since the nineteenth century. Recognizable reduncines of fairly small size are first known from the late Miocene (8.0–6.0 mya) in the Siwaliks (Barry *et al.* 2002) and in Africa. They may have started with horn cores that were gazelle-like but with strong transverse ridges (sometimes separated as an extinct genus *Dorcadoxa*). They quickly diversified before the Miocene ended (Vrba & Haile-Selassie 2006) and even spread briefly into parts of southern Europe. During the Pliocene in Africa there were a number of more or less kob-like lineages, sometimes with more advanced features of certain premolar teeth than in modern reduncines (Gentry 1981). A distinctive genus, *Menelikia*, appeared in East Africa and survived into the early Pleistocene. An interesting study by Spencer (1997) concluded that its food must have been homogeneously distributed like grass, but tender and soft. Could this have been some type of swamp vegetation? The oddest-known reduncine fossil is a unique Pleistocene frontlet from Olduvai Gorge, Tanzania, *Thaleroceros radiciiformis*, with large, disproportionately massive but short horn cores mounted on a united horn pedicel (Reck 1937, pl. 8).

Other Pleistocene fossils in Africa are mostly recognizable as related or ancestral to living species. The Southern Lechwe seems to have separated from the Waterbuck stock around the start of the Pleistocene, but it is worth noting that the skull of the Nile Lechwe has some sinus development within its frontal bones, a character otherwise better seen in the extinct *Menelikia*.

Fossils of *Redunca*, as at present understood, are less common than *Kobus*. In the Indian sub-continent, reduncines survived at least until the early Pleistocene. They were reminiscent of lechwes or kobs, but had stronger temporal ridges on their cranial roofs. It is noteworthy that such a water-associated group of antelopes, apparently poor dispersers and now restricted to well-watered areas of Africa, must, therefore, once have ranged across parts of Arabia, as did hippos. This implies former long periods of moist conditions along the Nile

Upper right occlusal surface of toothrow in Mountain Reedbuck *Redunca fulvorufula* with deciduous milk teeth still in position.

Valley, other Asian rivers and along moist coastal zones, notably in Arabia.

The occlusal complexity of present-day reduncine teeth resembles that of the much larger extant Bovini, and the temporal ridges of the Plio-Pleistocene Siwaliks reduncines prompted Gentry & Gentry (1978) to accept Reduncini as related to Boselaphini, which also have such ridges and from which Bovini evolved. This view was wrong, and the simpler and more antilopine-like characters of fossil reduncine teeth at Langebaanweg (Gentry 1980) suggested that parallel evolution may have occurred.

Kingdon (1982) discussed the ecological, behavioural and anatomical reasons for Reduncini sharing ancestry with the Antilopinae (in the sense used in this volume), and this phylogenetic affiliation has been confirmed by molecular studies (e.g. Gatesy *et al.* 1997, Matthee & Robinson 1999a, Birungi & Arctander 2001, Hassanin & Douzery 2003). Molecular studies agree in suggesting that Reduncini are probably close to the earliest origins of the Antilopinae, but vary in the details: Matthee & Robinson (1999a) placed the reduncine divergence after the caprines, but before the divergence of alcelaphines/hippotragines. A link with Cephalophini was proposed by Gatesy *et al.* (1997), an idea taken up by Hernández Fernández & Vrba (2005). Hassanin & Douzery (2003) treated Reduncini, Cephalophini, Antilopini and Aepycerotini as basal groups of Antilopinae. Kingdon (1982) and Vrba *et al.* (1994) and this volume have posited some form of association between Reduncini and the Oribi *Ourebia*.

Below the tribal level, molecular relationships among species of the genera *Kobus* and *Redunca* have now reached some general agreement with earlier morphology based assessments (Birungi & Arctander 2001) and the phylogenetic tree of relationships presented here reflects the results of these studies.

Reduncines are grazing antelopes with a diet of fresh rather than coarse grasses. Their prime need is for grassland habitats in the vicinity of water, such as lake margins or river flood-plains, and they have not developed any physiological capability for drought endurance. They find cover among tall grasses or in water, and the two lechwes feed in water. Waterbucks can be found in both grassland and adjacent woodland. The Mountain Reedbuck is exceptional in inhabiting montane rather than edaphic grasslands, but still needs regular access to water. Species of *Redunca* are less gregarious than *Kobus*, they lead more concealed lives within the cover afforded by long grass, and they are more active nocturnally.

The preferred habitats of most reduncines consist of valley sumplands, which are rich in food for grazers but are unstable because they dry out or catch fire. Antelopes find it difficult to cope with fluctuating water-levels, sticky soils and rapid growth of nearly impenetrable grasses. Only the lechwes, with swamp-adapted hooves, can reside permanently in wetlands. For the rest, accommodation

Tentative phylogenetic tree for Reduncinae (modified from Hernández Fernández & Vrba 2005).

to radical seasonal changes inhibits extreme specialization, making reduncines unusually homogeneous. The instability of their very productive habitats encourages substantial fluctuations in numbers. This is exacerbated by their inability to disperse. Seasonal changes lead to short-distance movements that also cause crowding, sometimes of spectacular proportions (notably in *Kobus*).

To accommodate both crowding and short-range dispersal, reduncines have very flexible relationships between the sexes. Females are relatively independent and are the object of intense competition between ♂♂. Substantial differences in the size, morphology and behaviour of the sexes correspond to separate male and female strategies. The ♀♀ of different reduncine species have more in common than the ♂♂ (which look and behave very differently from species to species).

Because they are the major bovid lineage adapted to valley grasslands, reduncines have considerable potential for rational exploitation, having the fastest growth rates of any bovid, insignificant disease problems (compared with cattle) and very acceptable meat and hides. Large populations of the more social species are unlikely to survive unless their potential for sustained yield cropping is realized because they occupy habitats with a high priority for agriculture or livestock development.

Jonathan Kingdon & Alan Gentry

GENUS *Pelea* Grey Rhebok

Pelea Gray, 1851. Proc. Zool. Soc. Lond. 1850:126 [1851].

Pelea includes only the Grey Rhebok *P. capreolus*, a small- to medium-sized antelope of slender proportions limited to South Africa, Lesotho and Swaziland, mainly in upland habitats.

The genus has a troubled history. It has been included with the Antilopini (Oboussier 1970a), Caprini (Gentry 1978), Neotragini (Georgiadis *et al.* 1990, Gentry 1992), or even in its own tribe or subfamily (Roberts 1951, Ansell 1972, Vrba 1976). Recent analyses of morphological (Vrba & Schaller 2000) and molecular data (Gatesy *et al.* 1997, Hassanin & Douzery 1999, Matthee & Robinson 1999a, Matthee & Davis 2001; but see Birungi & Arctander 2001) concur with those earlier classifications (e.g. Pocock 1910, Simpson 1945) that suggest that *Pelea* should be included as a primitive taxon within the Reduncini, and Grubb (2005) included it in his subfamily Reduncinae. Grouping of *Pelea* with other reduncines has

been unambiguously established in a composite phylogenetic tree (Hernández Fernández & Vrba 2005).

Pelea is distinguished from *Kobus* and *Redunca* by strong morphological differences. The skull of this species is similar to that of the Mountain Reedbuck *Redunca fulvorufula* in outline, but is characterized by: small auditory bullae; cheekteeth not so nearly specialized, with less prominent styles and much less complicated enamel figures in the wear pattern; long lachrymal and ethmoid fissure; and a low-placed ridge marking the origin of masseter. In addition to some behavioural differences, *Pelea* has no inguinal glands, no subauricular gland and the horns are quite different.

Peter Grubb

***Pelea capreolus* GREY RHEBOK (VAAL RHEBOK, RHEBOK)**

Fr. Rheboux; Ger. Rehantilope

Pelea capreolus (Forster, 1790). In: Levaillant, Erste Reise Afrika, p. 71. 'Ouwe-hoeck', now specified as South Africa, Western Cape, Caledon, Houhoek Pass; see Skead (1973: 79).

Grey Rhebok *Pelea capreolus*.

The name 'roebuck' appears often in early records of settlers in the Cape (South Africa); this animal probably reminded these settlers very much of the European Roe Deer *Capreolus capreolus*. The pronunciation and spelling over the years have changed through roe, rabock, reebok, raybuck to rhebok in English and 'ribbok' in Afrikaans (Skead 1980).

Taxonomy Monotypic. Synonyms: *lanata*, *villosa*. Chromosome number: not known.

Description A graceful, slender antelope of small to medium size, with neck long and slender, forehead swollen and muzzle elongated. Nose black, large and swollen (slight pressure after death yields droplets of moisture from this glandular structure). Ears long, narrow and pointed, with white hairs inside. Black-lidded eyes very prominent and surrounded by a conspicuous white ring. Some white also present on sides of the muzzle and chin. No subauricular patches. Upperparts of the body and flanks greyish-brown, face and outer parts of the legs tawny; underparts pure white. Pelage is soft, short, dense, thick and woolly. Dorsal 'guard' hairs have a brownish-grey base, a lighter shaft and a darker band near the tip; under 'guard' hairs are white. In cross-section, guard hairs are uniform oval or circular. Scales at the base of these hairs have a regular waved mosaic pattern, while those of the shafts and tips have irregular waved patterns. Scale margins are smooth, but rippled at tip (Keogh 1983). Tail bushy and white below. Hooves short, triangular and compact; lateral ('false') hooves are present. Preorbital and inguinal glands are absent, but

Lateral and palatal views of skull of Grey Rhebok *Pelea capreolus*.

there is a preputial gland (unique amongst the Reduncini), and pedal glands are present on all four feet (the glandular sacs contain a pale-coloured, foul-smelling secretion).

Horns, present in ♂♂ only, are straight, upstanding and ringed (about ten annuli) for about half their length. Skull characterized by a short, rounded braincase, small auditory bullae, and the long rostrum, nasals and lachrymal bones and ethmoid vacuity. Orbits are tubular and there are no preorbital fossae. First incisors are broad; other incisiform teeth are narrow, but second incisors are a little broader.

Geographic Variation None recorded.

Similar Species

Redunca fulvorufula. Co-occurs at higher altitudes in Swaziland and Lesotho, and several provinces in South Africa (Free State, Mpumalanga, KwaZulu-Natal, Eastern Cape, Western Cape and Limpopo), although Mountain Reedbucks tend to prefer tall grass areas. Subauricular patches are present; ears more rounded; belly sharply demarcated from the rest of the body; horns of Mountain Reedbuck ♂♂ curve forward. Females of the two species are difficult to distinguish and neither possesses horns. Mountain Reedbucks seldom lift their tail when running.

Distribution Endemic to a small region within southern Africa, inhabiting montane and plateau grasslands of South Africa, Swaziland and Lesotho (Skead 1980, 1987, Ferreira 1983, Lynch 1983, 1989, 1994, Rowe-Rowe 1994, Monadjem 1998, East 1999). Their distribution is discontinuous and patchy due to the decline in numbers, and they no longer occur north of the Orange R. in the Northern Cape, South Africa, or in parts of the North West Province (see Du Plessis 1969 for historical distribution). They formerly occurred widely

in the highveld of western Swaziland, but have disappeared from parts of their range; they remain fairly common in Malolotja N. R. and still survive locally in unprotected areas (Monadjem 1998). In Lesotho, they probably occurred widely in the past, but have been reduced to a few scattered remnant populations (Lynch 1994).

East (1999) notes that they are believed to have occurred in SE Botswana, in hilly country around Gaborone (presumably based on Shortridge 1934), but Smithers (1971) remarks that evidence of their occurrence in historical times is based on hearsay and there is no conclusive evidence of their former occurrence in Botswana.

The prehistoric distribution of Grey Rhebok is vague (Vrba 1975). Fossil remains from Kromdraai, Swartkrans and Sterkfontein in South Africa apparently date back to the lower Pleistocene.

Habitat Grey Rhebok are associated with rocky hills, mountain slopes and plateaux with good grass cover. They are found on slopes of up to 35 degrees in the Drakensberg, but prefer gentler slopes of less than 20 degrees (Ferreira 1983, Rowe-Rowe 1983). A preference for open, short grassveld (<20 cm) is associated with areas that have few stones or rocks and is related to defensive behaviour (Ferreira 1983). Habitat selection is according to the structure of the vegetation rather than floristic composition (Ferreira 1983). Rowe-Rowe (1982a), Beukes (1987) and Scott (1991) found that Grey Rhebok prefer short, burnt veld for feeding and longer grass for cover. In the Drakensberg there is a significant preference for the warmer north, north-east and east facing aspects throughout the year (Ferreira 1983, Rowe-Rowe 1983).

Abundance Owing to hunting pressure and habitat destruction, Grey Rhebok numbers have declined over the years. In South Africa, total numbers of Grey Rheboks are in excess of 9600, with at least 4600 found in protected areas and around 5000 on private land (East 1999). Grey Rheboks are the only bovid found in reasonable numbers in Lesotho, where the total population is thought to be in excess

of 200 animals (East 1999). Numbers in Swaziland are unknown, but Monadjem *et al.* (2003) report that they do well in Malolotja N. R. and are protected in Mlilwane Wildlife Sanctuary. East (1999) suggested that total population numbers stand at around 18,000.

The largest population in a protected area is in Ukhahlamba–Drakensberg Park (2000–3000 individuals), where ecological densities range from 1.8/km² to 4.3/km² (Rowe-Rowe 1994). Density at Highmoor State Forest in KwaZulu–Natal was 2.4/km² (Oliver *et al.* 1978), and at Sehlabathebe N. P., Lesotho, 1.6/km² (Kopij 2006). At Sterkfontein Dam N. R., Free State, densities were higher at 6.4/km² (Taylor *et al.* 2007), similar to the 6.7/km² in Bontebok N. P. in the Western Cape (Beukes 1984).

Adaptations Grey Rheboks occur in a range of climatic zones and vegetation types, from coastal fynbos to the Drakensberg alpine zone, and their densities vary due to the influence of the prevailing environmental factors. In colder areas, warmer air zones associated with topographic features are selected (for example, in the Drakensberg where the average minimum temperature during winter drops to below 0°C; Ferreira 1983). Although Mountain Reedbucks co-inhabit the hills and mountains in the range of Grey Rhebok, they have a different feeding behaviour and use physiographic features and vegetation types differently. While Grey Rheboks prefer short open veld, Mountain Reedbucks are common on steeper valley sides with taller grass and scattered woodland. In the Drakensberg, Mountain Reedbucks also have a narrower altitudinal range than Grey Rheboks. The latter occur at greater densities than Mountain Reedbucks and may occur at altitudes above the montane belt (above ca. 2800 m) (Vincent 1962, Ferreira 1983, Rowe-Rowe 1983). Grey Rheboks have developed a fleeing behaviour, important when evading natural predators in their ‘open’ environment. When disturbed, Grey Rheboks utter a sharp bark, taking flight towards open, higher areas from where the enemy can be easily seen. Flashing of the white underside of the tail also serves as a warning mechanism to conspecifics.

Foraging and Food Grey Rheboks are predominantly browsers (Beukes 1984, Ferreira & Bigalke 1987, Taylor 2004, Skinner & Chimimba 2005), and were classified as such by Gagnon & Chew (2000) in their review of the dietary preferences of African bovids. However, although they are almost entirely browsers, they feed selectively (Taylor & Skinner 2006a). In the Free State (summer rainfall region) faecal analysis showed that dicotyledons comprise 88% of their diet in areas with basal cover of dicotyledons less than 3% (Ferreira 1983). This changes only slightly during the year and ranges from >90% in winter to 78.5% in summer. In Bontebok N. P. (winter rainfall region), dicotyledonous shrubs and forbs account for 96.9% of the diet (Beukes 1984). Here roots, seeds and flowers contribute to between 1.5% and 14.6% of rumen contents (especially in the months Jun, Aug and Oct when these were more easily available). Shrubs and forbs lower than 250 mm were selected for, with the genera *Disparago*, *Metalsia* and *Aspalathus* the most important food plants (Beukes 1987, 1988). Observations when feeding on *Leucosidea sericea*, *Cliffortia nitidula* and an *Euryops* sp. further suggest that Grey Rheboks select the growing tips that provide the greatest concentration of protein (Ferreira & Bigalke 1987). Low nutrients, especially crude protein, effectively control Grey Rhebok

numbers in the sourveld of the KwaZulu–Natal Drakensberg. Here peak mortality occurs from Aug to Oct, the period immediately following the coldest and driest time of year when herbage quality is lowest (Mentis 1978, Oliver *et al.* 1978, Rowe-Rowe 1983, Rowe-Rowe & Scotcher 1986).

A typical diurnal and nocturnal feeding pattern comprises alternating bouts of 1–2 hours' duration of feeding and lying up/rumination (Taylor *et al.* 2006a). Grey Rhebok spend on average ca. 30% of daylight hours feeding; at night they are active for 57% of the time, though not all this time is spent feeding (Taylor *et al.* 2006a). They are less active during the middle of the day in summer (Oliver *et al.* 1978, Ferreira 1983), and, during winter, cover greater distances for foraging than during summer. Being water-independent, they appear to obtain most of their water requirements from their food; however, at Sterkfontein Dam N. R., Grey Rhebok were regularly seen drinking water from the dam between May and Aug (Taylor *et al.* 2007).

Social and Reproductive Behaviour Grey Rheboks are found in two social groups: harem herds (usually consisting of one adult ♂ plus up to five ♀ with young) and as single territorial adult ♂ (Esser 1973, Oliver *et al.* 1978, Rowe-Rowe 1982b, 1994, Ferreira 1983, Taylor 2004). Although there are no bachelor herds, young ♂ sometimes form temporary associations that may last for up to three weeks (Ferreira 1983). Typical herd size is between three and five animals, but up to 15 and even a group of 28 individuals has been recorded (see Lynch & Watson 1990). Larger herds are presumably ♀ and young from harem herds that have joined temporarily. Herd size differs between regions, with mean group size and typical group size in the E Free State recorded as 3.5 and 4.6 ($n = 184$), respectively (Ferreira 1983), and 2.9 and 4.0 in the KwaZulu–Natal Drakensberg (Oliver *et al.* 1978). In the Free State, herds do not fluctuate significantly in size and composition between summer and winter, and the frequency of occurrence of solitary ♂ is also constant (Ferreira 1983).

The social structure of territorial male Grey Rheboks can be described as a system of female defence polygyny (Taylor & Skinner 2006a). Territories are marked by means of faeces, and territorial ♂ are often seen defecating at visible landmarks, such as at the base of termite mounds or against shrubs, rocks or tall grass tufts (Ferreira 1983, Taylor & Skinner 2006b). Although scent-marking is performed throughout the year, Taylor & Skinner (2006b) recorded that the frequency of scent-marking in three territorial ♂ in the Free State was highest between Oct and Dec, coinciding with the period when they evicted juvenile ♂ (which, in turn, were more submissive at this time of year) from their natal herds and when ♀ were due to start lambing. Although territories are scent-marked, display and acoustical behaviour play a prominent role in territorial advertising. Territorial ♂ will advance with exaggeratedly slow movements towards a trespassing ♂, displaying laterally and frontally, while stamping and snorting. This behaviour usually has the effect of driving an intruder away. Physical encounters take place where this behaviour is unsuccessful.

Home-range sizes of territorial ♂ ranged between 23 and 135 ha, averaging 53 ha in the Free State (Ferreira 1983), 60 ha on Sterkfontein Dam N. R. (Taylor 2004), 77 ha at Highmoor (Drakensberg) (Oliver *et al.* 1978), 42 ha at Royal Natal N. P. (Drakensberg) (Southgate

1979) and 70 ha for Ukhahlamba–Drakensberg Park (Rowe-Rowe 1994). In seven different areas throughout South Africa, home-range size did not correlate with Grey Rhebok density. According to Ferreira (1983), their home-range size is determined by the quality of the habitat, and not by the pressure of density. Ferreira (1983) also found no correlation between group size and various categories of slope, topography, aspect, geology, altitude and vegetation height, and no seasonal differences in the frequencies with which animals were observed in these categories.

Males court ♀ in oestrus by sniffing the vaginal area, resting their heads on the female's buttocks and back, and tapping the inside of the female's hindlegs with their forelegs. Multiple matings may follow (A. Taylor pers. comm.). Pregnant ♀ leave the herd 2–3 days before parturition and return after about one week. Young are concealed for ca. 4–6 weeks during which they are regularly visited and suckled. Young can be found lying with their heads characteristically flat against the ground and at considerable distance from the mother (Oliver *et al.* 1978). Juveniles of up to eight months seek their mothers when danger threatens and follow closely during flight.

Yearling ♂ leave the harem herd or are evicted very aggressively by the harem ♂ between Oct and Dec, just prior to the start of the birth period (Rowe-Rowe 1982b, Taylor *et al.* 2006b). They become physically mature at about 1.5–1.75 years (Esser 1973) and soon try to establish territories. Males that fail to establish their own territories are forced to the peripheries of those of established ♂. Taylor *et al.* (2006b) also recorded four occasions on which harem ♂ evicted young ♀ of ca. 8 months of age from their herds; two of these ♀ were allowed to return after two months, but before being allowed back they remained on the peripheries of their home-ranges and avoided contact with their natal groups.

Four vocalizations are recognized: barking, moaning (or bleating), hissing and snorting (or grunting). When disturbed, they utter a sharp, nasal-sounding bark whistle before taking flight with their characteristic 'rocking-horse' gait. Adult ♂ generally utter this alarm; the flight is then led by an adult ♀ with the ♂ following at the back of the group. Both sexes snort when the source of disturbance is not recognized (and snorting may last for up to 45 min).

Reproduction and Population Structure Reproduction is seasonal (see Oliver *et al.* 1978, Ferreira 1983, Beukes 1984, Rowe-Rowe 1994, Taylor *et al.* 2006b). Mating occurs from Feb to May and a single young is born after a gestation of 37.3 weeks between Nov and Feb (Brand 1963, Taylor *et al.* 2006b), but sometimes from as early as Oct and as late as Jul (Taylor *et al.* 2006b). Beukes (1984) recorded a birth peak in Aug in Bontebok N. P. due to winter rainfalls in this region. Even in captivity, where they have access to good-quality forage, Grey Rheboks remain seasonal (Brand 1963, Skinner *et al.* 2002). During a study in the Free State, two ♀ started breeding at the age of 16 months and gave birth for the first time at two years. The inter-birth interval for adult ♀ was generally one year, although one ♀ had an average interval of nine months (Taylor *et al.* 2006b).

Sex ratios differ between the E Free State and the KwaZulu–Natal Drakensberg, being 1 : 2.2 in the Free State and between 1 : 1.5 and 1 : 1.9 in the Drakensberg (see Ferreira 1983, Scott 1991, Rowe-Rowe 1994). Juveniles (less than one year old) comprise 22% of the population (Southgate 1979, Rowe-Rowe 1982b). Average fecundity

rate in a study in the Free State was 74% and the sex ratio in offspring was 22 : 19 (Taylor *et al.* 2006b).

In Ukhahlamba–Drakensberg Park, mortality is highest between Aug and Oct, following the severe winter when food availability and quality drop to critical levels (Rowe-Rowe & Scotcher 1986). In the Free State, Taylor *et al.* (2006b) lost 27% of their study population due to hypothermia after heavy snow at the end of winter; ♂♂ and ♀♀ were affected to the same degree by the snow, but juveniles suffered more than adults (there was no evidence of mortality due to infectious disease or predation in this study). Potential life-span not known, but longevity in captivity is about 12 years (Jones 1993, Weigl 2005).

Predators, Parasites and Diseases Although Black-backed Jackals *Canis mesomelas* do prey on Grey Rheboks, Rowe-Rowe (1982b) showed that their influence on Grey Rhebok numbers is not significant. Other contemporary predators include Caracals *Caracal caracal* (e.g. Palmer & Fairall 1988) and large raptors.

In surveys of Grey Rheboks from Bontebok N. P., one trematode (*Fasciola hepatica*) and 12 nematode species were recovered (Boomker *et al.* 1981, Horak *et al.* 1982b, Boomker & Horak 1992; and see Lichtenfels *et al.* 2001 and Boomker & Durette-Desset 2003). The nematodes *Paracooperioides peleae* and *Ostertagia triquetra* have been recovered from this host only (Boomker *et al.* 1981, Boomker & Durette-Desset 2003). Taylor *et al.* (2005) identified five nematode species from Grey Rheboks at Sterkfontein Dam N. R., including *Cooperia yoshidai* and *P. peleae*.

In a ten-year-study of tick infestations of Grey Rheboks in Bontebok N. P., Horak *et al.* (1997) collected six tick species of which *Rhipicephalus nitens*, *R. glabroscutatum* and *Ixodes pilosus* were the most abundant on both Grey Rheboks and Bonteboks *Damaliscus pygargus pygargus*. In an earlier study, Horak *et al.* (1986) also recorded two species of lice, and three oestrid fly larvae, including *Gedoelestia* sp. from the eyes of three animals. Horak *et al.* (in Ferreira 1983) reported lesions in Grey Rhebok hides and eyes caused by infestation of the larvae of oestrid flies. Skead (1987) mentions infestation by the larvae of the antelope warble fly, *Strobiloestrus clarkii*. Subcuticular parasitic fly larvae make their meat unattractive (Rautenbach 1978).

Conservation IUCN Category: Least Concern. CITES: Not listed.

Grey Rhebok numbers have declined mainly due to habitat

alteration and hunting pressure. The most marked change in its habitat has been the vegetation; for example, the vegetation of the central plateau region of South Africa, from Graaff-Reinet northwards to the Orange R. and S Free State, has changed from sweet grassveld to degenerate false Karoo veld since the arrival of Europeans (see Ferreira 1983). Because Grey Rheboks flee to open spaces (where they become more vulnerable), and because landowners are antagonistic to this species (it is believed to be aggressive towards the sheep, goats and the more palatable Mountain Reedbucks with which they often co-exist), their numbers and distribution have declined. In KwaZulu–Natal, predation by uncontrolled dogs has been singled out as a major cause of losses (Rowe-Rowe 1994).

Grey Rhebok populations are stable in at least six national parks and 29 provincial reserves in South Africa, and occur in Malolotja N. R. and Mlilwane Wildlife Sanctuary in Swaziland, and Sehlabathebe N. P. in Lesotho (East 1999). The proposed Maluti–Drakensberg Transfrontier Conservation and Development Project should further contribute to the protection of this species.

Measurements

Pelea capreolus

HB (♂♂): 1100 (1040–1150) mm, n = 5

HB (♀♀): 1190 (1150–1360) mm, n = 5

T (♂♂): 140 (100–170) mm, n = 5

T (♀♀): 130 (120–160) mm, n = 5

HF c.u. (♂♂): 350 (340–360) mm, n = 5

HF c.u. (♀♀): 340 (330–350) mm, n = 5

E (♂♂): 171 (147–200) mm, n = 5

E (♀♀): 164 (152–184) mm, n = 5

Sh. ht (♂♂): 720 (690–740) mm, n = 5

Sh. ht (♀♀): 710 (690–730) mm, n = 5

WT (♂♂): 20.0 (16.0–24.0) kg, n = 5

WT (♀♀): 21.0 (20.0–23.0) kg, n = 3

Free State (adults >1 year old) (Ferreira 1983)

Maximum recorded horn length is 30.2 cm for a pair of horns from South Africa (Rowland Ward)

GENUS *Redunca*

Reedbucks

Redunca C. H. Smith, 1827. In: Griffith et al., Anim. Kingd. 5: 337.

The three reedbucks species of the genus *Redunca* represent the least derived members of the Reduncini (excepting *Pelea*) and the size gradient within this genus, as within the Reduncini as a whole, supports the hypothesis that the reduncines have descended from smaller ancestors (Kingdon 1982). The Oribi *Ourebia* may represent a highly specialized offshoot from the same ancestral stock and the two antelope groups share similarities in behaviour and ecology (Kingdon 1982), as well as having a uniquely structured ear-gland, or 'ohrenplaketten', in common (Hofmann 1972, Claasen & Jungius 1973). Vrba *et al.* (1994) even went so far as to include *Ourebia* in Reduncini. That *Redunca* represents the most conservative genus within the true reduncines was confirmed by the molecular study of Birungi & Arctander (2001), with the Mountain Reedbuck *R. fulvorufula* shown to make the earliest divergence.

There are three species of reedbucks, the smallest being the Mountain Reedbuck *Redunca fulvorufula*, with a widely disparate distribution in three mountainous regions of southern, East and West Africa. The other two, the Bohor Reedbuck *R. redunca*, and the Southern Reedbuck *R. arundinum*, are ecologically equivalent species, the first in savannas north of the equatorial forests, while the latter inhabits the south, with a region of overlap between the two species in Tanzania.

The Mountain Reedbuck is the closest in size and overall morphology to a generalized pecoran herbivore. Its restriction to cool uplands was probably the outcome of its immediate ancestor, an early reedbucks stock, having extended its range across a broad spectrum of grasslands. This pioneering reedbucks type then had to relinquish the lowlands to larger-bodied, more advanced populations of *Redunca* and, perhaps, *Kobus*. Today, the Mountain Reedbuck is physiologically distinct in being able to tolerate drier and colder regions and in being able to digest very much drier, coarser material (Hofmann 1973). This development in a single member of the Reduncini implies an ancient restriction to habitats with coarse grass resources and, by implication, a long history for all members of this genus. In fact, the currently earliest fossil of a reduncine similar to *Redunca* is from Lukeino, Kenya, dated to 6 mya (Gentry 1970).

Given their phylogenetic relationship with basal antelopes, the loss of functional pre-orbital and pedal glands in *Redunca* is significant and must have some relation to enlarged body-size. There are no implications here of a decline in sensitivity to scent signals; on the contrary, all reedbucks have, in addition to the ear glands, highly structured inguinal pockets that enclose scent-secreting inguinal glands. Loss of facial, pedal and other glands is consistent with the abandonment of territory-labelling systems because both scenting and physically demarcating a wet and highly obstructed substrate are impractical activities. Furthermore, home-ranges in sumplands that are generally rather homogeneous and prone to annual floods and fires, demand relatively short range, but decidedly seasonal, movements by reedbucks. In compensation, these habitats have exceptionally rich resources, with fast regrowth of palatable grasses

Seasonal distribution of Bohor Reedbuck *Redunca redunca* in an area east of the Nile, South Sudan. The dotted line separates *Hyparrhenia* to the east and *Oryza* communities to the west. Capital letters = 2–100/sq km. Lower case letters = 1/sq km. M = late Dry. D = very early Dry.

after fires, especially where the water table is close to the surface, as is often the case. As smaller, more cryptic and less social animals, *Redunca* species are better able to weather burn-offs without moving very far. Under these circumstances *Redunca* species seldom need to make any more than localized movements between wet-season (or flood-season) and dry-season pastures. This is well illustrated by records of Bohor Reedbuck concentrations on 'Duk Ridge', a levee on the eastern bank of the Nile in S Sudan. This is a locality where the local reedbucks populations have probably been following similar patterns of movements over very great periods of time. If so, proximity to water and their seasonal preferences for levee or flood-plain are likely to represent an enduring pattern of movements among valley-dwelling reedbucks.

Jonathan Kingdon

***Redunca fulvorufula* MOUNTAIN REEDBUCK**

Fr. Redunca de montagne; Ger. Bergriedbock

Redunca fulvorufula (Afzelius, 1815). Nova Acta Reg. Soc. Sci. Upsala 7: 250. No type locality originally identified; restricted to eastern Cape Colony (Lydekker 1914: 221) (South Africa, Eastern Cape).

Mountain Reedbuck *Redunca fulvorufula*.Lateral view of skull of Mountain Reedbuck *Redunca fulvorufula*.**Geographic Variation**

- R. f. fulvorufula* (Southern Mountain Reedbuck): South Africa, Lesotho, Swaziland, Botswana, S Mozambique. Larger, and more intensely rufous; also has larger horns.
- R. f. chanleri* (Chanler's Mountain Reedbuck): SE Sudan, Ethiopia, Uganda, Kenya, N Tanzania. Smaller and greyer, with less rufous tinge; horns shorter than the southern race.
- R. f. adamauae* (Western Mountain Reedbuck): isolated subspecies in Nigeria and Cameroon.

Taxonomy Polytypic species with three recognized subspecies (Ansell 1972). Synonyms: *adamauae*, *chanleri*, *eleotragus*, *lalandia*, *landiana*, *schoana*, *subalbina*. Chromosome number: $2n = 56$; the karyotype comprises 26 acrocentric and two bi-armed chromosome pairs. In some animals, 57 chromosomes have been detected. Both X and Y chromosomes are large and acrocentric (Rubes *et al.* 2007).

Description Mountain Reedbuck are the smallest of the reedbucks, but can be categorized as a medium-sized antelope. Ears are long, narrow and the tips rounded. Snout has distinctively raised, swollen-looking nostrils. Eyes are prominent. Black subauricular patches serve as scent dispensers (Hofmann 1972). Upperparts are predominantly grey, but the head and shoulders are a reddish-brown. Underparts are pure white and sharply demarcated from the rest of the body. Head and neck are reddish-yellow. Pelage soft and woolly. Fluffy tail greyish on top and pure white underneath. A description of guard hair characteristics, such as length, scale pattern and colour, is given by Keogh (1983). Inguinal glands in the groin are well developed. Sebaceous glands film the entire body, resulting in a pungent overall odour. Functional pedal and preorbital glands are absent. Males are slightly larger and heavier than ♀♀ (see Measurements).

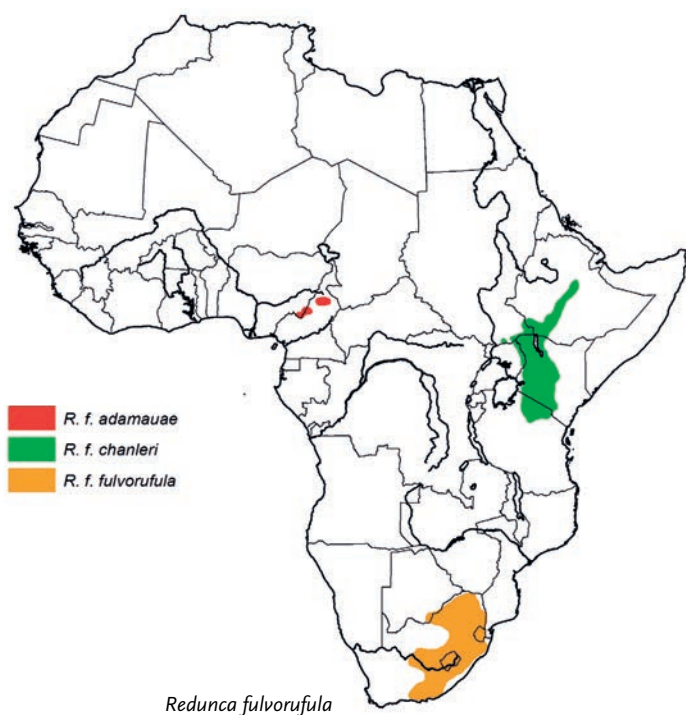

Only ♂♂ have horns; these are short, black, heavily ridged, curve forward and end in smooth, blunt points. They reach full length at around five years (Norton & Fairall 1991).

Similar Species

Redunca arundinum. Some marginal overlap in range in E South Africa. Larger in size, standing higher at the shoulder; typically has a black stripe on foreleg; one pair inguinal pouches.

Pelea capreolus. In southern Africa, both species occur at higher altitudes in the Free State, Mpumalanga, KwaZulu–Natal, Eastern Cape, Western Cape and Northern Cape Provinces in South Africa, and also in Swaziland and Lesotho. The ♀♀ of the two species are difficult to distinguish at a distance, as ♀♀ of both species lack horns. Characteristics of Grey Rhebok include: (1) they always lift their tail the moment they start running, showing the white underparts; (2) they generally avoid areas with tall grass; (3) the horns of ♂♂ are straight; (4) they usually take flight up the slope, but will sometimes run downhill when disturbed from above; (5) they have no subauricular patches; (6) their ears are pointed; (7) their neck is greyish-brown.

Distribution Endemic to Africa, occurring in three widely separated populations (represented by the respective subspecies) in southern Africa, East Africa and West Africa; these three populations are probably vestiges from a glacial period thousands of years ago when climate was different and caused the vegetation to be more suitable for Mountain Reedbucks all the way up the escarpments of the eastern side of Africa (Newmark 1996). Although there are

extensive areas of highland with apparently suitable habitat between Mt Hanang (the southern limit in East Africa) and the southern African population, these areas are occupied by the Common Reedbuck *Redunca arundinum*, which suggests that this species may be a direct competitor while the Bohor Reedbuck *R. redunca* is not (Kingdon 1982).

The Southern Mountain Reedbuck occurs in Mozambique, where it is restricted to the Lubombo Mts on the south-western border with South Africa, while in Botswana these reedbucks are present in the Mannyelanong Hill G. R., but are otherwise confined to other small, rocky hillsides in the south-east (East 1999). In South Africa they are widely distributed in the eastern mountainous areas above ca. 1200 m, ranging southwards into the Eastern Cape up to the Baviaanskloof and Kouga Mts (H. Gerber & H. Niewoudt pers. comm.). In Swaziland, they are present in the highveld and Lubombo regions (Monadjem 1998), and in Lesotho in the high mountains (Lynch 1994).

Chanler's Mountain Reedbuck is known from hilly areas in SE Sudan, and in Ethiopia is confined to broken country and rocky hillsides in scattered localities within the Rift Valley and southern lowlands. In Uganda, these reedbucks occur on rocky hillsides in eastern Karamoja, and in similar habitat in C and S Kenya where the species is protected in areas such as Aberdare, Nairobi and Lake Nakuru National Parks. In N Tanzania, they are present in localized areas of high-altitude grassland and rocky hillsides including protected areas such as Arusha and Tarangire National Parks and the Ngorongoro Conservation Area, but unprotected populations in areas such as the Hanang, Mbulu, Lolkisale and Loliondo Mts are threatened or extinct (East 1999).

The Western Mountain Reedbuck occurs only in Nigeria in Gashaka-Gumti N. P. and the Gotel Mts adjoining the park's southern boundary (East 1999, Nicholas 2004a, b), and in Cameroon in the Adamaoua Mts and the hunting zones below, as well as in the hunting zones between Bénoué and Bouba Ndjida N. P. (Pfeffer 1962, East 1999, T. Breuer pers. comm.).

Habitat Mountain Reedbucks live in cool, mountainous regions mostly above 1500 m and up to 5000 m (Stewart & Stewart 1963, Kingdon 1982, Lynch 1983, 1989, 1994, Rowe-Rowe 1983, Lynch & Watson 1990, Newmark 1996, Nicholas 2004b). They prefer grassy ridges and steep (20–40-degree) mountain slopes in broken rocky country, small outcrops and volcanic lava flows and cinder cones. Mountain Reedbucks favour areas with large bushes or scattered trees (for shade and predator evasion), but will move onto adjacent flats to feed or drink (Mentis 1974, Mason 1977, Irby 1979, Rowe-Rowe 1983, Dunbar & Roberts 1992). In southern Africa, they make use of all mountain slopes, including the moister, 'sour' southern and south-eastern slopes (Rowe-Rowe 1983). In Kenya, Mountain Reedbucks prefer the scrub-grass ecotone between slopes covered in camphor (*Tarchonanthus*) and open grassy valleys (Kingdon 1982). The availability of water is an essential habitat requirement.

Abundance A density of 5–7 individuals per km² is typical of most study populations (Irby 1977a). Estimated densities in protected areas in South Africa vary from 0.1/km² or less in areas such as Karoo, Addo-Zuurberg and Marakele National Parks to 3.0/km² in Golden Gate N. P. and 7.5/km² in Mountain Zebra N. P. (Anderson *et al.* 1996). In the Drakensberg, ecological densities range from 3.1–9.1/km² (Oliver *et al.* 1978, Rowe-Rowe & Scotcher 1986); at Sterkfontein Dam N. R. in the Free State, on the western boundary of the Drakensberg, densities were 11.5/km² (Taylor *et al.* 2007). In East Africa, Blankenship & Qvortrup (1974) estimated an average of 11/km² (Kekopey Ranch, Kenya).

The largest population of Southern Mountain Reedbucks can be found in Ukhahlamba Drakensberg Park with 1700–2000 individuals (Rowe-Rowe 1994); numbers in South Africa total nearly 32,000 (East 1999). In Swaziland, there are less than 200 individuals (Monadjem *et al.* 2003). Numbers of Southern Mountain Reedbucks are unknown for Botswana and Lesotho (East 1999). Both Chanler's and Western Mountain Reedbucks are uncommon to rare in their distribution areas (East 1999). Overall population estimates have been estimated as 33,000 for Southern, 2900 for Chanler's and 450 for Western Mountain Reedbucks (East 1999).

Adaptations Mountain Reedbucks have a specially adapted stomach (large subdivided rumen with keratinized mucosa that permits the maximum delay of coarse, fibrous food, a small reticulum with deep cellulase, and a large omasum with pronounced mucosal surface enlargement) that allows it to feed almost entirely on grass (Hofmann & Stewart 1972), which is particularly coarse and of low quality in the dry season. The smaller body size and aggregations (the smallest of the reduncines) are also adaptations to survive on this lower quality food in the drier uplands; their larger relatives keep in larger groups to valley habitat with its good quality grass.

Mountain Reedbucks are most active during the early mornings, late afternoons and at night. During the middle of the day they lie in the shade, often tightly together and right inside bushes (Irby 1981, 1982, Roberts & Dunbar 1991). Temperature is the most likely proximate factor regulating diurnal activity, movement and rumination patterns (Irby 1982, Roberts & Dunbar 1991). They tolerate a wide range of climatic conditions and ignore light rain. In heavy rainstorms or high wind they will orientate themselves with their hindquarters in its direction or seek sheltered slopes, standing or lying down until

the weather conditions improve. Seasonal activity variations in Chanler's Mountain Reedbucks are strongly related to rainfall, with levels of activity and feeding lower in the wet season when forage quality and availability increase (Roberts & Dunbar 1991).

Foraging and Food Mountain Reedbuck are predominantly grazers (for example, monocotyledonous plants constitute ca. 99.5% of the rumen contents of Chanler's Mountain Reedbuck; Irby 1977b, Mason 1977), and were classified as obligate grazers by Gagnon & Chew (2000). This is also borne out by studies involving stable carbon isotope analyses of animals in both southern and East Africa (Cerling *et al.* 2003, Sponheimer *et al.* 2003b). Mountain Reedbucks are selective feeders (Taylor & Skinner 2006a) and their preference for different grass species varies seasonally (Irby 1984a, Dunbar & Roberts 1992). On Loskop Dam N. R. in Mpumalanga, favourite grass species included *Themeda triandra*, *Hyparrhenia* spp. and *Cymbopogon* spp. (Irby 1977b), and in the Drakensberg of KwaZulu-Natal the distribution of Southern Mountain Reedbucks corresponds closely with the distribution of *Themeda triandra* and *Hyparrhenia* spp. (Rowe-Rowe 1983). Mountain Reedbucks also select for plant parts, preferring young green shoots when these are available. They may therefore benefit from the farming practice of frequent burning to stimulate new growth (Rowe-Rowe 1982a).

Roberts & Dunbar (1991) found unexpectedly high levels (up to 20.6%) of browse in Chanler's Mountain Reedbuck diet at the end of the long, dry period and for the first two months after the first rains. They suggested this to be an adaptive response to low forage quality and availability (although high-quality grass is available from one month after the first rains, gut-fill or induced imbalances in rumen pH may be the reason why Mountain Reedbucks only utilize a limited amount of this food item during this period). The two holotrichs found among 22 protozoan rumen ciliates in Southern Mountain Reedbucks also suggest that this species can digest some browse (Van Hoven 1983). Irby (1976) has shown that Southern Mountain Reedbucks have to eat more during the dry season to compensate for the low food value of the grasses during this period, but did not find any switching from monocotyledons to dicotyledons (Irby 1984a).

Feeding trials have shown Mountain Reedbucks to take ca. 584 g dry matter per animal per day, consisting of 13% crude protein, 54% nitrogen-free extract, 21% fibre, 3% fat and 8% minerals (Špála *et al.* 1987). Of the nutrients, 73% dry matter was consumed, 39% minerals, 76% organic matter, 73% crude protein, 76% nitrogen-free extract, 79% fibre, 66% fat and 75% energy. At the average body weight of 27.4 kg, the daily intake of metabolizable energy, 5947 kJ, exceeded the daily basal energy requirement by a factor of 1.695, which was higher than in domestic ruminants.

The first dry season following birth is a critical time for the young, as they have not accumulated the fat reserves of adults during the preceding wet season (Norton 1989). In the sourveld of the KwaZulu-Natal Drakensberg, food (and in particular food quality) is a major factor limiting numbers. Nutrients, especially crude protein, drop to critical nutritional levels during the coldest, driest time of the year (Aug–Oct), when a peak in deaths occurs (Mentis 1978, Oliver *et al.* 1978, Rowe-Rowe 1983, Rowe-Rowe & Scotcher 1986, Taylor *et al.* 2006b).

Mountain Reedbucks are dependent on drinking water (Norton 1989), but drink more often during dry weather than during cold, cloudy weather. They feed mostly in the early morning, late

afternoon and at night when they may move from the hillsides to feed on adjacent flat ground (Smithers 1971, Irby 1981, 1982, Roberts & Dunbar 1991, Taylor *et al.* 2006a).

Social and Reproductive Behaviour The social organization consists of territorial ♂♂, non-territorial ♂♂, bachelor groups and herds of ♀♀ with young. Non-territorial ♂♂ generally occupy the periphery of male territories or may temporarily form bachelor groups. Female herds typically consist of 1–8 individuals, with group sizes of 1–4 being most common (e.g. Dunbar & Roberts 1992, Taylor 2004). Larger groups (up to 40 individuals) may form temporarily (Irby 1977a). These larger herds are unstable as ♀♀, or ♀♀ with young, move from herd to herd. Seasons have some influence on group sizes in southern Africa with somewhat smaller groups forming in the late dry season and the largest average sizes occurring in the early dry season.

The social structure of territorial male Mountain Reedbucks can be described as a system of resource-defence polygyny (Irby 1979, Taylor & Skinner 2006a). Territorial ♂♂ guard, and sometimes actively defend, their territories throughout the year and only move from them to feed in adjacent areas when their territories are burned or to establish temporary contact with other ♂♂ (Mason 1977, Dunbar & Roberts 1992). They are clearly nervous and alert when outside their territories (Irby 1979). Female herds move from one male territory to another, and territorial ♂♂ have been seen herding ♀♀. In Kenya and in South Africa, ♀♀ preferred territories that contained the highest available slopes, which would provide security from predators (Dunbar & Roberts 1992, Taylor *et al.* 2007). Territorial ♂♂ at Sterkfontein Dam N. R. used smaller areas (8–21 ha; Taylor *et al.* 2007) than ♂♂ at Loskop Dam N. R. in Mpumalanga (28 ha; Irby 1977a, 1979), but used larger areas than ♂♂ in Kenya (3.1–5.5 ha; Dunbar & Roberts 1992). Female home-ranges overlap those of several ♂♂; female territories in South Africa range between 36 and 76 ha (mean = 57 ha) (Irby 1976). These female territories cover a sample of the available habitats, running from hilltop to valley.

A courting ♂ will approach a ♀ with outstretched head and neck. Foreleg striking, or laufsclag, has also been observed. If the ♀ is prepared to accept him, she adopts a submissive posture by lowering her head. Females leave their group to give birth in isolation. Young remain hidden for up to three months before joining the mother's group. This has been identified as a time of high mortality (Irby 1976). A mother will visit her young cautiously once or twice a day to suckle and clean it. The constant changing of hiding places (after every visit by the mother) and the ingestion of the young's faeces and urine reduces the likelihood of the young's detection by predators. When the young is in danger or is attacked it may utter an alarm call that will bring the mother to its aid. Lactation does not appear to inhibit fertilization since Els (1991) found 11% of reproductively active ♀♀ to be both pregnant and lactating. The bond between mother and young is broken when she is about to give birth to her new offspring; should she lose it, the bond may continue.

Territorial ♂♂ tolerate juvenile ♂♂ up to the age of ca. six months, but will drive them from the female herd when they reach the age of ca. 9–15 months (Kingdon 1982, Skinner & Chimimba 2005). It is during this time that juvenile ♂♂ are most exposed to stress, malnutrition, disease and predators, and an even juvenile sex ratio becomes altered to two or even three ♀♀ for every ♂ (Kingdon 1982; and see later).

Stotting or stiff-legged jumping has been observed to be combined with short whistles. Longer whistles are used as an advertisement of territory. The shrill alarm call is given by the herd ♂ when an intruder is seen. The latter sends the herd, now led by an adult ♀, running along the side of the hill or indirectly downhill. After fleeing some 300–400 m they pause and look for the source of disturbance. While it has been suggested that the flashing of the white underside of the tail is a warning mechanism for conspecifics, it may also be possible that it is a 'pursuit deterrent signal' to the predator.

Reproduction and Population Structure Mountain Reedbucks are capable of breeding throughout the year, although, in southern Africa, a peak in breeding activity is reported around Apr and May, and a peak in births in early and mid-summer (Oct–Jan) (Oliver *et al.* 1978, Irby 1979, Skinner 1980, Norton 1989, Els 1991, Rowe-Rowe 1994, Taylor *et al.* 2006b).

Mountain Reedbucks reach adult body weight at two years. Males produce spermatozoa (a description of the spermatozoa is given by Dott & Skinner [1989]) before the age of 12 months, but mate only after they have established their own territory. Els (1991) reported ♂♂ reaching sexual maturity at about 27 months. First oestrus in ♀♀ can be as early as nine months (when nutritional conditions are ideal), but normally they do not become reproductively mature until 12–14 months old (Irby 1979) and most ♀♀ conceive for the first time when 12–16 months of age (Els 1991). Thereafter, they may produce one young every 12–14 months for the rest of their lives. The average gestation period is 34.3 weeks (range 33.7–35.9 weeks; Irby 1979). Neonates weigh about 3 kg at birth (Kingdon 1982).

In the Drakensberg, ♂ : ♀ adult sex ratios ranged from 1 : 1.9 to 1 : 2.6 at three different study areas (Oliver *et al.* 1978, Southgate 1979, Rowe-Rowe 1982b); juveniles comprised 10–16% of the population, with the young to adult ♀ ratio 1 : 3.4. At Loskop Dam ♂ : ♀ ratio was 1 : 2 and young to adult ♀ ratio 1 : 3.3 (Irby 1977a). At Sterkfontein Dam N. R., average fecundity rate was 92% and

young ♂ : ♀ sex ratios were 12 : 8 (Taylor *et al.* 2006b). Potential life-span is 12 years and four months (see Mentis 1972); longevity in captivity has been given as 15 years (Weigl 2005).

Predators, Parasites and Diseases In both South Africa and Kenya, baboons *Papio* spp. are considered as a threat to infants only (Irby 1984b). Both Martial Eagles *Polemaetus bellicosus* and Verreaux's Eagles *Aquila verreauxii* were observed harassing adult ♀♀ on cliff faces in Kenya, apparently with the intention of causing them to fall (Roberts & Dunbar 1991). Other predators include jackals *Canis* spp., Cheetahs *Acinonyx jubatus*, Leopards *Panthera pardus*, Lions *Panthera leo*, Caracals *Caracal caracal*, Servals *Leptailurus serval*, Striped Hyenas *Hyaena hyaena*, African Wild Dogs *Lycaon pictus* and African Rock Pythons *Python sebae*.

Irby (1976) identified 17 helminth parasites, at least four ticks, lice and the parasitic fly *Strobiloestrus*, the larvae of which develop under the skin and are most frequent in immature animals during the wet season (see Kingdon 1982). Boomker *et al.* (2000) discussed what was known about the helminths of Mountain Reedbucks, including adding two new parasite records, *Moniezia benedeni* and *Trichostrongylus falcatus*, for the species. Seventeen species of helminths, including 15 nematodes, one trematode and one cestode were recovered from Southern Mountain Reedbucks at Sterkfontein Dam N. R. and Tussen die Riviere N. R. in the Free State (Taylor *et al.* 2005), one of them the newly described *Cooperia pigachei* (Boomker & Taylor 2004). At Sterkfontein Dam N. R. the most prevalent and abundant species were *Cooperia yoshidai*, *Longistrongylus schrenki* and *Haemonchus contortus*, with the latter two being more abundant during Nov and Dec than at other times of the year; at Tussen die Riviere N. R., helminths were less prevalent and abundant than at Sterkfontein Dam N. R., with the most important species *Nematodirus spathiger*, *Trichostrongylus falcatus* and *Cooperia rotundispiculum*. In Mountain Zebra N. P., Horak *et al.* (1991b) recorded eight species of ixodid ticks, including the Karoo paralysis tick *Ixodes rubicundus*, and Mountain Reedbucks were preferred hosts for *Rhipicephalus glabroscutatum* and *R. lounsburyi*.

In a study of Mountain Reedbucks in the Free State, 43 deaths were recorded over the course of two years, of which 32 resulted from hypothermia following a single snowfall event; this represented 51% of the population at the time. Females were affected by hypothermia more than ♂♂. There was no evidence of disease in the population from the examination of culled animals, and no evidence of predation (Taylor *et al.* 2006b).

Conservation IUCN Category: Least Concern (*R. f. adamaue* – Endangered C2a(i); *R. f. chanleri* – Vulnerable C1; *R. f. fulvorufula* – Least Concern). CITES: Not listed.

The main threats to Mountain Reedbuck include the expansion of human settlement, poaching, widespread disturbance by cattle herders and their livestock, and hunting by dogs (see Rowe-Rowe 1994, East 1999). Range expansion is limited by the specialized habitat requirements of Mountain Reedbucks; their strictly sedentary habits inhibit dispersal, rendering isolated populations vulnerable to extermination during prolonged periods of drought (Kingdon 1982).

Numbers of Southern Mountain Reedbucks appear to be stable, and they occur in sizeable numbers in both protected areas and on

Mountain Reedbuck *Redunca fulvorufula* head (young male).

private land. For example, in South Africa, East (1999) estimated that around 6880 individuals are protected in conservation areas, while the rest of the population resides on private land. Indeed, Mountain Reedbucks recommend themselves in several ways for improving productivity from farmland: their meat is palatable and usually free of parasites; they graze rough terrain frequently marginal for domestic stock; their social structure ensures an even distribution of the population over available habitat; and they have a high reproductive potential (Irby 1975, Skinner 1980). In South Africa, Mountain Reedbucks are protected in at least nine National Parks, and in numerous provincial reserves and conservancies. In Swaziland they are protected in Malolotja and Mlawula Nature Reserves and in Mlilwane Wildlife Sanctuary (Monadjem *et al.* 2003), while in Lesotho, where Lynch (1994) recorded single animals or pairs at a few localities in the central, northern and eastern parts of the country, they are known to occur in Sehlabathebe N. P. In Mozambique, their range will include Limpopo N. P., the latter part of a greater transfrontier park with South Africa. In Botswana, they are protected in the small (1.5 km²) Mannyanong Hill G. R., but there is no recent information on the species' status.

Chanler's Mountain Reedbucks occur in viable populations in Awash, Nechisar, Omo and Mago National Parks (Ethiopia), the Aberdares, Nairobi and Lake Nakuru National Parks (Kenya) and Arusha and Tarangire National Parks and the Ngorongoro Conservation Area (Tanzania) (East 1999). A healthy population of Western Mountain Reedbucks occurs in Gashaka-Gumti N. P. in Nigeria (Nicholas 2004b), and they are present in the Gotel and Hamman Kankadu Mts, adjoining the park's southern and eastern boundaries, while in Cameroon there is some protection from poachers in the hunting zones below the Adamaoua Mts, as well as in the hunting zones between Bénoué and Bouba Ndjida National Parks (T. Breuer pers. comm.). The continued persistence of both the Chanler's and Western subspecies depends

greatly on the protection and management of these populations.

Measurements

Redunca fulvorufula

HB (♂ ♂): 1340 (1190–1450) mm, n = 57

HB (♀ ♀): 1330 (1210–1460) mm, n = 67

T (♂ ♂): 187 (140–250) mm, n = 58

T (♀ ♀): 169 (130–260) mm, n = 8

HF c.u. (♂ ♂): 360 (330–380) mm, n = 58

HF c.u. (♀ ♀): 350 (310–370) mm, n = 67

E (♂ ♂): 144 (120–160) mm, n = 58

E (♀ ♀): 142 (120–170) mm, n = 68

Sh. ht (♂ ♂): 780 (720–840) mm, n = 22

Sh. ht (♀ ♀): 770 (730–820) mm, n = 12

WT (♂ ♂): 30.0 (22.0–37.0) kg, n = 108

WT (♀ ♀): 28.0 (22.0–36.0) kg, n = 129

South Africa (combined measurements from Anderson & Koen 1993, Taylor 2004 and S. Vrahimis pers. comm. data collected at Tussen die Riviere N. R., Free State, South Africa)

Norton & Fairall (1991) report a mean asymptotic adult mass of 31.4 kg for ♂ ♂ (n = 93) and 29.5 kg for ♀ ♀ (n = 229), with a maximum recorded mass of over 38 kg for both sexes.

Maximum recorded horn length for *R. f. fulvorufula* is 25.4 cm for a pair of horns from the former Cape Province, South Africa, and for *R. f. chanleri* 24.5 cm for a pair from Mt Kaka, Ethiopia (Rowland Ward)

Nico L. Avenant

Redunca arundinum SOUTHERN REEDBUCK

Fr. *Redunca grande*; Ger. Grossriedbock

Redunca arundinum (Boddaert, 1785). Elench. Anim. 1: 141. 'Habitat ad Cap. Bn. Sp.' (Cape of Good Hope); since selected as South Africa, Free State, Bethulie, based on known collecting localities of syntypes (Grubb 1999: 25).

Taxonomy Polytypic species. Numerous subspecies have been named, but only two are usually recognized (Ansell 1972, Meester *et al.* 1986). The status of the form *thomasinae* (from Malawi), which includes *penricei* as a synonym, is unclear. Ellerman *et al.* (1953) included this as a synonym of *arundinum*, but Ansell (1972) noted that it may instead be the prior name for *occidentalis*. Synonyms: *algoensis*, *arundinacea*, *caffra*, *cinerea*, *coerulescens*, *eleotragus*, *isabellina*, *multiannulata*, *occidentalis*, *oleotragus*, *oreotragus*, *penricei*, *thomasinae*. Chromosome number: not known.

Description The largest reed buck, with a fine, almost woolly coat. Head and body very variable in colour, ranging from yellowish-buff to greyish-brown. Back usually darker in colour than neck and head, and dorsal part of tail. Ears nearly naked on the backs (dark grey skin). White hair on insides of ears grows outwards in three longitudinal strips and the orifice is also ringed with white hair. Anterior surfaces of front legs have conspicuous dark brown vertical lines down the

front. Body colour continues onto upper surface of tail. Underside of body paler, nearly white, as are chin and throat. Long-haired underside of tail pure white, making a prominent visual signal when raised or flashed. Young lighter coloured than adults, appearing more yellowish. Melanistic individuals and albinos have been reported (Skinner & Chimimba 2005). There are also inguinal gland pockets in the groin; ♂ ♂ have one pair, but ♀ ♀ sometimes have two. The glandular pouches have a funnel-shaped opening and secrete a yellow waxy substance. Functional pedal and preorbital glands are absent. Some individuals possess a glandular, black, hairless patch situated near the base of the ear (conspicuous in some populations), but this is absent in other individuals (see Claassen & Jungius [1973] for further discussion of this gland). Males average 30% larger in body mass.

Only ♂ ♂ have horns, which grow up to 45 cm long and are black, annulated for two-thirds of their length, and resemble a diminished version of the horns of the Waterbuck *Kobus ellipsiprymnus*, curving evenly forward; the remaining third of the horns is smooth and tends

Southern Reedbuck *Redunca arundinum*.

to be hooked forward towards the tip. There is a soft bulbous swelling at the base of each horn, which has a conspicuous whitish colour and is most developed in old adults (Skinner & Chimimba 2005). They were long thought to be glandular, but Jungius & Claussen (1975) showed that they are composed of tissue from which the horns grow. The whitish colour is caused by small horn particles that flake off continually. Horns have been recorded in ♀♀, but they are typically abnormally shaped, curving downwards (Venter 1984).

Geographic Variation

R. a. arundinum: south of Zambezi R.

R. a. occidentalis: north of Zambezi R. to L. Victoria.

Similar Species

Redunca redunca. A species of the northern savannas with some overlap (of total range) in S Tanzania. Smaller, shorter-horned, with sandy colouration.

R. fulvorufula. A montane species with only overlap of range in extreme south-eastern Africa. Smaller, greyer reedbuck, with relatively smaller muzzle and swollen nose; horns curving forward level with tips of ears; two pairs of inguinal pouches.

Kobus vardonii. A social species restricted to flood-plains and open savannas around the headwaters of the Zambezi R. and southern tributaries of the Congo R. More robustly built, with lyrate horns on ♂♂; redder.

Distribution Endemic to Africa. A southern species originally ranging widely from the Cape Peninsula to L. Victoria in the east and extreme S Gabon in the west. In Tanzania, its range overlaps with that of the Bohor Reedbuck *Redunca redunca* (which is essentially an equatorial species). Examination of the two species' current and former

Lateral view of skull of Southern Reedbuck *Redunca arundinum* female.*Redunca arundinum*

distributions in Tanzania revealed that the Bohor Reedbuck dominated the lower reaches of major rivers and flood-plains while the Southern Reedbuck was commoner in the higher reaches of the same rivers but along their smaller tributaries and streams (Kingdon 1982).

Southern Reedbucks remain relatively widespread throughout their former range, with the exception of S Congo, where their presence was last confirmed in 1974 in Mount Fouari Faunal Reserve and they may now be extinct (East 1999). In Gabon, they survive in small numbers in the south-western and perhaps coastal savannas (though they seem to have disappeared from within the Gamba protected areas complex; P. Henschel pers. comm.), while in DR Congo they are presumably still locally common in the southern savannas, particularly on the high plateau grasslands of Upemba and Kundelungu National Parks (East 1999). In East Africa, they still range widely in S and W Tanzania, generally at low densities (Kingdon 1982, East 1999). Southwards, they occur widely in protected areas in Malawi and Zambia (East 1999), while in Angola (where they occurred throughout, except Cabinda and the more arid south-west) they survive locally within their former range (East 1999, Crawford-Cabral & Veríssimo 2005). In Mozambique, they survive in Gorongosa N. P. and in smaller numbers in areas such as Maputo Elephant Reserve, Banhine N. P., Zinhave N. P. and Marromeu G. R. (East 1999); they are also recorded from NE Mozambique right at the coast (Messalo R.; T. Wachter pers. comm.).

South of the Cunene and Zambezi Rivers, Southern Reedbucks still occur in their natural range in NE Namibia, but they have been introduced to private land outside of their former range in the northern parts of the country (East 1999). In Botswana, they still survive throughout the Okavango Delta, in Moremi G. R. and in the Linyanti area further north (East 1999). In Zimbabwe, they are reported (East 1999) to occur throughout, except in the Zambezi and Limpopo valleys and the western parts (Smithers & Wilson 1979; East 1999). In South Africa, they occur in Limpopo, Mpumalanga and North West Provinces, widely in KwaZulu–Natal, where they occur in considerable numbers on the eastern and western shores of L. St Lucia and marginally in the Eastern Cape. Although largely eliminated from the Free State, they occur in scattered localities on private land and have been reintroduced to protected areas such as Willem Pretorius G. R. Southern Reedbucks have been reintroduced to several reserves in Swaziland, and are now flourishing in some areas (such as Malolotja N. R.) (Monadjem 1998). Lynch & Watson (1990) sighted one in Sehlabathebe N. P. in Lesotho, but this may have been a vagrant from KwaZulu–Natal.

Habitat The most significant habitats in South Africa are valleys in which the grass cover is tall (or there is suitable herbaceous cover) and permanent water is available (Jungius 1971a). Typically, this species lives on ‘islands’ of grass and they actively avoid the surrounding woody vegetation. Jungius (1971a) noted that when persistent firing and heavy grazing was abandoned in parts of Kruger N. P., South Africa, fire-climax grasses such as *Themeda triandra* were replaced by a tall grass veld made up of *Elyonurus argenteus*, *H. dissoluta*, *Heteropogon* spp. and *Andropogon* spp. This community change favoured the Southern Reedbuck, the key species being *Hyparrhenia dissoluta*, which grows culms of up to 2.5 m that remain upright for most of the year, thus providing essential cover (Jungius 1971a). The other key habitat was reed-beds on wet soils, depressions and river beds. Here reeds *Phragmites communis* dominate, growing up to 4 m high, providing both food and cover for the reedbuck. In the foothills of the Drakensberg in KwaZulu–Natal, Howard (1986a) found that they tended to inhabit vleis (wetlands) and hilly veld (natural grasslands) in summer (since these provided adequate cover by way of boulder outcrops, gullies and ledges), switching to agricultural land and adjacent cover in winter. Areas of flat open veld were avoided at all times. Southern Reedbuck range to 1800–2000 m in the Drakensberg mountains (Rowe-Rowe 1994).

Abundance A common and widespread species in South Africa, Rowe-Rowe (1994) highlighted just how abundant this species could become, under ideal (but essentially temporary) conditions, densities of 1 reedbuck per 3–4 ha having been recorded in Eastern Shores State Forest of KwaZulu–Natal (Venter 1979). On mixed farmland, Howard (1983) estimated 1/13 ha to 1/7 ha on a farm that had a high proportion of fire-resistant winter pastures and cover. Aerial surveys generally result in density estimates in the order of 0.1–0.2/km², or less (East 1999). Aerial surveys in Nyika N. P., Malawi, where Southern Reedbucks are common, produced a density estimate of 1.9/km² (Mkanda 1998), but this was almost certainly an underestimate, given the difficulty of detecting reedbucks from the air. The fact that this species occupies ‘islands’ of suitable habitat makes

generalized density figures very difficult to compute. Furthermore, its responses, both positive and negative, to protection and changes in fire regimes mean that very rapid build-ups or declines in numbers can take place. East (1999) used a contemporary average density of 0.3/km² for areas where it is still ‘common’, and 0.03 elsewhere, to arrive at a total population estimate of 73,000.

Adaptations Southern Reedbucks, like other reduncines, are adapted to a very abundant, but unstable, food supply. This predominantly temperate and sub-tropical species has a lower drought tolerance than the Bohor Reedbuck and is not able to last long without water. It probably has less resistance to solar radiation and desiccation than the Bohor Reedbuck, an important factor in the overlap zone between these species in Tanzania.

Jungius (1971a) identified the inguinal gland pockets as the source of popping sounds that are released by a sudden backwards and sideways jerk at the peak of ritualized high jumps. He only recorded popping during flight behaviour, but cited a game scout’s observation that it was emitted during courtship behaviour. Jungius (1971a) recorded popping being followed by whistling and pronking, both behaviours common to the Bohor Reedbuck.

Nasal whistling is produced by suddenly forcing air through the nasal passages and nostrils and Eibl-Eibesfeldt (1957) proposed that the evolutionary derivation and ‘primary’ function of this signal was an expression of fright or alarm. Jungius (1971a) considered the ‘secondary meanings’ for whistling in the Southern Reedbuck were acoustic advertising, displays between rival ♂♂, or a ♂ making contact with a ♀. Whistling can take place during flight, while jumping or from an alert, standing position, or the whistling may combine with pronking, notably when the animals are in long, thick grass. Jungius (1971a) explained static whistling in terms of the whistler’s great feeling of insecurity and uncertainty as to where to flee! He considered whistling a way of indicating presence to neighbours and, when culminating in a real chorus of whistles, the response-whistles also functioned as territorial advertising that indicated ‘territorial rights’. A common preliminary to whistling, but one that is restricted to ♀♀, consists of a low clicking sound, also nasal in origin.

Social grooming has not been recorded in Southern Reedbucks, but they rub their cheeks on their flanks, nibble and lick themselves and scratch neck and head with the hindfeet. Normally, they rest in the cover of tall grass or reed-beds, but occasionally will lie out in full sun. When resting together, individuals lie several metres apart, and never close together.

Foraging and Food Southern Reedbucks are predominantly fresh grass grazers, but will occasionally take small quantities of herbs, and in some areas may even browse extensively (Jungius 1971a, b). These dietary preferences are borne out by studies involving stable carbon isotope analysis (Sponheimer *et al.* 2003b). Jungius (1971b), working in Kruger N. P., noted that the most important grasses in the reedbucks’ year-round diet were *Hyparrhenia* spp., *Trachypogon* spp., *Panicum* spp., *Cenchrus ciliaris*, *Ischaemum brachytherum*, *Chloris guayana* and *Heteropogon contortus*. During winter, hygrophilous grasses were important, notably *Leersia hexandra*, *Imperata cylindrica*, *Cymbopogon validus*, *Hemarthria altissima*, *Phragmites communis* and *Eragrostis* spp. Herbs, notably *Commelina* spp., *Polygonum* spp. and

Cyperus spp. were also taken. Where there is extensive tree and bush cover, and a dearth of edible fresh grasses, the reedbuck may browse dwarf shrubs and *Acacia* and *Albizia* foliage (mostly during the winter). Seasonal movements are primarily determined by the need for cover, thus hillsides are avoided while the ground is bare, although these are preferred habitat once the grass is tall enough to conceal the reedbuck. With the onset of fires and heavy grazing of the slopes by other herbivores the reedbucks descend into the valley bottoms where they can find extensive brakes of *Phragmites* and green grasses growing in wet soils.

Southern Reedbuck *Redunca arundinum*.

Jungius (1971b) found that most feeding took place at night, but that animals extended their grazing and activity periods during the cooler dry season when bouts of feeding and ruminating took place over much of the day. In the rains, reedbucks only became active an hour or less before dark and for up to 2.5 h after dawn. During the day (the only period the animals could be monitored), grazing occupied about 3 h in 12, and a series of ruminating bouts made up a similar total. The rest of the day was spent resting (between 7 and 8 h in total). Extended grazing and frequent trips to water in the dry season presumably compensated for reduced quality forage and to meeting moisture requirements that were otherwise met from dew and succulent herbage in the wet season (Jungius 1971a, Estes 1991a).

Social and Reproductive Behaviour Southern Reedbucks live in male–female pairs, or mother–young pairs with or without an attendant ♂ and Jungius (1971a) never found Kruger N. P. reedbucks associating in herds. He never saw ♂♂ or ♀♀ associate in bachelor groups, but did occasionally observe temporary aggregations of up to 20 individuals, but only in the colder, winter months from about May to Aug. If aggregations were disturbed the individuals immediately dispersed. In the only other major study on the species to date, Howard (1986b), working in the highland region of KwaZulu–Natal, recorded that of more than 550 different sightings, the most usual were solitary adult ♂♂ or ♀♀ and subadults were also occasionally solitary. Of groups, Howard (1986b) found all-female groups made up about 14%, male bachelor groups 8% and family groups 14% of all sightings. Before, and during, the rut, the proportion of solitary adult ♂♂ was highest. During winter, adult ♀♀ tended to be either solitary, associated with adult ♂♂, or in family groups. Adult ♂♂ became solitary towards the summer when family groups broke down and ♀♀ tended to associate together with subadults in female groups (Howard 1986b).

A ♂ and ♀ occupy a territory or home-range that seems to lack clearly demarcated boundaries, but elicits distinctive behaviour in the holders. For example, ♂♂ commonly mount any small eminence such as a termite mound (uncharacteristically ostentatious behaviour in an otherwise cryptic animal), stand on watch and whistle in response to the sight of any other reedbuck. Whistling may or may not be accompanied by a short series of high bounds or almost static, ritualized bouncing jumps or ‘stots’. Within the area shared by male–female pairs, auditory, visual and, presumably, olfactory signals permit almost continuous indirect mutual awareness although physical contact may be irregular, particularly while the ♀ is nursing. Visits away from the territory, some quite distant, were observed by Jungius (1971a), but he was unable to determine how stable pairs were nor was he able to follow the movements of known individuals affected by drought or fire. He found that male home-ranges or territories fluctuated and differences were influenced by the condition of individual ♂♂, by external ecological cycles and by the relative density of conspecifics. Thus, two territories close to a permanent waterhole were only 35 ha in the dry winter, when there was a lot of reedbuck traffic, but expanded to 48–60 ha in the summer long-grass season.

Jungius (1971a) recorded various threat displays used by the territorial ♂, including defecation and urination in a ‘proud’ attitude in front of a contestant with legs held stiff and head erect. Jungius

(1971a) regarded this as an odd form of threat, resulting in either an immediate attack reaction or causing the contestant to move off. Other threat displays involve horn presentation, which may lead to opponents pushing each other with the horns locked and eventually to fighting when the opponents lunge forward and clash horns. Such displays may continue at intervals throughout the day, the contestants occasionally breaking off to graze or rest, but fighting seldom, if ever, leads to serious injury. At the conclusion of fighting, the victor sometimes adopts the 'proud' attitude and defecates, but seldom chases the defeated opponent. Young ♂♂ or ♀♀ may show submission to aggressive territorial ♂♂ by lowering their heads and holding their horns backwards.

In KwaZulu–Natal, Southern Reedbucks do not appear as strictly territorial as those in Kruger N. P.: at St Lucia a social hierarchy is evident by which dominant ♂♂ compete to serve ♀♀ in oestrus, while in the highland regions, ♂♂ display evidence of territoriality only during the rut with dominant ♂♂ occupying territories closest to the food source (Venter 1979, Howard 1983, 1986b; and see Rowe-Rowe 1994). Howard (1986b) hypothesized that this difference between populations could be explained in terms of environmental differences between the areas of study. In his study population in upland KwaZulu–Natal, there was a close correlation between the amount of cover and the number of reedbucks supported by any given area, and this might have been the result of only a finite number of individuals being able to establish territories in limited habitats where cover was abundant. Howard (1986c) recorded home-range sizes in these highlands as varying from 73 ha for adult ♂♂ (subadult ♂♂ had ranges of 210 ha) to 123 ha for adult ♀♀; on the shores of St Lucia, Venter (1979) found mean home-range sizes of 5 ha for ♂♂ and 6 ha for ♀♀. Both male and female individual ranges showed considerable overlap in Howard's study (1986c).

Females do not easily accept approaches from ♂♂ other than their apparent 'mate' and Jungius (1970) saw ♀♀ thwart strange ♂♂ by avoidance and even kicking. Mounting resembles other antelopes in being extremely rapid, and courtship (which involves a territorial ♂ approaching the ♀ with head laid back and nose forward) may be accompanied or followed by rare examples of physical contact as the ♂ licks or rubs his head on the ♀. Females seclude themselves for about a month before giving birth. The young are classic 'hiders' and mothers presumably have a very well developed spatial memory because they do not betray any perceptible signals when visiting their young. Suckling lasts up to 4 min but there may be up to half an hour of play and movement before the juvenile retreats into cover, changing its hideout with every nursing session. Juveniles only emerge and join their mothers at about three months. Female offspring mature and leave the maternal home-range within their second year, around the time that she is due to give birth again. Male offspring mature more slowly and are tolerated for longer, but make elaborately obsequious gestures to the resident adult ♂.

Reproduction and Population Structure Age at first parturition in ♀♀ has been given as between 20 and 24 months (Howard 1983) and 23 and 35 months (Venter 1979) in KwaZulu–Natal. Males reach puberty at nine months, but do not take part in the rut until they are older (Rowe-Rowe 1994). No strict breeding season has been observed, but there is a birth peak between Dec and May (Fairall 1968, Jungius 1970) in Kruger N. P. and from Dec

to Jan in the KwaZulu–Natal highlands (Howard 1983); no obvious peak has been observed at St Lucia (Venter 1979). In Kyle N. P., Zimbabwe, births run from Sep onwards (Ferrar & Kerr 1971).

Gestation period is about 7.5 months (Mentis 1972). Irregular oestrus, staggered maturation times in young ♀♀ and variation in the gestation period might all serve to temper any trend towards truly seasonal breeding (Jungius 1970, 1971a).

Sex ratio at birth is 1 : 1 (Venter 1979, Howard 1983), but among adults Venter (1979) recorded a sex ratio of 1 ♂ to 1.4 ♀♀, and Howard (1983) a ratio of 1 : 1.1. In KwaZulu–Natal, juveniles (less than one year) comprised 19% of the population. Howard (1983) gave the mean life-span of ♂♂ in the wild as four years and ♀♀ as five years, and very few reedbucks live beyond ten years (Venter 1979, Howard 1983). Jones (1993) gave a longevity record of 16 years and nine months in captivity.

Predators, Parasites and Diseases Records from Kruger N. P. between 1954 and 1966 (Pienaar 1969a) showed that Leopards *Panthera pardus* were by far the greatest threat to Southern Reedbucks, with 124 kills, which represented 78% of the Leopards' total recorded kills. Cheetahs *Acinonyx jubatus* followed with 60 (68% of recorded kills), then African Wild Dogs *Lycaon pictus* 36 (87%) and Lions *P. leo* 35 (20%). Less regular predators included crocodiles (3 observed kills), Spotted Hyenas *Crocuta crocuta* (2), a Chacma Baboon *Papio ursinus* (1) and an African Rock Python *Python sebae* (1). The main response to predators is to freeze, skulk into cover and lie down, pressed close to the ground. So-called 'alarm' whistles and jumping or stotting gaits are almost certainly directed at other reedbucks, not the predator (although the predator often appears to lose interest after such displays).

Southern Reedbucks suffer from a similar range of helminths and parasites as Bohor Reedbucks. In KwaZulu–Natal, animals recovered from Howard's (1983) study area were infested with four ixodid tick species (*Boophilus* sp., *Ixodes* sp., *Rhipicephalus evertsi* and another *Rhipicephalus* sp.), while animals taken from the Eastern Shores had seven species and several animals recovered from Charter's Creek and St Lucia had six species; *Rhipicephalus evertsi* was the only tick common to the four localities (Horak *et al.* 1988b). The lice *Damalinea reduncae* and *Linognathus fahrenheitsi* were present on the reed buck from each locality. A single reed buck examined in Zambia was host to three ixodid tick species, namely *Amblyomma variegatum*, *Rhipicephalus appendiculatus* and *R. evertsi* (Zieger *et al.* 1998a).

Helminth parasites have been investigated in detail by Boomker *et al.* (1989c). These authors recovered ten nematode species, two cestodes (*Moniezia benedeni* and *Taenia hydatigena*) and one trematode (*Paramphistomum* spp.) from 26 animals taken in Howard's (1983) study area. *Cooperia yoshidai* was the most numerous and most prevalent helminth with peak burdens occurring in summer. At St Lucia 31 Southern Reedbucks harboured between four and 11 nematode species, one cestode and one trematode. *Cooperia yoshidai* was again the most abundant and prevalent parasite, with peak burdens during autumn to spring. Boomker *et al.* (1989c) provided an amended list of helminth parasites of Southern Reedbucks in South Africa, including 21 nematode species, three cestodes and a trematode (*Paramphistomum* spp.). In Zambia, Zieger *et al.* (1998a) recovered the nematodes *Cooperia rotundispiculum* (a new record) and *Setaria bicoronata* from one individual.

Conservation IUCN Category: Least Concern. CITES: Not listed.

The Southern Reedbuck has been peculiarly vulnerable to all types of hunting and poaching because it is slow and easily brought to bay by dogs and is of a convenient size to be dismembered and carried off by a single or very few hunters (Jungius 1971a). Its early decline and local extirpation over much of southern Africa has been documented by several authors (Harris 1840, Kirby 1896, Sclater 1900). Like the Bohor Reedbuck, this species has a preference for well-watered habitats that attract agricultural and pastoral settlement. Consequently, over much of its original range the Southern Reedbuck has been extirpated or confined to protected enclaves. Protected areas known to represent strongholds for the species include Selous G. R. (Tanzania), Kafue N. P. (Zambia), Nyika N. P. (Malawi), Gorongosa N. P. (Mozambique), the Okavango Delta region (Botswana), and Kruger N. P. and Greater St Lucia Wetland Park (South Africa) (East 1999). East (1999) warned that some peripheral populations, such as those in S Gabon, faced an uncertain future, but that they should survive so long as protected areas and conservancies remained viable.

Measurements

Redunca arundinum

TL (♂ ♂): 1600 (1560–1790) mm, n = 16

TL (♀ ♀): 1580 (1380–1690) mm, n = 20

T (♂ ♂): 250 (220–300) mm, n = 16

T (♀ ♀): 250 (200–300) mm, n = 20

E (♂ ♂): 160 (150–180) mm, n = 16

E (♀ ♀): 160 (140–170) mm, n = 16

WT (♂ ♂): 51.8 (42.7–68.2) kg, n = 16

WT (♀ ♀): 38.2 (31.8–50.9) kg, n = 20

Zimbabwe (Smithers & Wilson 1979)

In the highlands of KwaZulu–Natal, Howard (1983) recorded the average mass of ♂ ♂ as 67.7 kg (n = 60) and ♀ ♀ at 47.2 kg (n = 70); average total length for ♂ ♂ was 1690 mm (n = 60) and for ♀ ♀, 1550 mm (n = 70). At St Lucia ♂ ♂ had a mean mass of 67.8 kg (n = 12) and ♀ ♀, 49.4 kg (n = 46) (Venter 1979)

Maximum recorded horn length is 48.9 cm for a pair of horns from KwaZulu–Natal, South Africa (Rowland Ward)

Redunca redunca BOHOR REEDBUCK (COMMON REEDBUCK)

Fr. Redunca (Cobe de Roseaux); Ger. Gemeiner Riedbock

Redunca redunca (Pallas, 1767). Spicil. Zool. 1: 8. No locality cited; based on 'Le Nagor' of Buffon from Senegal, 'dans les terres voisines de l'île de Gorée' (mainland opposite Goree I.).

Bohor Reedbuck *Redunca redunca*.

Taxonomy Polytypic species. Seven subspecies have been recognized (Haltenorth 1963, Ansell 1972), mainly on the basis of small differences in pelage colouration and horn shape, but the limits and intergradation between them are not clear. Kingdon (1997) listed only four, among others including *nigeriensis* in *redunca*; we provisionally retain the two as separate, but a review of subspecies limits is necessary. Synonyms: *bayoni*, *bohor*, *cottoni*, *dianae*, *donaldsoni*, *nagor*, *nigeriensis*, *odrob*, *reversa*, *ridunca*, *rufa*, *tohi*, *typical*, *ugandae*, *wardi*. Chromosome number: not known.

Description Bohor Reedbucks are medium-sized, sandy-coloured antelopes in which the slender proportions of ♀ ♀ contrast strongly with the thick-necked, hook-horned ♂ ♂. Leaf-shaped ears have sandy backs, but fronts are lined with dense white hair. Head and body are a rich sandy colour above with white underparts and white chin and bib covering the upper throat. Black eyelids have white surrounds so that the dark eyes stand out visually. Pelage around the black subauricular patches (which are occasionally absent in some individuals) is also white. A dark vertical line may or may not be present down the front of the foreleg. Coat is sleek and soft and somewhat woolly in young and juveniles. Body colour continues onto outer surface of the tail, but long-haired underside is pure white. There are large inguinal gland pockets in the groin; functional pedal and preorbital glands are absent. Sebaceous secretions film the entire pelage, scenting the entire animal quite pungently. Only ♂ ♂ have horns, which are commonly short, black, heavily ridged and curve forward sharply.

Lateral view of skull of Bohor Reedbuck *Redunca redunca*.

Geographic Variation

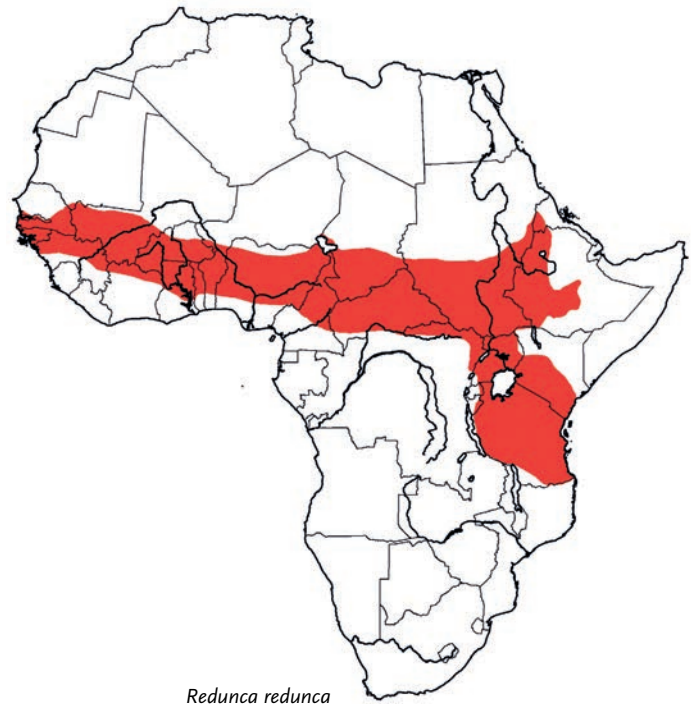

- R. redunca redunca*: Senegal east to Togo. Relationship to *nigeriensis* unclear. Smallest subspecies; lacks dark stripe on the forelegs; short tightly curled horns, with forward-pointing tips.
- R. r. nigeriensis*: Nigeria, N Cameroon, S Chad and Central African Republic. Tips of horns often depressed below the level of the frontal plane. Possible synonym with *R. r. redunca*.
- R. r. cottoni* (including *dianae*): Sudd region in S Sudan, NE DR Congo and possibly N Uganda. The largest subspecies with the longest horns, their tips less hooked and sometimes point inwards.
- R. r. bohor* (Abyssinian Bohor Reedbuck): W, C and SW Ethiopia, and Blue Nile of Sudan. Body colour a grizzled buffish-yellow; horns short and stout, but with the hooks pointing forward.
- R. r. wardi* (including *tohi*): Uganda, E DR Congo and East Africa. Sharply hooked horns, very richly tinted in colour, having black tips to the hairs on the dorsal surface; a dark stripe present on the forelegs, and underparts white.

Similar Species

- Redunca arundinum*. Overlaps in total range in S and W Tanzania. Larger, longer-horned reedbuck, with a more southerly distribution, and dark fronts to forelegs.
- R. fulvorufula*. Strictly montane reedbuck, of very limited distribution in East Africa and Cameroon. Smaller, greyer, and with relatively smaller muzzle and swollen nose.
- Kobus kob*. A broadly sympatric, but social species. Much more robustly built, taller, redder (or, in Sudd, ♂♂ black and white).

Distribution Endemic to Africa, ranging north of the forest zone from Senegal, Gambia, N Guinea and SW Mauritania through the woodlands and flood-plain grasslands of the savanna zone of West Africa through N Cameroon (Adamaoua Plateau northwards), S Chad, the savanna woodlands of the Central African Republic, extreme N and NE DR Congo, C and S Sudan, to W and C Ethiopia and south to L. Tanganyika and the Rovuma R. in Tanzania.

In West Africa, they have undergone fairly large range contractions, particularly in Togo, where formerly widespread in the north, and now possibly extinct; Ghana, where formerly widespread in savanna woodlands, but now of uncertain status; Niger, where they have been eliminated from much of their former range in the south-western savannas and along the border with Nigeria (but survive in W N. P.); and Nigeria, where they have been eliminated from most of their former range in the northern and central parts (East 1999). They are also possibly extinct in Côte d'Ivoire (F. Fischer pers. comm.); the species was not recorded at all in Comoré N. P. by Fischer *et al.*

Redunca redunca

(2002), despite its former presence in the northern parts (Roth & Hoppe-Dominik 1990). There is no evidence that Bohor Reedbuck ever occurred in Sierra Leone (Grubb *et al.* 1998).

Elsewhere, Bohor Reedbucks formerly occurred in the south-western savannas of Eritrea, but there is no recent confirmation of the species' status in that country; likewise, their current status in Burundi, where Verschuren (1988) reported at the time that they may still occur in Ruvubu N. P., is unknown (East 1999).

In some marginal parts of its range, such as the Aberdares in Kenya and the Ethiopian Highlands, it co-exists with the coarse-grass grazing Mountain Reedbuck *Redunca fulvorufula*. Over much more extensive areas, in Tanzania, its range overlaps with that of the Southern Reedbuck *Redunca arundinum* (which is adapted to southern temperate and austral seasonal cycles). However, a more detailed examination of the two species' current and former distributions in Tanzania revealed that the Bohor Reedbuck dominated the lower reaches of major rivers and flood-plains while the Southern Reedbuck was commoner in the higher reaches of the same rivers but along their smaller tributaries and streams (Kingdon 1982).

On the extreme north-eastern margins of its range this species has colonized montane areas, such as the Bale Mts, beyond its usual preferred habitats. Climatic change and the retreat of glacial habitats in Ethiopia after 16,000 BP and subsequent forest clearance by humans might help explain this peripheral but significant extension of range and habitat.

Habitat Associated with woodland and flood-plain grassland across much of their range. For example, in N Cameroon they occur in two discrete habitats: in seasonally flooded grasslands (*Vetiveria nigritana*, *Echinochloa pyramidalis*) in the Sahelo-Sudanian areas (Scholte 2005) and in *Isberlina* woodland in the Sudano-Guinean zones (Van Lavieren & Esser 1979). The most distinctive feature of adaptation to their habitats is how animals accommodate to radical seasonal changes in edaphic and fire-climax grasslands: tall and rank

in the wet or flood season, dry, burnt or trampled flat in the dry season. In the wet-season phase, animals are surrounded by ample cover, food and water, and all contacts with other animals, whether conspecifics or predators, are at very close quarters. In the dry-season phase, individuals may or may not be able to find some cover but the greater part of their environment is open, often waterless, and dangerously exposed. Many features of the Bohor Reedbuck's behaviour only become comprehensible when viewed in the light of this annual contrast.

In common with other reduncines, the Bohor Reedbuck is effectively water-dependent, but it shows a strong preference for extensive areas of flood-plains and open inundated grasslands where access to water may become restricted in the dry season. Seasonal movements out of burnt, overgrazed or waterless areas are usually relatively local, often involving a general shift up or down the catena. Typically, animals congregate closer to water and fresh grass growth during the dry season. There is a strong preference for flat, low-lying land but they also live on slopes, foothills and upland plateaux, especially along the margins of major sump areas. The most significant of these peripheral areas is the Ethiopian Highlands, where they occur to about 3200 m (Abdi 1987, Yalden *et al.* 1996) on montane grasslands, moorlands and secondary woodland grassland mosaics. As much of the Ethiopian upland habitats are anthropogenic, deriving from human clearance of montane forest and woodland, it is likely that Bohor Reedbucks have colonized such areas in relatively recent times. Significantly, almost all such areas lie close to westward-flowing tributaries of the Nile R., where one of the largest blocks of flood-plain habitat in Africa, the Sudd, supports a major population. The most isolated north-eastern subpopulation of Bohor Reedbucks, on the Bale Massif, seems to have crossed the Rift Valley and derives from a western Ethiopian source.

Abundance Originally a very common and widespread species, the Bohor Reedbuck has a preference for flat, well-watered habitats that also have high agricultural and pastoral potential. It is therefore in rapid decline over the greater part of its range. In exceptional and very restricted localities, such as the Gemmeiza levee in S Sudan, temporary densities of up to 110/km² were recorded (Mefit-Babtie 1983). In the Nile/Jonglei section of the Sudd region, aerial surveys of 67,900 km² revealed a total of 33,380 animals in the late dry season (an overall density of 0.5/km²), at which time a high proportion of animals were exposed. By contrast only 2547 were seen during the height of the wet season, when animals were easily concealed in grass. Although some of this discrepancy of over 90% could be attributed to migration off plains to the east of the survey area it was also clear that aerial counts, especially those conducted while the grass is long, can substantially underestimate Bohor Reedbuck numbers (Mefit-Babtie 1983). Fryxell (1980) estimated a dry-season population of nearly 30,000 in Boma N. P. Recent surveys conducted in the dry season in S Sudan, found Bohor Reedbucks to be abundant in the Jonglei, with large concentrations in the central plains together with Mongalla Gazelle *Eudorcas albonotata* and Tiang *Damaliscus lunatus*: as many as 11,000 animals were estimated to occur in the Jonglei area, with a further 2050 in Boma (a notable reduction from Fryxell's earlier estimate) and 257 in Southern N. P. (Fay *et al.* 2007).

In the Sahelo-Sudanian habitat of Waza N. P. (N Cameroon), of which approximately 40% is flood-plain, numbers were estimated,

mostly through terrestrial counts, at 4000 in 1960, dropping to 500 in 1967 and to less than 100 following the 1970s droughts (respectively, 2.4 to 0.3 to 0.06/km²) (Scholte 2005, Scholte *et al.* 2007). In the Sudanian-Guinean area of N Cameroon, Van Laveren & Esser (1979) surveyed Bouba Ndjida N. P. and estimated the total population at 5663 (ground counts) and 3221 (aerial counts), or a density of 2.6 and 1.5/km², respectively.

Butynski *et al.* (1997b) made an overall estimate of 5.6/km² in prime, protected habitat at Ruma, Kenya, a figure that corresponds well with figures deriving from the Ankole-Masaka 'tsetse clearance scheme' where 6630 Bohor Reedbucks were shot in about 1000 km² of suitable habitat (Kingdon 1982). Campbell & Hofer (1995) estimated 1.0/km² in Serengeti N. P., a figure that might approximate to an average for populations in relatively undisturbed areas of patchy habitat. Field (1970b) estimated 0.65/km² for good habitat around L. Edward, Uganda. Elsewhere, aerial surveys in many parts of Africa have produced figures of 0.1–0.3/km² (East 1999). Such very low figures could reflect any of the following constraints: dense vegetation cover, cryptic behaviour (crouching reedbucks are very difficult to see), uneven sampling of extensive plains where animals disperse widely in the wet season, but congregate in the dry, or counts from heavily hunted (and therefore depleted) areas.

East (1999) calculated total population size at around 100,000 individuals, including about 4500 animals for the Sudan, but acknowledged that this was likely to be a substantial underestimate.

Adaptations Bohor Reedbucks, like other reduncines, are valley grazers adapted to a very abundant but unstable food supply. Hofmann (1973) differentiated this species from the Mountain Reedbuck by describing the latter as a montane 'roughage grazer' and the Bohor Reedbuck as a sump-land 'fresh grass grazer'. Some physiological peculiarities can be added to this distinction in diet. Judging from the ability of some individuals to survive for weeks on dry plains (up to 25 km from water) in the S Sudan, this species would seem to have a higher drought tolerance than the Southern Reedbuck. As 'shaders' (Percival 1928) they can dispense with water so long as they can find even vestigial shade and graze off fresh grass regrowth. This ability to last longer without water might be augmented by greater resistance to solar radiation and desiccation than the Southern Reedbuck and permit them to exploit much wider, hotter tropical flood-plains. Schoen (1971) noted that the entire pelage and skin of the Bohor Reedbuck is infused with sebaceous secretions that might act as a seal against water loss as well as providing insulation against radiant heat.

Typically, Bohor Reedbucks are 'hidiers', avoiding detection by predators through freezing or sinking smoothly to the ground, where they lie down, neck extended, their colouring blending in well with the grass. Their social behaviour, by contrast, is noisy and conspicuous. Whistling and bounding are the two most characteristic behaviours. In any interaction within a closed environment there is the primary problem of identifying the sex and status of individuals. The leap and whistle are probably the main mechanism by which the reedbucks recognize each other. There are, therefore, differences in the amplitude, length and style of leaps and in the pitch and number of whistles. This species has to invest these displays with information content appropriate to a normally closed, long grass habitat. In addition to the auditory and visual signals it seems likely that there is

at least one strong olfactory signal. Bohor Reedbucks have 'pockets' in the groin that contain inguinal glands and it would seem that these pocket glands are responsible for loud 'popping' sounds that accompany high leaps. Presumably the pockets evacuate puffs of scent during these leaps and give other Bohor Reedbucks detailed information on the age, sex and condition of the jumper. Whistle/leap displays are most frequent in young ♂♂ and ♀♀ and contrary to most accounts seem to be directed at other reedbucks, especially adult ♂♂, rather than predators. Such displays have been observed in the open, in daylight, amongst mixed sex, mixed-age aggregations (Vesey-FitzGerald 1967), but it would seem likely that the whistles and leaps are specifically designed to take effect in long grass and at night (Kingdon 1982).

This species appears to be exceptionally mobile and flexible in its social behaviour: ♂♂ typically defend well spaced-out mating territories, but readily accommodate to fires and the destruction of cover and food by congregating on temporary pastures. In the dry season they commonly undertake long treks between diurnal hiding places and nocturnal pastures and water-sources.

Food and Foraging That Bohor Reedbucks are fresh grass grazers has been borne out by both observations and stomach analysis (Field 1970b, Hofmann 1973; and see Gagnon & Chew 2000) and studies involving stable carbon isotope analysis (Cerling *et al.* 2003). In Rwenzori Mountains N. P., Uganda, Field (1970b) recorded a very strong and perennial preference for *Sporobolus consimilis*, leading to concentrations of these animals in *S. consimilis* swards. Other preferred grasses are *Hyparrhenia filipendula*, *Heteropogon contortus* and *Themeda triandra*, all dominant species in fire climax

and heavily grazed grasslands. He noted that *Cynodon dactylon* and *Cenchrus ciliaris* were preferred in the rains and *Sporobolus pyramidalis* and *Panicum repens* in the dry season. At the southern margins of their range, Vesey-FitzGerald (1967) recorded them as most numerous on swards of *Echinochloa*, *Cynodon* and *Cyperus* spp. Along water channels it favours *Leersia* and newly sprouted *Vossia* and grazes *Imperata* on regularly burnt pastures. Hofmann (1973) noted that dicotyledons were rare, but these could include *Capparis*, *Sida* and the aromatic leaves of a small forb.

Although active mainly at night, grazing may also take place during the day in some areas. Nocturnal grazing can take place a very long way from daytime refuges. Seasonal differences in the amount of time devoted to grazing seem to be a response to the availability and quality of grasses (D. F. Vesey-FitzGerald pers. comm.).

Social and Reproductive Behaviour Bohor Reedbucks' social structure is highly flexible and adjustable to the annual cycle of change in their grassy environment. Typically, ♀♀ (1–5 adults) with young have home-ranges that overlap those of single, spaced-out adult ♂♂; bachelor male groups numbering up to 19 may spend time within the established mating territory of a dominant ♂ and are tolerated unless there are ♀♀ around. In a very short-term study in Serengeti N. P., ♀♀ were found living within home-ranges of 15–40 ha and their movements overlapped those of other ♀♀. Male mating territories were estimated to be between 25 and 60 ha (Hendrichs 1975b). In many narrow valley environments, Bohor Reedbucks appear to remain well spaced in twos or small groups throughout the year. In less confining valleys, as in Kidepo Valley N. P., Uganda, there are regular dry season congregations of reedbucks numbering up to 23 animals. Likewise, in Bale Mountains N. P., Ethiopia, large aggregations (up to 59 individuals) were observed during the dry season as a result of local immigration to swamp grassland habitat (Afework *et al.* 2010). Subgroups can be recognized within these aggregations, each accompanied by an adult ♂.

In the vast open flood-plains of the Sudd region, Sudan, dry-season fires and intensive grazing by both wild and domestic herds deprive Bohor Reedbucks of cover over immense areas. Across some 200 km of dry, open plains an aerial flight in Mar (at the end of the dry season) revealed occasional solitary ♂♂ that could be seen almost continuously. Often such ♂♂ were sheltering under the flimsiest of shade. When disturbed by the aeroplane these ♂♂ invariably ran in a tight circle, implying some attachment to one spot in spite of an absence of other animals, water and any obvious grazing. In contrast to these solitary ♂♂, the majority (of both sexes) of Bohor Reedbucks on the Sudd flood-plains desert the driest, burnt areas and collect closer to water and fresh grass grazing. These aggregations are commonly relatively dispersed, particularly when the reedbucks are mixed up with numerous other grazers. On both the eastern and western borders of the flood-plain (and sometimes on temporary pastures), Bohor Reedbucks congregate so closely that they almost resemble 'herds'. On the 'Duk Ridge', which lies between the eastern Sudd flood-plains and the Nile R., Bohor Reedbucks concentrate in a relatively narrow north-south belt for the worst part of the dry season and then disperse eastwards with the arrival of the rains. Along the narrowest section of this levee, at Gemmeiza, this pattern of dispersal is modified because large numbers of reedbucks remain in the area for

Bohor Reedbuck *Redunca redunca* calf 'freezing' prone.

Bohor Reedbuck *Redunca redunca*.

more than half the year. The Gemmeiza population has long been known to trophy hunters for exceptionally long-horned reedbucks, suggesting a direct correlation between sustained high densities and larger horns. The Bohor Reedbucks in this locality are also of special interest for the light they might throw on the evolution of sociality in an otherwise semi-solitary species.

When ♀♀ come into oestrus the hormonal clues for ♂♂ may include increased activity in the subauricular patch-glands as copulation and increased male interest have been seen to coincide with sudden visible exudation from these glands (T. Nuti pers. comm.). At Kikagati, Uganda, a ♂ was seen to approach an apparently oestrous ♀ and run around her, jumping and uttering a harsh, toy trumpet-like bleat. In some respects Bohor Reedbucks resemble other reduncines in their courtship, a ♂ approaches a ♀ with head lowered and stretched out and if the ♀ is in oestrus and permits a close approach the ♂ repeatedly strikes up at her belly with his foreleg. Copulation is extremely fast and accurate. When a ♀ visits her offspring, to suckle it, breaking off contact can be difficult; J. Kingdon (pers. obs.) has watched a young chasing its mother round and round a termity until the mother suddenly detached herself,

giving the distinct impression that she used the termite mound as a contact-breaking device.

Reproduction and Population Structure Because the young are kept very well hidden for at least two months, actual birth records are scarce. Very young animals are scarcely ever seen during the peak of the drought in S Sudan, due partly, perhaps, to the fact that grass fires would incinerate or expose most very young animals and partly to subsequent exposure to predators and heat-stress. Such constraints are likely to exert strong selection for birthing during the wet and flood seasons. Breeding activity, therefore, seems to peak in the wet season (Apr–Oct over most of their range) (Kingdon 1982). Gestation has been estimated at about 225 days. In Bale Mountains N. P., Ethiopia, with a very different ecology, almost 60% of ♂♂ exhibited territorial behaviour during the wet season and over 78% of young were observed during the dry and early wet season (May–Oct), although young were recorded in all months of the year (Hillman 1986a). Males reach adult size and sexual maturity at about two years, but ♀♀ are probably capable of conception at a little over one year (P. Fox pers. comm.). In Katavi N. P., Caro (1999b)

recorded a sex ratio of 0.45 males to females, and 0.33 young per female.

There are reports of captives living to 18 years, but maximum longevity recorded in captivity is 10.7 years (Weigl 2005).

Predators, Parasites and Diseases Adults are taken by all the main large predators, including Lions *Panthera leo*, Leopards *P. pardus*, Cheetahs *Acinonyx jubatus*, Spotted Hyenas *Crocuta crocuta*, African Wild Dogs *Lycaon pictus*, Nile Crocodiles *Crocodylus niloticus* and African Rock Pythons *Python sebae*. Young are taken by large raptors, jackals *Canis* spp., Serval *Leptailurus serval* and Caracals *Caracal caracal*.

Bohor Reedbucks have been recorded hosts to a number of helminths, including: *Carmyrius papillatus* in the rumen, *Stilesia globipunctata* in the small intestine, *Trichuris globulosa* in the caecum, *Setaria* spp. in the abdominal cavity, *Dictyocaulus* sp. in the lungs and *Taenia* cysts in the muscles (Mefit-Babtie 1983, Tag Eldin *et al.* 1986). Other recorded parasites are *Schistosoma bovis*, *Amphistoma* sp., *Oesophagostomum* sp., *Stilesia* sp., *Cooperia rotundispiculum*, *Haemonchus contortus* and *Hypoderma* larvae. Van Hoven (1983) recorded 18 protozoan parasites from rumen contents in the Bohor Reedbuck, including seven entoninia and two new *Diplodinium* species. They are also hosts to ticks, such as *Amblyomma* spp. and *Rhipicephalus evertsi* (Mefit-Babtie 1983, Ntiemo-Baidu *et al.* 2004).

Conservation IUCN Category: Least Concern. CITES: Not listed.

The primary threats to the species include habitat destruction, drought and overhunting. In some parts of their range, such as N Cameroon, flood-plain degradation through the construction of upstream dams has been a major reason for the decline of Bohor Reedbucks, while in other parts of their range (Tanzania, Chad), the spread of settlement, cultivation and agriculture have had an impact on their available habitat. None the less, even in N Cameroon, Bohor Reedbucks can still be observed even in flood-plain areas with (relatively) high population pressure (P. Scholte pers. comm.). Over much of their current range Bohor Reedbucks are most likely to be killed by humans with dogs, a mode of hunting to which they are peculiarly susceptible because they are quickly outpaced by dogs and readily brought to bay. They are also easily snared or shot, particularly when dazzled by lamps at night. They are often hit by vehicles at night and have been recorded being drowned.

Becoming uncommon in many parts of its former range, especially in West and central Africa, the Bohor Reedbuck survives in a number of important parks and other conservation areas, including Boucle du Baoule (Mali), Niokolo-Koba N. P. (Senegal), Arly-Singou Faunal Reserve (Burkina Faso), Bouda Ndjida N. P. (Cameroon), Manovo-Gounda-St Floris N. P. (Central African Republic) and Bale Mountains N. P. (Ethiopia) (East 1999). There is no recent information on their presence in Boucle du Baoule N. P. (Mali), which has been severely depleted of edible animals. It may no longer occur in Comoé N. P. in Côte d'Ivoire (Fischer *et al.* 2002), while its presence in Mole and Digya National Parks in Ghana (reported by East 1999) is doubtful.

They are surely on the verge of extinction in Akagera N. P., their last-known stronghold in Rwanda (Apio & Wronski 2011). It occurs in all but the most arid of East African conservation areas (East 1999).

Measurements

Redunca redunca

HB (♂ ♂): 1250–1450 mm

HB (♀ ♀): 1150–1300 mm

T (♂ ♂): 200–250 mm

T (♀ ♀): 150–230 mm

Sh. ht (♂ ♂): 700–800 mm

Sh. ht (♀ ♀): 650–800 mm

WT (♂ ♂): 45.0–65.0 kg

WT (♀ ♀): 35.0–55.0 kg

Throughout the range (Haltenorth & Diller 1980); means and sample size not given.

Maximum recorded horn length is 42.5 cm for a pair of horns from Gemmeiza, Sudan (Rowland Ward)

GENUS *Kobus*

Kobs

Kobus A. Smith, 1840. Illustr. Zool. S. Afr. Mamm. Part 12, pl. 28 plus text.

Kob *Kobus kob* superficial myology.

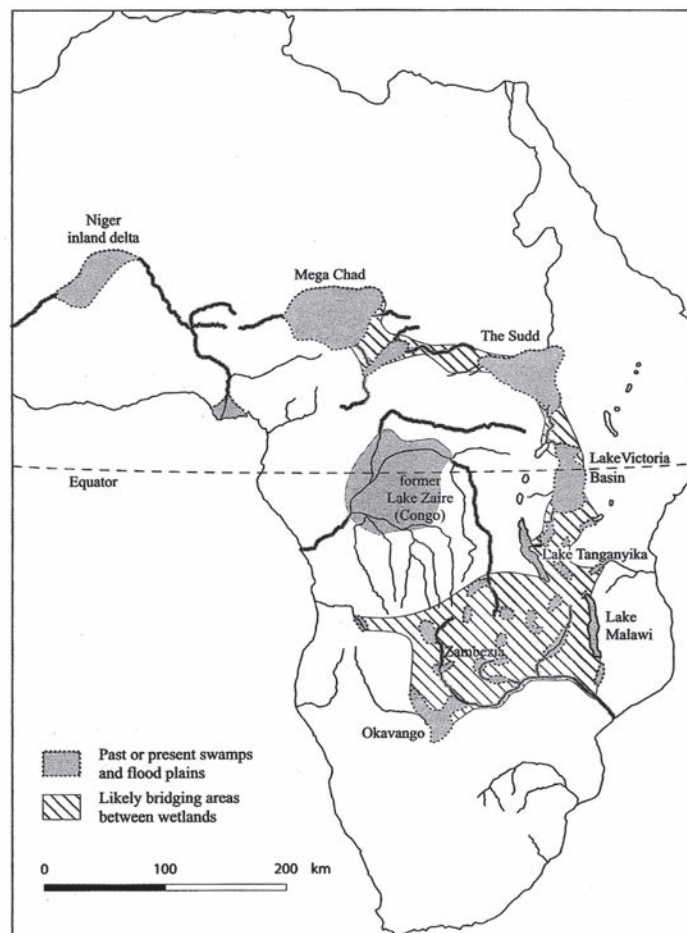

The genus *Kobus* embraces all the larger reduncines, which, in this work, are considered to number five species. Some 15 species of fossil African *Kobus* have been described, dating back some 7 mya, an age several times older than that estimated by molecular clocks. Fossils identified as *Kobus* are known from the Indian subcontinent, so there is an Asian dimension to reduncine evolution, although the surviving species probably represent an exclusively African radiation.

As with other reduncines, the primary habitats of *Kobus* are valley grasslands wherein these antelopes make local movements, of variable amplitude, in pursuit of super-abundant but unstable resources, namely fast-growing, nutritious valley grasses. Members of the genus are strong, sturdy antelopes but are relatively slow and with little stamina. These differences can be best appreciated by contrasting the proportions of Kob *Kobus kob* with those of the Grant's Gazelle *Nanger (granti)* complex, antelopes of comparable shoulder height. A lack of stamina and speed may have played a significant part in the restriction of early reduncines to wet, muddy habitats where many predators are at a disadvantage. In this perspective, all *Kobus* species probably had to evolve special strategies to mitigate predation, such as deeper retreat into swamp, hiding in dense vegetation and 'hiding' in large, dense herds.

The species have a wide range of weights, from about 50–290 kg, and although there has been a broad and unambiguous trend within the Reduncini to evolve from smaller to larger, the contemporary species of *Kobus* are broadly equally successful within their particular niches in spite of their diversity of weights and sizes. This suggests that there are probably optimal body-sizes for each of the particular niches that *Kobus* now occupy. Furthermore, in the evolution of reduncines, it was probably essential for true swamp-dwellers to

reach a minimal size (of about 60 kg) before they had the muscle and weight to cope with heavily obstructed reedbeds, deep muds and floods. Could a combination of taking refuge from predators and exploiting the intrinsic food resources of swampy habitats have driven the trend towards larger size in *Kobus*? The tendency for Waterbuck *K. ellipsiprymnus* to escape predators by wading into water hints that the Waterbuck might represent an early, but essentially secondary, return onto dry (but still very well-vegetated) ground.

The most likely speciation pattern for *Kobus* was adaptation by two *Redunca*-like populations to two (spatially and climatically distant) extremes of valley habitats. One of these would have tended towards seasonal drying out, and the other towards more or less permanently wet swamp. If exclusively intra-African, and on a continental scale, the former was more likely to have been south of the Sahara, but, perhaps, still within its aridifying influence. The second was likely to have been closer to the Equator, with its two wet seasons and greater likelihood of ever-wet conditions. This prediction of a phylogenetic bifurcation has been borne out by two studies of the *Kobus* radiation. According to the molecular results of Birungi & Arctander (2001), *Kobus* emerged from a *Redunca*-like ancestor and diverged into two branches – 'non-swamp'

Web of tropical wetlands linking Zambezia and Okavango with L. Victoria basin, the Sudd and L. Chad.

Kobus and the swamp-dwelling lechwes. More plausibly, another study (Brashares *et al.* 2000, drawing on Gatesy *et al.* 1997) allied lechwes with the still larger Waterbuck, suggesting that the primary bifurcation was between a smaller (50–100 kg) Puku/Kob lineage and a larger (60–130 kg) Lechwe/Waterbuck lineage.

The Kob has exploited the super-abundance of grazing resources on flood plains to reach huge densities and survive in a combination of greater numbers and mobility between dry and wet season pastures. In their much more modest seasonal concentrations, some reedbuck populations illustrate the ecological context in which such a strategy might have evolved. The Kob is a boom-and-bust species that can rapidly recoup its numbers after droughts and until recently occupied a region that extended from Senegal to W Kenya. The Puku, which is sometimes treated as conspecific with Kob (and see Birungi & Arctander 2000), probably represents a later, southern off-shoot of the Kob.

At the time of a primary bifurcation between ancestral Puku/Kob and ancestral Lechwe/Waterbuck, the depression that is now L. Victoria was probably one of the prime areas of shallow, grassy wetlands in Africa. To the north it connected to the Nile R.; to the south, only Lakes Tanganyika and Rukwa separated it from the wide scatter of flat sump-lands at the headwaters of the Zambezi and southern Congo rivers. For these reasons it is likely that the Equatorial L. Victoria region was where a common Lechwe ancestor first emerged.

In the progressive adaptation of lechwes to swamp-dwelling there would have come a time when these antelopes were unable to survive outside swamps. From that point on, populations within specific basins would have tended to become genetically distinct. The northern and southern foci of lechwe dispersion probably became separated from one another quite early on, possibly even before the latest episode of flooding of the L. Victoria basin. Intermittent droughts during the Pleistocene would have reinforced such separation and even the Southern Lechwe shows clear genetic differences between populations that inhabit geographically closely clustered, but separate, basins. These differences can be ascribed to more recent disconnections between populations that were formerly part of a shared gene pool.

The swamp-loving lechwes, so far as is known, never reached West Africa, but the Nile's former connections with the Niger make an extension of proto-lechwe range to L. Chad and the Niger's inland delta plausible. During very wet periods, when their spread was most favoured, the earliest forms probably had opportunities to spread over a more or less continuous network of river systems, swamplands and lake margins from the Okavango delta in the south to at least the Sudd in the north, with extensions further west quite likely. Nonetheless, out in the far west, repeated periods of Saharan expansion and aridification of shallow basins would have inhibited large-bodied *Kobus* from becoming wholly swamp-adapted.

Fossils and some differences between the western population of *K. e. defassa* and the south-eastern *K. e. ellipsiprymnus* give credence to the proposal that Waterbuck differentiated in West Africa from an ancestor that was more like a Lechwe than a Kob. The former are tropical, tolerate high temperatures and more humid conditions; the latter tolerate colder temperatures as well as drier habitats and probably emerged later. Fossil Waterbuck first appear at about 2.3 mya in sites that lie close to or north of the Equator and, in addition to becoming larger, their horn bases show a gradual loss of the Lechwe-like backward curve and distal hook (Gentry 2010). Still earlier, about 4 mya, a fossil lechwe-sized reduncine, *Kobus sigmoidalis* appeared,

Frontal aspect of the Black Lechwe
Kobus leche smithemani.

was particularly common in the mid Pliocene, and fits the profile of a Lechwe/Waterbuck ancestor.

Unlike lechwes, the very much larger Waterbuck seldom congregates in great numbers but they are much more widely, albeit patchily, dispersed along river-courses over a large part of Africa. Their diet consists of valley-bottom grasses, but they resemble other reduncines in seeking out dense thickets, reedbrakes and other dense vegetation to rest up in. They are 'hidiers' that gain some immunity from small and medium-sized predators by virtue of their large size, high fecundity and efficient exploitation of a wide variety of valley habitats.

In addition to its ancestral implications, the emergence of *K. e. ellipsiprymnus* in the south-east and *K. e. defassa* in the centre-west follows a biogeographic pattern that is of general significance in the evolution of African biota. In the exceptionally benign ecological and climatic conditions of the recent past the two populations of Waterbuck interbreed along a very broad and complex overlap zone. During several dry cold Glacial periods the overall ranges of Waterbuck can be confidently predicted to have shrunk into two much more restricted core regions (Kat 1993), a prediction corroborated by molecular studies (Lorenzen *et al.* 2006b). The western *K. e. defassa* has probably enlarged its range from a core of moist watersheds that feed the Congo, Nile, Niger and other great rivers. The eastern *K. e. ellipsiprymnus* is likely to have expanded from a precariously narrow eastern African littoral zone which runs north-south and consists of moist habitats sustained by precipitation off the Indian Ocean. The mechanism that has kept the two populations apart (probably more than once) is the long corridor of arid country that has periodically opened up to connect the Horn of Africa with the Namibian and Kalahari deserts, and which has been identified as the eco-geographic barrier that caused the bifurcation of many related forest and moist woodland-adapted animals and plants into distinct eastern and central African forms (see Kingdon 1990). In the case of Waterbuck populations, the length of their separation has been insufficient to result in total reproductive isolation, but Kingswood *et al.* (1998b) have found fixed chromosomal differences that imply reduced fertility in hybrids or their offspring (see species profile).

Jonathan Kingdon

Kobus kob KOB

Fr. Cobe de Buffon; Ger. Grasantilope.

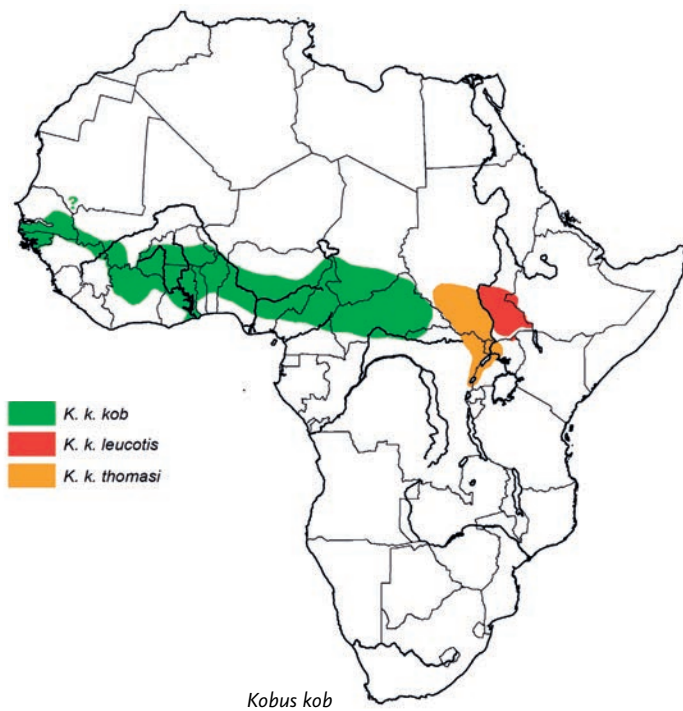

Kobus kob (Erxleben, 1777). Syst. Regni Anim. 1: 293, 1777. 'Senegal'.Kob *Kobus kob* male.Lateral, palatal and dorsal views of skull of Kob *Kobus kob*.

Taxonomy Kobs were at one time regarded as a separate genus (*Adenota*), but were later included in the genus *Kobus* on evidence of hybridization with other members of the genus (Gray 1972). Ansell (1972) listed ten subspecies, but more recent treatments favour recognition of only three (Kingdon 1997, East 1999); some of these show wide intra-specific genetic divergence (Birungi & Arctander 2000). Lorenzen *et al.* (2007) question the taxonomic status of *K. k. kob* and *K. k. thomasi* as two separate subspecies due to the joint evolutionary history of their mtDNA sequences. A study by Birungi (1999) analysing the entire mitochondrial cytochrome *b* gene supported the idea that the Puku *Kobus vardonii* might well be regarded as a subspecies of the Kob rather than a distinct species (see Haltenorth 1963). Synonyms: *adansoni*, *adenota*, *adolphi*, *adolphi-friderichi*, *alurae*, *annulipes*, *bahrkeetae*, *buffonii*, *cob*, *coba*, *forfex*, *fraseri*, *koba*, *kul*, *leucotis*, *loderi*, *neumanni*, *nigricans*, *nigroscapulatus*, *notatus*, *pousarguesi*, *riparia*, *thomasi*, *typicus*, *ubangiensis*, *vaughani*, *wuil*. Chromosome number: $2n = 50$; the X chromosome is a large acrocentric and the Y chromosome is a small metacentric/submetacentric (Taylor *et al.* 1967, Kingswood *et al.* 2000). Gray (1972) documents records of hybridization between Defassa Waterbuck *K. ellipsiprymnus defassa* and Kob, and between Nile Lechwe *K. megaceros* and Kob, and these are expected to exhibit reduced fertility (Kingswood *et al.* 2000).

Description Kobs are medium-sized antelopes. Horned ♂♂ are robust (about 50% heavier than ♀♀) with a muscular neck; hornless

♀♀ are more slender. There are more or less prominent white rings around the eyes and there is a white throat patch. Facial characteristics include black muzzle and nostrils, as well as white lips and chin. Ears are large and laterally placed; white inside and at the outer base, brown on the outer surface with black tips. In White-eared Kob *K. k. leucotis*, ears are white and pelage dark brown. Eyes in all subspecies are large and brown. Pelage is short, ranging from light brown to reddish, and dark brown depending on age, sex and subspecies. Ventral coat and inner parts of legs are white. Upper front of hindlegs is white; otherwise limbs are similar in colour to body. There are large dark vertical stripes on front of forelegs; smaller dark patches on front of hind legs. Tail short, thin, lighter underneath with terminal tuft that is dark on top. Rudimentary preorbital glands are present, and Kobs possess one pair of inguinal glands. Large, diffuse sebaceous glands make the pelage greasy and strong-smelling.

Although only ♂♂ bear horns, horned ♀♀ occur at a rate of 1/1000 animals (Buechner *et al.* 1966). The male's horns are thick, lack spirals and are strongly ridged at the base, extending upwards, backwards and upwards again giving them an S-shaped appearance. The horn tips are either parallel or extend slightly outwards or inwards. Horns are wider at their tips than at the base in most cases. Female horns are thin and twisted without prominent ridges (Fischer 2001). In the dentition, p4 is usually the last deciduous tooth to be replaced, and is easily identified by three distinct cusps, whereas the permanent tooth has only two (Ledger & Smith 1964).

Geographic Variation

- K. k. kob* (Buffon's or Western Kob): Senegal to Central African Republic and DR Congo. Coat colour is golden-brown and sometimes reddish-brown, with white underparts and white areas above the eyes; forelimbs have black front edges; ♀♀ show more variation in colour from rather pale to having black back and/or face; notably smaller than either Uganda or White-eared Kob, with smaller horns.
- K. k. thomasi* (Uganda Kob): NE DR Congo, SW Sudan and Uganda. General appearance like *K. k. kob*, but larger and about 40% heavier (see Measurements); in some northerly areas ♂♂ are variable in colour, having dark patches or even almost black coats.
- K. k. leucotis* (White-eared Kob): SE Sudan, SW Ethiopia and extreme NE Uganda. Pelage in ♂♂ is dark reddish-brown, sometimes almost black (young ♂♂ and ♀♀ have a chestnut hue); ears white, as the name implies; in older ♂♂ the muzzle, chin, throat and inner surfaces of legs also become white.

Similar Species

- Kobus megaceros*. Sympatric with *K. k. leucotis*. Larger, mature ♂♂ are black and white with relatively shaggier coats; ♀♀ larger, with shorter faces, less sleek coats (but similar in colour to Kob).
- K. vardonii*. Allopatric. Similar but longer-haired.
- K. ellipsiprymnus*. Defassa Waterbuck is broadly sympatric, south of the Sahel and west of the Rift Valley. Much larger, with longer, straighter horns on ♂♂. Dark brown.
- Ourebia ourebi*. Sympatric over much of the range. The Oribi is similar to young Kob, but with naked patch of black skin beneath ear, short, straight-tipped horns and pelage mainly sandy to rufous.
- Redunca redunca*. Sympatric over much of the range. Subadult ♂♂ of Uganda and Buffon's Kob resemble adults, but pelage longer, horns hooked and lack black markings on forelegs.

Distribution Kobs are endemic to Africa with a patchy distribution within a geographical belt running from Senegal to Uganda, Sudan and SE Ethiopia. In the past natural barriers such as mountain ranges, forests and deserts would clearly inhibit Kob dispersion (Wanzie 1991), but the nearly continuous distribution of Buffon's Kob across the flat lands well to the south of the Sahara would have been facilitated, rather than hindered, by river and flood-plain systems during humid periods. Late Pleistocene remains of this species are reported from S Egypt (Osborn & Osbornová 1998).

Historical Distribution Buffon's Kob has the widest distribution range of all the subspecies, and was formerly distributed from Senegal, Guinea-Bissau, Gambia, the extreme south of Mali and SW Mauritania, eastwards through all countries, including Sierra Leone, to SW and SE Niger, C and N Nigeria, C and N Cameroon, S Chad, Central African Republic and N and NW DR Congo (East 1999). The White-eared Kob, on the other hand, has the most restricted range of the three subspecies, being confined to the flood-plains east of the Nile R. in SE Sudan (Stevenson-Hamilton 1919, Forbes 1948, MacKenzie 1954, Mefit-Babtie 1983, Hillman & Fryxell 1988). White-eared Kobs also occurred in the Gambella area of SW Ethiopia, at least seasonally when migrants entered from Sudan (Sorell 1952), and NE Uganda (as vagrants from Sudan). The Uganda Kob formerly occurred widely throughout Uganda, and also ranged into SW Sudan, NE DR Congo, SW Kenya and lakeside areas of NW Tanzania (Kingdon 1982, East 1999).

Current Distribution Kobs have undergone extensive declines across much of their range. In West Africa, Buffon's Kob is extinct in Gambia and apparently in Sierra Leone (see Camara 1990, Grubb *et al.* 1998, Jallow *et al.* 2004) and most likely in S Mauritania, and now survives mainly in and around protected areas in much of the remainder of its range.

In Sudan, the flood-plains east of the Nile have, even in recent decades, supported up to a million White-eared Kobs that undertake seasonal migrations on a scale to rival that of the Common Wildebeest *Connochaetes taurinus* in the Serengeti ecosystem (Fryxell 1985, Fryxell & Sinclair 1988, Hillman & Fryxell 1988). Although numbers of White-eared Kobs were thought to have been depleted, recent surveys indicate that they still survive in good numbers particularly in the north and along the western boundary of Boma N. P. (Fay *et al.* 2007). White-eared Kobs still occur as sporadic migrants in Kidepo Valley N. P. in NE Uganda and in Gambella N. P. in Ethiopia.

Uganda Kobs survive mainly in Uganda, particularly in western and north-western parks and reserves (such as Queen Elizabeth N. P. and Murchison Falls N. P.), and in NE DR Congo, in Garamba and Virunga National Parks; a few Uganda Kobs remain in SW Sudan, mostly in Southern N. P. Populations of Uganda Kobs that formerly occurred in SW Kenya and NW Tanzania have been eliminated from these areas by expanding human settlements and unsustainable hunting (East 1999).

Habitat Kobs are confined to regions of open or wooded savanna that have year-round access to water. They are common in riverine and lake-shore grasslands, flood-plains, open grassland, open woodlands, grassy shrublands and on grasslands within the forest/savanna transition zone. Exceptionally, Kobs have been claimed to

have once occurred in or around mangrove swamp forest in Guinea-Bissau (Wanzie 1991). In Nigeria, a combination of cover from woody plants and good visibility was judged important for Kobs (Amubode & Akossim 1989, Sodeinde 1989). In Uganda, Kingdon (1982) emphasized the role of other grazers, of fire, a high water table and even the Kobs' own numbers in maintaining a sward suited to grazing by Kobs; indeed, he posited that this species evolved to exploit the shifting mosaic of heavily grazed conditions that are common in riparian habitats. Kingdon (1982) pointed out that the Kobs' dependence on daily movement routines serves to reinforce the animals' attachment to proven resting or short-term grazing sites and that longer-term fluctuations in population size may cause concentrations to build up or decline at particular sites. Better-drained, raised areas become 'islands of occupation' during the wet season and Kobs sometimes continue to be attracted to such sites out of season and over many years. Kingdon noted that male territorial grounds, which attract both sexes, tend to be located on open ground close to geographic discontinuities, such as rocky gulleys, slopes or other changes in topography. He also noted that during daily movements between pastures and water, such discontinuities induce pauses and that over a period of hours Kobs continue to collect on these grounds until the build-up of numbers seems to offset the risk of possible ambush from predators. Use of the landscape by Kobs was mapped by Bindernagel (1968), showing the year-round movements and territorial grounds of a resident population of Kobs in N Uganda. Deutsch & Weeks (1992) confirmed that ♀♀ preferred high-visibility territories and territorial grounds in Uganda to avoid predators. Recently burnt areas are preferred as are those with short pasture. Mineral licks are visited regularly and hence influence habitat preferences (Sodeinde 1989).

Abundance Overall, numbers of Kobs are declining throughout their range. Whereas East (1990) estimated that the total numbers of Buffon's Kobs could exceed 225,000, a decade later his estimate was in the region of 95,000 (East 1999). The population of the White-eared Kob was estimated at more than 100,000 by East (1999), a significant decline from the nearly 1 million animals that were known to occur in the Boma ecosystem in the early 1980s (Fryxell 1985, Hillman & Fryxell 1988). Recent surveys in the dry season covering some 150,000 km² of S Sudan have shown that this population has survived the period of civil war relatively well, with the population in Boma N. P. alone estimated to number nearly 700,000, with a further 46,000 animals on the contiguous Lotilla plains and nearly 12,000 in the Jonglei area (Fay *et al.* 2007). Numbers of Uganda Kobs within parks and reserves may be reasonably stable, with an estimated total population size of 100,000 for this subspecies (East 1999).

The highest densities of Kobs (1000/km²) have been reported around drinking sites in the dry season (Fryxell 1987; and see Scholte 2005), but even at other times densities might be as high as 140/km² (Balmford *et al.* 1992). Where Kobs are well protected, local densities of 15–40 animals/km² are common (Modha & Eltringham 1976, Wanzie 1988, Amubode & Akossim 1989), but in areas of heavy hunting pressure densities decline to less than 1/km² (Fischer 1998).

Adaptations Kingdon (1982) considered that the major evolutionary innovation of *Kobus kob* has been their ability to move en masse from one resource to another and that this species evolved to

White-eared Kob *Kobus kob leucotis* male head.

take advantage of heavily grazed conditions on fertile pastures in the vicinity of lakes and rivers (created by hippos, African Buffalo *Syncerus caffer* and other large ungulates), and that Kobs have subsequently extended their range further into fire-climax grasslands. Kobs can maintain their own pasture when occurring at high densities.

Kobs do not necessarily seek shade and frequently can be observed lying in the sun during the hottest part of the day. However, Fryxell (1987) has reported that, where possible, White-eared Kob individuals almost always sought shade in SE Sudan. Kobs depend on free water, which they usually drink in the morning or afternoon, making their movements very predictable. Their ability to form large groups that stay together while being chased is an adaptation to mitigate the effectiveness of predator attacks.

While Uganda and Buffon's Kobs perform only small-scale seasonal movements, White-eared Kobs extend such movements, effectively becoming migratory in relation to food, floods and water supply, at which time they form mobile herds of many thousands (MacKenzie 1954, Fryxell & Sinclair 1988). Kobs have the ability to increase rapidly in number when they are protected and conditions are favourable.

Foraging and Food Kobs are almost exclusively grazers, borne out not only by field observations but also by studies involving stable carbon isotope analysis (Cerling *et al.* 2003), and were classified as obligate grazers by Gagnon & Chew (2000) in their review of the dietary preferences of African bovids. Kobs are selective in terms of species as well as parts of plants eaten (Agbelusi 1989). Uganda Kobs showed a preference for short to medium-height pyrophilous perennial grasses such as the Andropogoneae (Field 1972). In Comoré N. P. (Côte d'Ivoire), preferred grass species for Buffon's Kob were *Hyparrhenia rufa*, *Andropogon africanus* and *Schizachyrium sanguineum* (Prauser 1980, Radl 1987). In Sudan, *Echinochloa pyramidalis* was favoured (Fryxell & Sinclair 1988).

Seasonal changes in diet occur (Field 1972) due to better palatability of certain grass species in the wet season (*Bothriochloa*, *Heteropogon*, *Imperata*) or greater abundance (*Brachiaria*, *Cynodon*, *Setaria*). In Uganda, leaves of shrubs such as *Sida* sp. and *Capparis tomentosa* were eaten occasionally (Hofmann & Stewart 1972); non-grass species accounted for 4.8% of plant matter eaten, although fruits were not part of the diet

(Radl 1987). Fat content of graminoids showed a significant correlation with Kob density in Nigeria (Amubode & Akossim 1989). Greenness of grass was an important predictor for female presence throughout the year, but most influential during the dry season (Deutsch 1994).

Social and Reproductive Behaviour Social organization in the Kob is dependent on density and includes two discrete mating systems. Typically, 50–90% of adult ♂♂ (three years or older; Leuthold 1966, Fischer & Linsenmair 1999) defend territories that are either resource-based (Buechner 1961, Mühlenberg & Roth 1985, Amubode & Akossim 1989) or based on territorial grounds (leks) (Buechner & Roth 1974, Floody & Arnold 1975, Fryxell 1987, Wanzie 1988, Balmford 1992). When the overall density of Kobs declines within the same population (as in Comoé N. P. post 1974), the territorial mode can change from a lek system at high densities (>14 animals/km²) to a resource-defence system (Fischer & Linsenmair 1999, and references therein).

In contrast to ♂♂, adult ♀♀ and young do not occupy territories, but form groups that are unstable, changing in both size and composition on a day-to-day basis, and sometimes numbering up to 120 animals (Fischer 1998). Groups are larger when visibility is good (during days or moon-lit nights, or when grass is short), but decline when visibility decreases (Fischer & Linsenmair 2000); even large groups often contain only one adult ♂. Unstable multimale groups occur only outside territories, for example, where animals group together before visiting dangerous drinking sites. Non-territorial ♂♂ live in bachelor groups of 2–200 animals.

Annual female home-ranges in Comoé N. P. averaged 245.8 ± 34.8 ha while those of ♂♂ were 91.7 ± 11.3 ha (Fischer & Linsenmair 2001b). Female home-ranges in Queen Elizabeth N. P. (Uganda) averaged 1560 ha (Balmford 1992); male home-ranges in the same area were 520 ha for non-territorial and 300 ha for territorial ♂♂. The home-ranges of most ♀♀ underwent shifts in location between seasons, but not those of territorial ♂♂ in Comoé N. P. Daily walking distance of ♀♀ in Comoé N. P. was 2300 ± 100 m (Fischer & Linsenmair 2001b) and 2480 m in Queen Elisabeth N. P. (Balmford 1992).

The size of single territories has been estimated at 2–127 ha (Grant *et al.* 1992, Fischer & Linsenmair 1999), but on leks an arena of some 200–400 m in diameter (i.e. no larger than a single conventional territory) may be shared by 30–40 ♂♂ spaced at distances of 15–30 m, such that effective territory size is compressed to a notional 10–60 m in diameter only (Leuthold 1966, Floody & Arnold 1975). The continued presence of the territorial ♂♂, as well as the activity of the transient ♀♀, results in these arenas having little or no grass; however, limited availability of food is more than compensated for by the presence of ♀♀ and opportunities for mating.

Resource territories are defended close to the birthplace (Wanzie 1988, Fischer & Linsenmair 1999). Males patrol their territories (in Comoé N. P. covering on average 2400 ± 200 m during daylight hours) and frequently whistle 4–5 times in a row, possibly advertising their territory tenure or their reproductive status. Object horning (bushes or soil) probably serves similar purposes. Since ♂♂ that enter foreign territories intensively sniff the ground it is likely that olfactory signals are important for Kobs although no explicit scent-marking behaviour is known. Visual communication is important, with territorial neighbours probably knowing each other from

Kob *Kobus kob*.

sight. Agonistic behaviour consists of a parallel walk and lateral body presentation with extensive vertical and lateral head-shaking with penile erection; more static agonistic behaviour consists of an erect posture often looking away from each other. Serious fighting occurs if the intruder does not withdraw. Components of fights are heavy clashes as well as horn-twisting and front-pressing close to the ground. This sometimes results in broken horns and almost inevitably in wounds at the head and neck. The fight is over if one combatant flees, being chased and targeted for stabbing by the winning chaser. Fighting over territory tenure is rare when population density is low and tenure in such populations can be as long as four years (Leuthold 1966, Fischer & Linsenmair 1999). In contrast, territories on leks can usually be defended for a few days only. Males who lose their territory tend to join bachelor herds and may attempt another turn at territoriality after regaining strength.

Where lekking occurs ♀♀ appear to visit territorial grounds where oestrous individuals are invariably mated. Females have access to all territories within their home-range but their choice of mate is likely to be determined by their reproductive physiology, which, in turn, may very well be influenced by external influences such as the scents and activities on territorial grounds. Males on central territories are preferred and the choices of other ♀♀ are copied, using olfactory clues (Balmford *et al.* 1992, Deutsch & Nefdt 1992). Males stay on their territories even when no ♀♀ are around except while visiting drinking sites in the dry season.

Courtship includes the ♂ sniffing and licking the ♀, flehmen, repeated foreleg lifting (laufs Schlag) and rising up bipedally up to 20 times before a vigorous ejaculatory thrust. Females may bleat when harassed by ♂♂. The ♀ can terminate courtship at any stage by lying down or leaving the territory (Balmford *et al.* 1992). Males rarely try to hinder ♀♀ leaving their territory and have not been observed to be successful in their attempts. Females may mate up to 17 times with up to nine different ♂♂ (Balmford *et al.* 1992) during their 24-hour oestrus. If fertilization does not occur, ♀♀ cycle at 20- to 26-day intervals and mate again until conception is achieved (Buechner *et al.* 1966). Females separate from groups shortly before giving birth. After parturition the ♀ visits and suckles the calf twice per day, but never moves very far away. Male calves move about alone or in the female herds as early as three months old. After weaning at 6–7 months, ♂♂ join bachelor herds and are chased away by territory holders when approximately one year old (by which stage their horns are about the length of their ears).

Behaviour depends on group size, with animals in smaller groups and single animals spending less time on behavioural traits that make them prone to predation, such as feeding and ruminating (Fischer & Linsenmair 2007). Anti-predator behaviour includes ♂♂ and ♀♀ approaching predators while whistling and jumping on the spot with stiff legs. Alarm whistles are shorter and emitted in higher temporal frequency compared with the territorial whistle of ♂♂.

Social grooming does not occur in Kobs, but ♀♀ lick their young and ♂♂ sniff, rub and lick ♀♀ during courtship. Females might poke, butt and snap at other ♀♀ when they get too close while feeding. There is no greeting behaviour and Kobs ignore each other when joining groups. However, ♂♂ approach each ♀ entering their territory and determine her reproductive status by sniffing the anal region.

Reproduction and Population Structure Kobs are polygamous. Spermatogenesis starts when ♂♂ are about one year of age. Ovulation begins when ♀♀ are 13–14 months old. Length of cycle is 20–26 days, with oestrus lasting probably less than 24 hours (Buechner *et al.* 1966). Breeding in most populations occurs throughout the year, although breeding peaks are known; for example, there is a birth peak in the dry season between Nov and Feb in Nigeria (Happold 1987), a mating peak in the late wet season (Oct–Nov) in Comoé N. P. (Fischer & Linsenmair 2002), Sep–Dec in S Sudan (Hillman & Fryxell 1988), and in the two wet seasons (Mar–May and Sep–Nov) in Uganda (Balmford 1992). Gestation has been recorded at about 180 days (Happold 1987), and 233–240 days (Buechner *et al.* 1966). A single calf weighing 4–5 kg is born; twins were either born dead or died shortly after birth (Buechner *et al.* 1966). There is a postpartum oestrus, and ♀♀ have the capacity to bear three calves within two years. In Comoé N. P. recruitment is much lower, with one calf every other year (Fischer 1998).

In Comoé N. P., adult ♀♀ accounted for 61.2% and adult ♂♂ 10.2% of the population (Fischer & Linsenmair 2002); the authors of this study attributed the sex ratio (0.34 males/female) to high poaching pressure, since Geerling & Bokdam (1971) had observed a sex ratio of 0.74 at a time when poaching pressure was lower. In 1986, during a severe drought, the overall sex ratio of Kobs around Waza N. P., Cameroon, was 0.53, not dissimilar to that in 1997, after a period with average rainfall; however, in 1986 the percentage of young was

only half of that in 1997 (Scholte 2005). A population of Uganda Kobs contained 16% adult ♂♂ and 54% adult ♀♀ (Balmford 1992). Adult sex ratio in Comoé N. P. population was 0.73 males/female in the 1970s and dropped to 0.34 in the 1990s (Geerling & Bokdam 1971, Mühlenberg & Roth 1985, Fischer 1998). Annual natality in Comoé N. P. ranged from 12.8 to 30.0% and newborn mortality was 48.5%. In captivity, Kobs live for more than 20 years (Weigl 2005). The oldest individually recognizable ♂ in the Comoé N. P. died in his eighth year and the oldest ♀ in her ninth year.

Predators, Parasites and Diseases The most important predators are Lions *Panthera leo*, Leopards *P. pardus*, African Wild Dogs *Lycaon pictus* and Spotted Hyaenas *Crocuta crocuta*. Wanzie (1986) found Lions to be the most important predator of Kobs in Waza N. P., accounting for 68.5% of predation (and see Van Orsdol 1984). Where Lions are rare, as in Comoé N. P., Leopards and Spotted Hyaenas take over the primary predator role. Baboons *Papio* spp. are known to take young calves and Side-striped Jackals *Canis adustus* predate young during their lying-up stage. One case of a Martial Eagle *Polemaetus bellicosus* killing a Kob was observed in Cameroon and a total of 15.3% of all deaths were due to drought in the same area (Wanzie 1986). African Rock Pythons *Python sebae* are also known to take Kobs in Uganda.

Thal (1971) reported the following ecto- and endo-parasites infesting Buffon's Kob: *Amblyomma variegatum*, *Linguatula nuttali*, *Stilesia* sp., *Fasciola gigantica* (and see Bindernagel 1972), *Setaria bicornata*, *S. pillersa* and *Theileria* sp. In Ghana, Ntiemoa-Baidu *et al.* (2005) recorded the following ixodid ticks on seven animals: *Haemaphysalis aciculifer*, *Rhipicephalus lunulatus*, *R. senegalensis*, *R. simpsoni* and *A. variegatum*. Küpper *et al.* (1983) found the following parasites and diseases in Kobs from the Comoé N. P.: *Theileria mutans*, *Babesia* sp., *Anaplasma marginale*, *Trypanosoma brucei*, *Eimeria intricata*, *Ascaris* sp., *Strongyloides* sp., *Trichuris* sp. and *Paramphistomum* sp.; Okaeme (1987) also recorded *Paramphistomum cervi* in Buffon's Kob. Graber *et al.* (1973) reported *Taenia hyaenae* in the muscles.

Conservation IUCN Category: Least Concern (*K. k. kob* – Vulnerable A2cd; *K. k. leucotis* – Least Concern; *K. k. thomasi* – Least Concern). CITES: Not listed.

Although very abundant in the past, Kobs are victims of unsustainable hunting over most of their range. Buffon's Kobs, formerly one of the most abundant antelopes in West and central Africa, are declining in most parts of their range, and are already extinct in Gambia and Sierra Leone (and perhaps Mauritania), and are considered rare in Guinea-Bissau, Guinea, Nigeria and N DR Congo. In many areas where they survive, they are largely confined to protected areas, although poaching has led to large-scale declines in many key populations. For example, Kob numbers declined by more than 80% within 20 years in Comoé N. P. in Côte d'Ivoire (Fischer & Linsenmair 2001a) and in N Central African Republic (Bouché *et al.* 2010), and numbers in Arly-Singou Faunal Reserve and surrounds (Burkina Faso) decreased from 5000 in 1982 to 700 in 1999 (Chardonnet 2001b). Such declines show that populations of Buffon's Kobs are very vulnerable to hunting, notwithstanding the fact that some 85% of the current population is estimated to occur in and around protected areas (East 1999). On the other hand, the population numbers in Waza N. P. decreased from 25,000 in 1962 to 2000 in the mid-1980s, largely due

to a general drying out of the habitat caused by droughts (especially in 1969–74) and disruption of the natural flooding regime from 1979 by the construction of the Maga Dam on the Logone flood-plain, which formed L. Maga. Rinderpest (1982/83) and poaching also probably contributed to declines. Further declines 1982–86 were exacerbated by the 1985/86 drought. Numbers recovered to 5000 in the 1990s (Scholte 2005, Scholte *et al.* 2007).

Protected areas important for the survival of Buffon's Kobs include Niokolo-Koba N. P. (Senegal), Comoé N. P., Arly-Singou Faunal Reserve (Burkina Faso), Mole N. P. and Bui N. P. (Ghana), Pendjari N. P. (Benin), Waza, and Bénoué and Faro National Parks of the North Province (Cameroon), Zakouma N. P. (Chad) and various reserves in Central African Republic (East 1999). Under strict protection Kob numbers can recover quickly, allowing sustainable off-takes of about 7% of the population (Mayaka *et al.* 2004).

White-eared Kobs were believed to have been affected by the ongoing civil war in S Sudan, particularly since this migratory subspecies is believed vulnerable in its wet-season concentration area along the southern margins of the Sudd; East (1999) estimated that less than 1% of the population is resident in nominal protected areas (such as Boma and Badingilo National Parks). However, White-eared Kobs appear to have withstood the pressures well, and the migrations described by Fryxell (1985) and Mefit-Babtie (1983) are continuing in what appear to be general patterns and size similar to those documented in the early 1980s (Fay *et al.* 2007).

Although some 98% of the remaining Uganda Kobs in East Africa occur in protected areas, particularly Queen Elizabeth N. P. and in Murchison Falls N. P. and Toro-Semliki (Uganda), these vestiges represent less than 1% of its original distribution in East Africa (J. Kingdon pers. comm.). The status of park populations likely will not change, although ongoing instability in DR Congo may affect populations in Garamba and Virunga National Parks (East 1999).

In conclusion, even though Kobs still occur in large numbers in some protected sites the species' future should cause grave concern. Due to their preference for open areas and the need to drink daily, these relatively slow animals are easy to hunt and their habitat tends to have prime agricultural or pastoral potential; population densities are therefore likely to decline further. Especially in West Africa and Sudan, formal protection of the species is not effective. West African national parks need to be managed professionally and efficiently. The flood-plain ecosystem that supports a viable population of White-eared Kobs in Sudan should receive protection status. 'They respond very well to protection and build up their numbers rapidly. Their potential as a managed resource is very considerable: ... an exceptionally valuable natural resource is going to waste unless more positive wildlife policies are implemented' (Kingdon 1982). Sustainable use projects of Kobs outside protected areas, especially the higher density areas in central Africa, might help to ensure the future survival of the species and provide practical incentives for their protection.

Measurements

Kobus kob

K. k. kob

HB (♂ ♂): 1410 (1360–1450) mm, n = 6

Kobus vardonii Puku

Fr. Puku; Ger. Puku

Kobus vardonii (Livingstone, 1857). Missionary Travels and Researches in South Africa, p. 256. Zambia, Barotseland, Chobe Valley, near Libonta (40° 30' S, 23° 15' E).

Puku *Kobus vardonii*.

Taxonomy The Puku was named in honour of a British elephant hunter, Major Frank Vardon, in the 1850s. Some authorities consider the Puku a subspecies of (e.g. Haltenorth 1963), or superspecies with (Ansell 1972), the Kob *Kobus kob*. Although Gentry (1990) included all Kobs and Pukus in *Kobus kob*, they have more recently been considered as two distinct species based on morphological data (Vrba *et al.* 1994). Molecular data (Birungi 1999, Birungi & Arctander 2000) reveal that the Puku lineage is highly distinct from that of other Kobs, but that the Puku is paraphyletic with respect to the Kob. Two subspecies have been recognized (Ansell 1972). Synonyms: *senganus*. Chromosome number: not known.

Description The Puku is a medium-sized, sexually dimorphic bovid. Pukus can be considered as the southern savanna equivalent of the Kob (Rodgers 1984b), although they differ in their smaller size, paler colouration, shaggier coat, absence of black markings, and shorter, thicker horns. Face has white bands extending forward from the top of the eyes to their inner margins. Upper lip is white and there is a white patch just behind the rhinarium on the sides of the muzzle. Forehead generally browner in colour than the rest of the body; upperparts golden-yellow, extending down outsides of the limbs. Throat, underparts of the body and insides of the limbs white. Tail same colour as body, with tuft of long hair towards tip. Pukus have well-developed inguinal pouches (40–80 mm deep), and, in contrast to other reduncines, active face glands (face glands are only poorly developed in Kob).

Horns (rarely recorded in ♀♀; see Ansell 1960b) are strongly ridged for two-thirds of their length, and smooth towards the tips.

Lateral view of skull of Puku *Kobus vardonii*.

Geographic Variation Geographical variation between the scattered and isolated remaining Puku populations has not been investigated, but considerable potential exists and its properties will depend on several, as yet unstudied, features (e.g. the history of population isolation, gene flow between populations, selection pressures). Ansell (1972) referred to the nominate *K. v. vardonii*, from parts of Angola, Zambia and NE Botswana, and also provisionally accepted *K. v. senganus* as a subspecies from the upper Luangwa Valley, Zambia. Swynnerton & Hayman (1951) allocated all Tanzanian populations to this subspecies, which also once occurred in Malawi. Further investigations into geographical variation in the Puku are needed, especially as recent work suggests that Pukus in Tanzania differ considerably from those in Zambia and may represent two evolutionary distinct forms (Cotterill 2003a, b).

Similar Species

K. ellipsiprymnus. Sympatric across much of the range. Larger size, and darker grey colouration with white buttock markings (in *ellipsiprymnus*, but not *defassa*); preference for dry bush and savanna habits.

K. leche. Sympatric in parts of Zambia (e.g. Kafue N. P.) and Botswana (De Vos & Dowsett 1966, Child & Richter 1969). Distinctive, elegant, swept-back horns and black marking on forelegs. Often form large aggregations and regularly move through shallow areas of open water.

K. kob. Allopatric, ranging from Senegal to Uganda, Sudan and SE Ethiopia.

Distribution Endemic to Africa. Historically, Pukus were widely distributed across the south-central African plateau (Schouteden 1947, Ansell 1978). East (1999) recorded Pukus present in eight countries (Angola, Botswana, DR Congo, Malawi, Namibia, Tanzania, Zambia, and marginally in Zimbabwe), distributed across south-central Africa, although some of these populations were reported to be very small and/or transient.

Current Distribution Rodgers (1984b) speculated that the current distribution of Puku was caused by the fragmentation of a once inter-

connected network of populations associated with major river valleys and is an explanation for the Puku's current association with upper basins of large rivers such as the Rufiji, Upper Congo and Zambezi. Many of these populations are small and under intense pressure from illegal hunting, and large populations of Puku can now only be found in Zambia and Tanzania (East 1999).

In Zambia, ca. 85% of Pukus occur within the protected area system, especially in parts of the Luangwa Valley (North and South Luangwa National Parks), the northern region of Kafue N. P., and Nsumbu and Mweru-Wantipa National Parks and Tondwa Game Management Area in the north-east (East 1999). Pukus have been reintroduced into several game ranches in Zambia, where they have proved a successful game ranching species. In contrast to Zambia, most Tanzanian Puku are restricted to the unprotected Kilombero Valley, where this still large population is under increasing pressure from changes in land use (Haule *et al.* 2002, Jenkins *et al.* 2003, Bennington *et al.* 2010). It is estimated that the Kilombero Valley contains at least 50% of all remaining Pukus (East 1999); a smaller population survives around L. Rukwa, but a population that survived along the northern shores of L. Malawi was extirpated before 1960 (Rodgers 1984b). In Malawi, they survive in Kasungu N. P. and Vwasa Marsh G. R., with occasional vagrants seen in Nyika N. P. (East 1999). Populations of Pukus still occur in NE Botswana on the Chobe River flood-plain (Child & von Richter 1969, Stuart 1989, Cotterill 2000, Dipotso & Skarpe 2006), and they occurred occasionally along the Upper Zambezi in NW Zimbabwe until the 1930s (F. P. D. Cotterill pers. comm.); they occur as a very rare vagrant in the middle Zambezi Valley (e.g. Dunham & Tsindi 1984), presumably through dispersal of animals from the Luangwa Valley in Zambia (Wilson & Cumming 1989). In Namibia, Pukus probably occur only as vagrants in the eastern Caprivi Strip.

Pukus were formerly abundant in much of Katanga, DR Congo (notably Upemba N. P.), but were greatly reduced by poaching along

with all large mammal populations (Frechkop 1954, von Richter *et al.* 1990, Hasson & Wolanski 1999); they survive in Kundelungu N. P. and perhaps in the Luama Hunting Zone. In Angola, there is no reliable information on the status of Pukus in the north-east (Lunda Norte and Lunde Sul provinces), where they were formerly widespread; they probably still survive in greatly reduced numbers, with a small population also in Luando Reserve (East 1999, Crawford-Cabral & Veríssimo 2005); Crawford-Cabral & Veríssimo (2005) also remark on their occurrence in the south-east, in the swamps and flood-plains between the Cuando and Luiana Rivers, but there is no information on their status in this area.

Habitat Pukus are closely dependent on perennially moist grasslands, and are a characteristic species of the grassy dambos that dominate the drainage across the south-central African plateau (Cotterill 2000, Moore *et al.* 2007). Favoured habitat types include river flood-plains and nutrient-rich, swamp grasslands, and they are rarely found far from permanent water during the dry season. In Kasanka N. P., Zambia, Goldspink *et al.* (1998) found the highest abundance of Pukus in open areas of river flood-plains and dambos. Although associated with wet areas and swamp vegetation, Pukus avoid deep standing water, and in that sense are ecologically distinct from lechwes. Lake-level rise was invoked as the reason for the decline in the L. Rukwa population in Tanzania (Rodgers 1984b) and an avoidance of water is the driving force behind reported movements out of flood-plains onto higher ground during the wet seasons (e.g. Jenkins *et al.* 2002a).

Descriptions of Puku habitat preference are most commonly reported from the dry season (e.g. Rodgers 1984b, Goldspink *et al.* 1998, TWCM 1999, Waltert *et al.* 2009), when the animals are easy to count from the air or on foot patrols. Many authors have reported that Pukus leave the flood-plains when the water level rises and move into more densely vegetated habitats on raised ground (e.g. Child & von Richter 1969, Goldspink *et al.* 1998). Jenkins *et al.* (2002a) compared Puku habitat use in the land at the edge of the Kilombero Valley flood-plain and found the highest levels of activity (assessed using dung and tracks) in the grassland with lower use of farmland and miombo woodland. They also found highest rates of Puku activity along flood-plain margins at the end of the wet season (Apr–May); however, Pukus did not use these areas in the dry season (when direct observations confirmed concentrations on the central flood-plain). Assessment of Puku use of woodland habitat and raised ground during the wet season has been largely neglected to date, but these habitats probably play an important role in Puku ecology (e.g. in explaining ecological responses to habitat loss or predation pressure). Given that the wet season is the period of calving and when human–wildlife conflict is at its highest, there is priority need to better understand habitat use by Pukus during the period spent away from savanna flood-plains.

Abundance East (1999) estimated the total population size at 130,000, with ca. 66,964 in the Kilombero Valley, Tanzania (TWCM 1999) and a further 21,000+ in Zambia. A recent aerial survey of the Kilombero Valley employed two complementary methods to assess the population size of Puku (TWRU 2003). When surveyed using the same methods as used on previous counts (e.g. TWCM 1994,

1999) the population was estimated at $23,301 \pm 5602$ SE, a notable decrease from the previous estimates of $55,769 \pm 19,428$ SE in 1989, $53,020 \pm 13,577$ SE in 1994 and $66,964 \pm 12,629$ in 1998. However, a more intensive survey was also undertaken (using 2.5 km transect spacing as opposed to 10 km) specifically to count the Puku and this resulted in a population estimate of $42,352 \pm 5927$ SE (TWRU 2003). Based on ground surveys, Bonnington *et al.* (2010) presented evidence of a significant decline in local Puku abundance over a five-year survey period at two sites in the Kilombero Valley from 1999 to 2003. Waltert *et al.* (2009) estimated the population in L. Rukwa at ~ 770 individuals, a decline from estimates made in the 1980s by Rodgers (1984b).

The population of Pukus on the flood-plains along the Chobe R. was believed to be in decline since the last census in 1965–67, following profound habitat changes caused by an increase in elephants and other large herbivores in the area. However, the population has shown a strong increase in numbers compared with the 1960s, although the concentration of the population has shifted eastwards, possibly as a result of direct human disturbance in the western part of the riverfront (Dipotso & Skarpe 2006).

Adaptations A key feature of Pukus and other kobs is their readiness to aggregate and their ability to assimilate poor-quality food, which promotes a rapid growth rate (Kingdon 1997). The high population growth rate of Pukus has been suggested to explain the rapid recovery of some populations following cessation of unsustainable poaching levels (Goldspink *et al.* 1998) and has also been discussed in relation to the commercial harvest of meat from large populations (Kingdon 1982).

The stomach structure of the Puku is typical of a roughage feeder and is similar in form to the Uganda Kob and Waterbuck *Kobus ellipsiprymnus*, which possess features typical of a grazer antelope dependent on water (Stafford & Stafford 1990).

Foraging and Food Pukus are obligate grazers (as classified by Gagnon & Chew [2000] in their review of dietary preferences in African bovids) and feed primarily on short grasses alongside permanent water bodies. Preferred grasses include *Brachiaria* (especially Jan–Mar), *Eragrostis* (Jul–Aug), and *Vossia* shoots in Dec (Child & von Richter 1969). Other grasses eaten include *Sporobolus*, *Panicum*, *Digitaria*, *Cynodon* and *Chloris*. Puku respond quickly to the presence of new food sources following fire and in the Kilombero Valley, Tanzania, they quickly appeared on lawns at the edge of the flood-plain in the wet season following the clearance of miombo woodland to make way for new teak plantations (G. R. Corti pers. comm.). Feeding activity is generally limited to early mornings and late afternoons but can also occur during the night.

Most of the information available on Puku habitat selection originates from Rosser's (1989, 1992) study in South Luangwa N. P., Zambia, with comparisons made between three seasons, wet (Nov–Apr/May), cool and dry (May–Aug) and hot and dry (Sep–Nov/Dec). Female Pukus selected six vegetation communities (swale sedge, swale forb, swale short grass, swale *Echinochloa*, back plain *Echinochloa* and *Oryza*) during the wet season (Rosser 1992). Habitat preferences changed according to the season and there was increased selection for long grass during the late dry season (Rosser 1992). Forage was superabundant during the wet months with

little variation in quality or quantity between the main vegetation communities. However, during the drier months, female selection was correlated with moisture (May), the percentage of green material (Jul) and the proportion of grass material composed of leaf (Sep). Male habitat selection differed between bachelors and territory holders (Rosser 1992). During the wet season, bachelor ♂♂ selected the mopane community and territorial ♂♂ selected the swale sedge community. In the drier months, although all ♂♂ selected the swale short grass community, bachelor ♂♂ also selected longer grass communities.

Social and Reproductive Behaviour Group composition varies and social bonds between the sexes are rare. Males defend territories (mean size 4.4 ha, Rosser 1992) and have not been observed lekking. In areas of suitable habitat and high Puku density, many ♂♂ have no territories and aggregate together in bachelor groups. Surveys in Kasanka N. P., Zambia, found that group size varied from one (lone males) to a maximum of 39, and density ranged from $25.2/\text{km}^2$ to $45.8/\text{km}^2$ (Goldspink *et al.* 1998). Male groups were smaller than female groups and maximum group size was 25 and 39, respectively. Males were mostly confined to bachelor herds, but a few lone individuals were noted stationed on prominent areas of relief. In Rodgers' (1984b) aerial survey of the Kilombero Valley, Puku modal group size was 1, 2 and 6–10, with a small number of larger groups (11–15 individuals). This group structure was also reported from a ground-based count in the Kilombero Valley by Corti *et al.* (2002), who found that modal group size for ♂♂ was 1, but it was larger for females (6–10) and calves (11–15). The results of these studies are largely consistent with earlier studies (De Vos & Dowsett 1966, Child & von Richter 1969), although De Vos & Dowsett (1966) recorded herds of up to 50 individuals.

Territorial ♂♂ differ from bachelor ♂♂ in both physical characteristics and behaviour (Rosser 1990). Territorial ♂♂ have thicker necks, copiously secrete from a seasonal 'neck-patch' and are more vocal (whistling) compared with bachelor ♂♂.

Goldspink *et al.* (1998) reported a scarcity of ♂♂ in Kasanka N. P. and a polygynous mating system probably based on the acquisition of territories. Comparisons of highly dispersed territories held by ♂♂ in sites with low habitat quality with grouped territories in areas of high habitat quality (and Puku density) revealed differences between male morphology and behaviour. Males in grouped territories had a higher incidence of horn damage, higher neck-patch intensity, higher territory loss rate and smaller territories (Rosser 1992). Females in the study area selected the largest territories with the largest area of short grass defended by ♂♂ with the darkest neck-patches and best condition. Female distribution and mate choice is thought to be simultaneously and independently related to both territory properties (e.g. high-quality forage, predation risk) and male phenotype (e.g. quality of the neck-patch). Males defended territories throughout the year, such that there is a trade off of foraging efficiency (unable to disperse to more optimal habitat to forage) against benefits conferred from territory ownership (Rosser 1992).

Males herd only oestrous ♀♀ and approach ♀♀ with head high, which is followed by laufsclag, urine-sniffing and finally flehmen and copulation. Calves lie concealed in thick vegetation for about a

month after birth and are retrieved and suckled each morning and evening (Estes 1991a). Males play no role in parental care.

Reproduction and Population Structure Rosser (1989) found calves in all months of the year, with a peak in births during the four wet-season months; only a few ♀♀ give birth during the dry season when food quality, quantity and cover is reduced. As with other kobs, Pukus' reproductive phenology is related to food availability, which in turn is related to seasonal patterns of rainfall and levels of standing water. Puku reproductive phenology is adapted to ensure calf survival through maximizing maternal nutrition to meet the demands of late pregnancy and early lactation, and possibly also takes advantage of ground vegetation to protect calves.

Oestrous behaviour rarely lasts more than 24 hours and the length of the oestrous cycle varies from 19 to 21 days. Gestation time is eight months (Rosser 1989) and a single calf is born weighing about 5 kg. Calves are weaned at seven months. Inter-birth interval is about 390 days (Rosser 1987). Estes (1991a) reports that ♂♂ are mature at three years and ♀♀ at two years, though Rosser (1987) reported them capable of conceiving as yearlings. Studies have consistently reported a female-biased sex ratio (De Vos & Dowsett 1966, Goldspink *et al.* 1998).

Predators, Parasites and Diseases Pukus are usually associated with open areas of wet grassland but readily move into cover if disturbed (Goldspink *et al.* 1998). The Kilombero Valley Puku population was struck by an eye infection during 1998 that may have increased their susceptibility to people and predators (reported in Jenkins *et al.* 2003). No quantitative data are available on predation pressures on Pukus, but they are likely to be the main prey of Lions *Panthera leo* and Spotted Hyaenas *Crocuta crocuta* when aggregated on flood-plains during the dry season. A single animal examined by Zieger *et al.* (1998b) in Zambia was host to the following ixodid ticks: *Boophilus decoloratus*, *Rhipicephalus appendiculatus* and *R. evertsi*.

Conservation IUCN Category: Near Threatened. CITES: Not listed.

Habitat fragmentation caused by expanding human settlements and cultivation is a major threat to Puku populations. Suitable habitats are either vacated by Pukus when disturbance/poaching is high (Goldspink *et al.* 1998) or are divided into smaller areas with a reduced population size and often with limited connectivity with the founders (e.g. Rodgers 1984b). The social/breeding system is particularly vulnerable to disruption by habitat fragmentation and hunting, with the longer-term impact of a collapse of population recruitment.

Pukus are relatively easy to approach during the dry season, when densely aggregated on flood-plains, and are consequently very vulnerable to illegal hunting. Unsustainable hunting and especially heavy poaching appear to have extirpated the Puku across its range (East 1999). Populations have collapsed since the early twentieth century, with widespread extirpations. The proliferation of firearms and the urban demand for bushmeat in central Africa during early 1900s signalled the first demise in Puku populations. Today, the burgeoning bushmeat problem in addition to the demand for land

by expanding human populations is subjecting the remaining Puku populations to intense pressure. The vulnerability of Pukus to unsustainable hunting underlies their decimation (Hughes 1933, Vesey-Fitzgerald 1961, Cotterill 2000). In Kasanka N. P., areas of suitable habitat remained unoccupied by Pukus due to high levels of poaching and disturbance (Goldspink *et al.* 1998).

In the Kilombero Valley, Jenkins *et al.* (2002) reported that the major threat to Pukus came from the expansion of cattle herds onto the flood-plain boundary and damage to wet season habitat by farmers who cleared miombo woodland. The fertile soils, flat land and good road and rail access to the Kilombero Valley makes it an attractive destination for immigrant farmers and new areas of forest are cleared each year for agricultural expansion (Haule *et al.* 2002). Levels of off-take by local people are difficult to determine, but are likely to be high in areas near to human settlements (Jenkins *et al.* 2002), because the Puku is a highly desired source of meat and also a valuable non-food resource (the skin is used for drums and furniture). Almost 20% of school children in Haule *et al.*'s (2002) household questionnaire survey reported eating Puku in their last meal.

When human settlements and farms expand into the areas traditionally used by antelopes during the wet season there is a greater risk of crop damage. In a questionnaire survey in the Kilombero Valley, 13% of respondents reported damage to crops by the seasonally abundant Puku, but animals like the Bushpig *Potamochoerus larvatus* (58%) and Yellow Baboon *Papio cynocephalus* (25%) that are present in the miombo woodland-evergreen forest-farm mosaic all year round accounted for most damage (Haule *et al.* 2002). During the wet season Pukus disperse out of protected zones into the surrounding mosaic of farms and miombo woodland bringing them into closer contact with humans. This is when poaching levels are probably most severe, but this part of the Puku's life history and ecology is poorly understood.

Comparisons of recent aerial surveys of the Kilombero Valley (TWCN 1994, 1999, TWRU 2003) revealed the small population (previously less than 120 individuals, East 1999) in the Selous G. R. has been extirpated and increased human activity in the south-eastern Kilombero Valley is effectively prohibiting its recolonization. The same surveys also indicated a decline in numbers of the main population (TWRU 2003). It is clear that the Kilombero Pukus have declined recently, and that increasing human activity, especially cattle-rearing, seriously threatens the remaining population (Haule *et al.* 2002, Jenkins *et al.* 2002, TWRU 2003, Bennington *et al.* 2010). Waltert *et al.* (2009) have also suggested that the Puku's current distribution to the south-west and east of Rukwa G. R. may be negatively affected by the seasonal presence of livestock and humans.

Today, besides Kilombero, key areas for the survival of the Puku include: Katavi N. P. in S Tanzania, Kafue N. P., the Luangwa Valley and Nsumbu-Tondwa-Mweru Wantipa in Zambia, and the smaller populations in Kasungu N. P. in Malawi and Chobe N. P. in Botswana (East 1999). Priority action to conserve the Puku across its range should include the following: (a) improving policing levels and management within existing protected areas; (b) habitat management and conservation in areas outside of parks that Pukus use during the wet season; (c) a detailed study of the interaction between seasonality, cattle distribution and Puku habitat selection

in the Kilombero Valley; (d) upgrading the conservation status of the Kilombero Valley in Tanzania, with establishment of a core protected area to include both dry and wet season refuges; (e) national surveys across the species' entire range to fully quantify and monitor abundance and distribution; (f) a thorough taxonomic reassessment of historical (using museum specimens) and extant populations employing morphological and molecular characters; and (g) continued promotion as a game ranch species within its historical range.

Measurements

Kobus vardonii

TL (♂♂): 1467 mm, n = 17

TL (♀♀): 1337 mm, n = 27

Sh. ht (♂♂): 921 mm, n = 17

Sh. ht (♀♀): 837 mm, n = 27

WT (♂♂): 77.3 kg, n = 17

WT (♀♀): 61.3 kg, n = 27

Zambia (Rosser 1987); mean values

Maximum recorded horn length is 56.2 cm for a pair of horns from the Luangwa Valley, Zambia (Rowland Ward)

Richard Jenkins

Kobus leche SOUTHERN LECHWE

Fr. Le Cobe lechwe; Ger. Moorantilope (Litschi)

Kobus leche Gray, 1850. Gleanings, Knowsley Menagerie 2: 23. Type locality originally described as 'banks of the river Zoaga, Lat. 21°'; now known to be the Botete R. past its junction with the Thamalakane at 20° 7', Botswana, although the species no longer occurs there (Smithers 1971).

Southern Lechwe *Kobus leche*.

Lateral view of skull of Southern Lechwe *Kobus leche*.

Taxonomy The morphological and phenotypic distinction between the Southern Lechwe *Kobus leche* and the Nile Lechwe *Kobus megaceros*, which occurs in Africa north of the Equator, is supported by karyotypic differences between the species (Kingswood *et al.* 2000). Four distinct lechwe populations (one extinct) are recognized as subspecies, based on a combination of differences in pelage colour, body size and skull measurements (Ansell 1972, Ansell & Banfield 1979), and corroborated by genetic studies (De Meneghi *et al.* 1995, Birungi & Arctander 2001). The latter authors found that genetic variability was lowest in the Red Lechwe *K. l. leche*, possibly due

to a genetic bottleneck that the Zambian population experienced in the past. A fifth population from Katanga in SE DR Congo, conventionally considered a form of the nominate species, may warrant treatment as another subspecies (provisionally the approach adopted here) or a separate species altogether (see Cotterill 2005). Synonyms: *amboellensis*, *anselli*, *grandicornis*, *kafuensis*, *lechee*, *leechi*, *notatus*, *robertsi*, *smithemani*. Chromosome number: 2n = 48; the X chromosome is a large acrocentric and the Y chromosome is a small metacentric/submetacentric (Kingswood *et al.* 2000). Putative subspecies *K. l. leche* and *K. l. kafuensis* exhibit karyotypic similarities (Kingswood *et al.* 2000). Gray (1972) reports a case of hybridization, in captivity, of a Nile Lechwe *Kobus megaceros* with a Southern Lechwe.

Description Stocky, medium-sized antelope, easily recognized by trotting gait with head thrust forward below the shoulders, accentuating the hindquarters, which are higher than the forequarters. Muzzle relatively short, eyes large and widely spaced. Tip of muzzle, gape, orbital surrounds and undersides of ears white. Posterior belly-skin naked and grey, as are udders. Pelage woolly in young, short to medium length in adults, light to dark brown or black (usually darker on the dorsal aspects), with thorax, insides of legs, throat,

Southern Lechwe *Kobus leche* female.

chin and undersides of ears and underside of tail white. Anterior of forelegs and lower hindlegs (excluding knees and pasterns) and tip of tail are dark brown or black. Hooves elongate and splayed when in contact with the substrate. Fetlocks naked or thinly covered with hair. Inguinal glands rudimentary; preorbital and pedal glands are absent.

The horns, present in ♂♂ only, are long, lyrate and annulated, with sharp forwardly curving tips.

Geographic Variation

K. l. leche (Red Lechwe): Botswana, Namibia, Angola and Zambia.

Pelage reddish-brown, usually slightly darker on the dorsal aspects; asymptotic mass of ♂ about 60% greater than ♀ (Williamson 1979).

K. l. kafuensis (Kafue Lechwe): restricted to the Kafue Flats, Zambia.

Distinguished by light brown pelage with dark brown to black patterning on forelegs, extending into patches on the shoulders of ♂♂; similar body size to nominate form, but mass of adult ♂ only about 30% greater than ♀ (Robinette & Child 1964); horns longer than those of Red Lechwe and Black Lechwe.

K. l. smithemani (Black Lechwe): restricted to the Bangweulu Swamps and Chambeshi system, Zambia. Pelage brown to dark brown or black, particularly on the dorsal aspects of older animals and especially in ♂♂; smaller than Red and Kafue Lechwe and mass of adult ♂ only 30% greater than ♀ (Grimsdell & Bell 1975).

K. l. robertsi (Roberts' Lechwe): extinct. Formerly restricted to the Luongo R., Luapula, Zambia. No significant association with other three subspecies (Ansell & Banfield 1979).

The lechwe recorded as occurring in SE DR Congo, previously assumed to be a form of the nominate species, has now been described as the Upemba Lechwe *Kobus leche anselli*, surviving in the Upemba wetlands of the Kamalondo depression (Cotterill 2005). It appears to be more closely related to the Black Lechwe than any of the other subspecies, while, like all the subspecies, its relationship to the extinct Robert's Lechwe remains enigmatic. Cotterill (2005) described this taxon as being smaller than the Red Lechwe, much smaller than the Kafue Lechwe in dimensions of skull and horns,

and most similar in stature and size to the Black Lechwe, but in all respects more gracile. However, the pelage of the Upemba Lechwe is similar in general colouration to the Kafue and Red Lechwes.

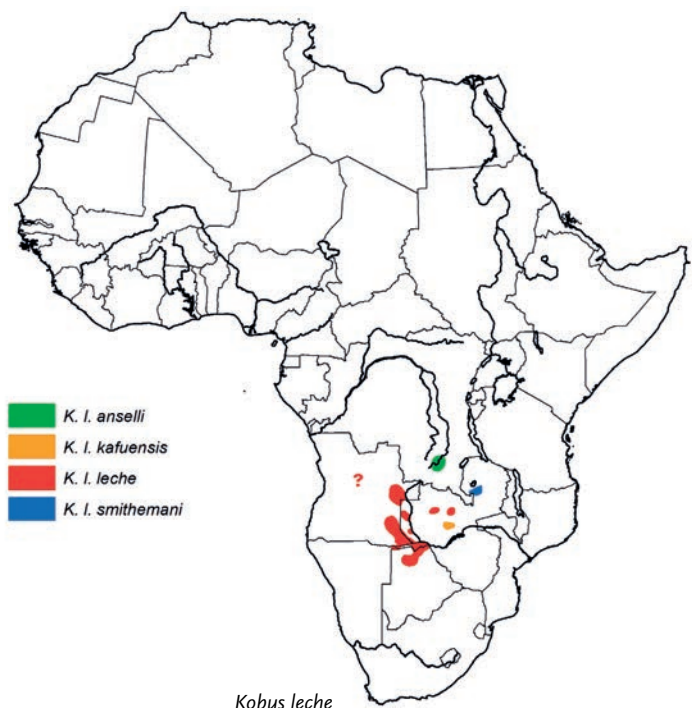

Similar Species

Kobus ellipsiprymnus. Sympatric with Red Lechwe, principally in the Busanga Plains of Zambia and the Okavango Delta of Botswana. Easily distinguished by greater size and grey, woolly pelage.

K. vardonii. Sympatric in parts of Zambia (e.g. on the Basunga Plains of Kafue N. P.) and Botswana (De Vos & Dowsett 1966, Child & von Richter 1969). Similar in appearance, but stockier build and more uniform reddish-brown, thicker pelage.

Distribution Endemic to Africa. The distribution of the Southern Lechwe is discontinuous, with major populations restricted to extensive wetlands in Botswana, Namibia, Angola and Zambia, and SE DR Congo. Present distribution is much the same as its historical distribution, except that range has contracted, particularly over the last century. There are no records of Southern Lechwes ever having occurred in Zimbabwe (Smithers & Wilson 1979).

The Red Lechwe is found in significant numbers in the Okavango Delta, and the Kwando/Linyanti/Chobe system of N Botswana; the Okavango, Kwando/Linyanti/Chobe, Mashi and Zambezi River systems of NE Namibia; and the upper Zambezi and middle Kafue of Zambia. Red Lechwes were also once common in Sioma Ngwezi N. P. of SW Zambia and the Lukanga Swamps of the upper Kafue in Zambia, the Kwando (Cuando) system of SE Angola (contiguous with the Kwando/Linyanti/Chobe system of Namibia and Botswana), the Zambezi flood-plains of E Angola, the Cuanza and Luando Rivers of C Angola, and the Cunene R. of SW Angola. The status of these last-mentioned populations is unknown, although reports indicate that they persist, with the exception of the Cunene population (Crawford-Cabral & Veríssimo 2005).

*Kobus leche*

The Kafue Lechwe is confined to the Kafue Flats, a large wetland area of the middle Kafue R. system of C Zambia.

The Black Lechwe is confined to the southern half of the Bangweulu Swamps of N Zambia. It is unlikely to survive in its former range on the Chambeshi flood-plains along the upper Luapula flood-plain that forms the common frontier between Zambia and SE DR Congo, at the western extremity of the Bangweulu Swamps. A population of Black Lechwes introduced in 1974 from the Bangweulu Swamps to the Bwela Flats on the upper Chambeshi between Kasama and Chinsali is reportedly extinct.

Remnants of a distinct population of lechwes known to occur in the Lualaba R. system of the southern Congo Basin of DR Congo, including the western extension of Upemba N. P., persist in the Kamalondo depression and have been described as the Upemba Lechwe (Cotterill 2005).

The extinct Robert's Lechwe is described as having been restricted within the Luongo and Kalungwishi drainage systems of the lower Luapula locality of NE Zambia, contiguous with the Congo Basin catchments of both the Black and Upemba Lechwe, but apparently a distinct population.

Habitat Lechwes are associated with wetlands of the Zambezan phytochorion of southern Africa, preferring the shallow water margins of flood-plains and swamps (less than a metre deep), although they may occasionally swim across deep-water areas. They typically frequent light woodlands and termitaria grasslands on the periphery of inundated flood-plains, flood-plain grasslands and water-meadows among seasonally inundated flood-plains, shallow water-meadows of permanently inundated swamps and lagoons, and occasionally papyrus and reed-beds of permanent deep-water swamps. Vegetation across these ecotones includes grasses, reeds and sedges such as *Loudetia* spp., *Sporobolus* spp., *Setaria* spp., *Oryza barthii*, *Echinochloa* spp., *Vetiveria nigritana*, *Brachiaria* spp., *Paspalum scrobiculatum*, *Acroceras macrum*, *Panicum repens*, *Leersia* spp., *Vossia cuspidata*, *Cynodon dactylon*, *Eragrostis* spp., *Phragmites* spp., *Typha* spp., *Cyperus* spp., *Eleocharis* spp. and *Pycnus* spp., aquatic herbs such as *Aeschynomene* spp., *Ipomoea* spp., *Polygonum* spp., *Potamogeton* spp., *Pistia stratiotes*, *Nymphoides* spp., *Nymphaea* spp. and *Utricularia* spp., and trees such as *Acacia* spp., *Albizia* spp., *Ficus* spp., *Syzgium* spp., *Phoenix reclinata* and *Hyphaene ventricosa*.

Abundance Estimates of abundance based on sampling techniques are relative, and thus more useful for determining population trends rather than actual numbers. Unless otherwise specified, the following estimates of abundance have been drawn from East (1999).

The most stable and well-documented population of Red Lechwes is in the Okavango Delta, Botswana, where numbers were estimated during the mid-1990s to be 69,520. Numbers of Red Lechwes in Botswana's Kwando/Linyanti/Chobe system appear to have declined from some 10,000–15,000 in the 1970s (Williamson 1979) to 2310 in the mid-1990s. The Red Lechwe population of Namibia's Protected Areas and communal lands of the Caprivi Strip was estimated to be 4470 in the late 1980s, with the majority (4300) occurring in the communal areas. Populations of Red Lechwes elsewhere are not well documented, but significant populations remain in the Liuwa Plains (including the upper Zambezi flood-plains) and Busanga Swamps of Zambia (R. Jeffery & R. Nefdt pers. obs.). The overall numbers of Red Lechwes, then, in central and southern Africa are likely to

be not less than 80,000, with the majority of the population in the Okavango.

The Kafue Lechwe population has been monitored for many years, and probably has the most reliable time-series of population records of all the subspecies. In the 1930s, numbers were reputed to be in the order of 250,000 (Pitman 1934). Although this early estimate was not determined by systematic surveys, it is plausible considering that the maximum carrying capacity of the Kafue Lechwe's range has been estimated to be 360,000 (Bell *et al.* 1973). In the early 1970s, estimates consistently put the population at between 90,000 and 110,000 (Bell *et al.* 1973). By the early 1980s the population had been reduced to between 40,000 and 45,000, but it then slowly increased fluctuating thereafter between 50,000 and 70,000 (Jeffery *et al.* 1993). The most recent estimate (2005) put the population at $38,448 \pm 7392$ (Chansa & Kampamba 2010).

As with the Kafue Lechwe, historical population estimates of Black Lechwes were high, with a figure of 450,000–600,000 being proposed for the Bangweulu Swamps (Pitman 1934). Early records have been extrapolated with ecological criteria to suggest a more realistic estimate of 200,000 Black Lechwes for the early 1900s up to 1936 (Grimsdell & Bell 1975). Dramatic increases in water levels of the Bangweulu Swamps and hunting after 1936 are likely to have had a major impact on Black Lechwe numbers. By 1944, the population had decreased to between 30,000 and 60,000, falling further to about 17,000 in 1969, but increasing slightly by 1973 to 25,000 (Grimsdell & Bell 1975). The population increased further to about 40,000 by 1983, but decreased again to about 32,000 by 1994 (Kamweneshe *et al.* 1994, Thirgood *et al.* 1994). A figure of 150,000 Black Lechwes has been proposed as the carrying capacity for the current range of Black Lechwes in the Bangweulu Swamps (Grimsdell & Bell 1975).

The Upemba Lechwe population of DR Congo has declined from about 20,000 to less than 1000 since the 1980s (Cotterill 2005).

The overall population trend of lechwes in central and southern Africa is negative, probably as a result of excessive hunting, habitat encroachment and both natural and human-induced changes in the flooding regimes of the lechwes' wetland habitats (Grimsdell & Bell 1975, Sayer & Van Lavieren 1975). Negative population trends have been exacerbated in the 1990s by increased human access to wetlands following a period of lower than average rainfall hence reduced water levels. There may have been as many as a million lechwes in southern and central Africa in the early 1900s, taking into account the species' historical distribution and abundance suggested above. By 2000, the total population of the species was probably in the order of 200,000.

Adaptations Although different and not as extreme as the adaptation to aquatic habitats of the Sitatunga *Tragelaphus spekii*, the Southern Lechwe's slightly elongated and splayed hooves facilitate locomotion in muddy swamps while their naked fetlocks minimize the risk of infections of hooves under constantly damp conditions. Southern Lechwes are thus well adapted to wetland habitats, and are often found foraging in water up to shoulder-height. They are proficient swimmers and readily cross inundated flood-plains, lagoons, channels and even rivers to reach habitats preferred for a variety of activities. During periods of extreme flooding, lechwes move to drier (and often more wooded) areas on the margins of their usual range. They also move into drier areas during periods

of heightened reproductive activity, but during calving may take refuge in deeper swamps that are less prone to disturbance. Diurnal movements may occur between flood-plain margins and deeper swamps, probably alternating between foraging, resting and seeking refuge. Lechwes readily take to the water when threatened by predators and other disturbances.

Stomach physiology is similar to other water-dependent grazers, such as reedbucks *Redunca* spp., Waterbucks *Kobus ellipsiprymnus*, Pukus *K. vardonii* and Kobs *K. kob*. Stafford & Stafford (1991) have suggested functional adaptation to grazing on aquatic grasses.

Lechwes provide an example of how a species may adapt its reproductive behaviour to changes in ecology, including those induced by human activities. Peak calving period in most populations has been reported to be between Jun and Oct. However, following the construction of hydro-electric facilities on the Kafue R. in Zambia and change in the flooding regime of the Kafue Flats, calving in the Kafue Lechwe shifted by three months into the wet season between 1989 and 1991 (Nefdt 1996). It is possible that rising water levels stimulate lechwe to mate, resulting in maximum calving after the flood recedes, a period where exposed high-quality forage provides ideal conditions for lactating ♀♀ and their calves. Delaying or prolonging flooding of the Kafue Flats by a few months due to operation of the hydro-electric dams may have caused mating in the Kafue Lechwe population to occur later, thus delaying the period of peak calving (Nefdt 1996).

Foraging and Food Southern Lechwe are grazers, feeding mainly on flood-plain and aquatic grasses, including *Vossia cuspidata*, *Panicum repens*, *Acroceras macrum*, *Paspalum orbiculare*, *Oryza barthii*, *Oryza longistaminata*, *Cynodon dactylon* and a number of *Echinochloa*, *Brachiaria*, *Leersia*, *Sacciolepis*, *Eragrostis* and *Setaria* spp. (Rees 1978a, b, Williamson 1979, 1990, Nefdt 1993). They also feed on sedges, reeds and other aquatic plants, including *Scirpus*, *Pycneus*, *Cyperus*, *Eleocharis* and *Aeschynomene* spp., and may feed in water up to shoulder height. The exposure of large expanses of flood-plain grasslands during flood recession can lead to the concentration of lechwe in large numbers, and densities as high as 1000/km² have been recorded in the Kafue Flats.

Food supply is greatly dependent on the seasonal flooding of wetlands. In southern Africa, peak flooding generally occurs towards the end of the wet season (Mar–Apr) receding gradually through the cool dry season, but considerably later in the Okavango Delta (Jul–Aug) where it is dependent upon distant floodwaters reaching the Okavango R. and its delta system from the Cubango and Cuito Rivers deep in Angola. On the Kafue Flats, seasonal flooding has been artificially regulated by hydro-electric impoundments since 1971.

Changes in the waterline by seasonal inundation of flood-plain habitats result in lechwes moving between areas with a diversity of plant communities (Nefdt 1993). Lechwes are subject to their greatest nutritional stress at the height of flooding when flood-plain grasslands are too deeply inundated for grass to grow or lechwes to forage easily. Under these circumstances, lechwes may be forced out of flood-plain habitats into peripheral woodlands to graze on poor quality grasses and even to browse on shrubs. Lechwes may thus move over several kilometres within a day, often crossing dry areas, after which they usually drink upon arriving at new water sources.

In common with other ungulates, Southern Lechwes spend most of their time (between 54 and 76% depending on age/sex class) feeding and ruminating, with all activities demonstrating the effect of seasonal and environmental conditions on behaviour (Williamson 1993). However, diurnal variation in activity patterns is far less distinct than in dryland antelopes due to their association with wetlands, reducing their exposure to heat-stress and enabling them to indulge in all activities at all times of the day (Williamson 1993).

Social and Reproductive Behaviour Lechwes are among the most gregarious of the ungulates, and may move considerable distances (20 km or more in a matter of days) in large mixed herds of as many as 5000 animals following flooding and flood-recession in their wetland habitats. Group sizes and associations can be broadly divided into several types. The most common are mixed-sex herds that consist typically of over 65% ♀♀ and calves. Males continuously compete for ♀♀ and supremacy, resulting in dominant ♂♂ excluding large numbers of mature and immature ♂♂ from these herds. Excluded ♂♂ assemble in bachelor herds, and where such population densities are high, such as in Black and Kafue Lechwes, male herds can consist of more than 1000 individuals (Williamson 1979, Nefdt 1993).

Mating systems and associated reproductive behaviour are highly variable both within and between subspecies, and appear to be determined by social structures and population densities that in turn are influenced by the variability of habitats and conditions they must adapt to within the wetlands environment. Red and Black Lechwe breed on stable resource-defence territories, or defend harems of ♀♀ that move within relatively small home-ranges (Williamson 1994a, Nefdt & Thirgood 1997), whereas Kafue Lechwes breed predominantly on mating arenas or 'leks' (Schuster 1976, Deutsch & Nefdt 1992, Balmford *et al.* 1993, Clutton-Brock *et al.* 1993, Nefdt 1995).

Reproductive studies of Kafue Lechwes (Balmford *et al.* 1993, Clutton-Brock *et al.* 1993, Nefdt 1995, Nefdt & Thirgood 1997) show that this subspecies exhibits the most variability in mating behaviour, probably owing to the highly variable habitats and ecological conditions they encounter, and probably exaggerated by artificial flood regulation of hydro-electric facilities at either extremity of the Kafue Flats. Mating strategies include: scramble competition in large mixed-sex herds, resource-based territories, harem defence polygyny and lek-breeding. Harassment of oestrous ♀♀ by many ♂♂ in large mixed-sex herds, and the subsequent reduction in successful matings, may play a part in over 90% of all ♀♀ preferring to mate with ♂♂ defending tiny territories or 'leks' (Nefdt 1995).

Leks are traditional sites used as mating grounds, where up to 100 ♂♂ defend tiny territories that ♀♀ visit solely for mating. A sexual frenzy is the norm at these leks during sunrise and sunset, with ♀♀ attempting to mount ♀♀ (over 100 attempts per hour) and ♂♂ copulating with oestrous ♀♀ every 10 min. Deliberate mate choice by oestrous ♀♀ on these leks is quite clear with 10% of lek ♂♂ achieving 80% of all matings (Deutsch & Nefdt 1992, Clutton-Brock *et al.* 1993). It appears that ♀♀ also use olfactory cues in the soil on lek territories to choose mating partners (Deutsch & Nefdt 1992).

Between one and three ♂♂ often mate with more than 30 ♀♀ in a day (Clutton-Brock *et al.* 1993, Nefdt 1993). A few peripheral

territorial ♂♂ are able to intercept oestrous ♀♀ and mate, but this usually represents less than 5% of all matings. Younger ♂♂ often exhibit cleptogyny, by roaming between lek territories and intercepting oestrous ♀♀, and ejaculating within seconds of mounting.

A single ♂ may mate with over 300 ♀♀ on the same 100 m² lek territory over a period of one month, but successful ♂♂ are usually replaced within seven days. With such turnover rates, it is estimated that not more than 1000 ♂♂, out of a total male population of 20,000, are able to mate per year. Therefore, approximately 5% of ♂♂ in the entire Kafue Lechwe population are the fathers of all offspring each year.

Although Black Lechwes have also been reported to breed on leks (Grimsdell & Bell 1975), more recent studies have been unable to record such behaviour and found that ♂♂ defended contiguous 1–2 ha resource-based territories (Thirgood *et al.* 1992). During the wet season, from Nov to Mar, networks of thousands of these territories are spread across the vast flood-plains of the Bangweulu. On some elevated sites, ♀♀ form harems and dominant ♂♂ defend these small areas. These sites superficially resemble leks, but resources on the territories influence females' choice, and, therefore, these areas must still be regarded as resource-based territories. Lekking may not develop in the Bangweulu because vegetation resources and hence female lechwes are evenly distributed. Harassment rates of oestrous ♀♀ on single territories are considerably lower than in the Kafue Flats. Males with territories containing better grazing generally gain more ♀♀ and achieve higher mating rates than ♂♂ defending territories with poorer resources.

Males ascertain the reproductive status of the ♀ by sniffing her vulva or urine flow and performing flehmen. If the ♀ is in oestrus, he moves alongside her, lifting his foreleg from the ground (laufs Schlag), while grunting and flicking his tail. If the ♀ is receptive, copulation may follow, intromission being achieved with a single pelvic thrust, although many mountings sometimes occur (Robinette 1963).

Females about to give birth leave the herd singly or in groups. The calf remains hidden for the first few weeks, the ♀ returning

to suckle at regular times throughout the day. Thereafter, only very young calves accompany their mothers, moving independently when older. Individual crèches of up to 50 calves have been seen on the Kafue Flats.

A variety of vocalizations and behavioural displays have been recorded in Southern Lechwes. Vocalizations consist mostly of bleats, grunts and snorts, these varying in pitch, intensity and duration depending on age and sex, and functional associations with greetings (such as mother–young calls), dominance, courtship, alarm and distress (Williamson 1994a). Typical behavioural displays include erect postures and horn threats in dominant ♂♂, laying back of horns and rapid head-tossing in submissive ♂♂, agonistic horning, agonistic grazing, grooming, head and neck stretched forward with rapid tongue-flicking in ♂♂ approaching ♀♀, courtship displays including laufs Schlag and flehmen, and post-copulatory displays (Williamson 1994a).

Reproduction and Population Structure Breeding occurs throughout the year in Southern Lechwes, but with peaks in calving between Jun and Oct (Robinette & Child 1964, Grimsdell & Bell 1975, Sayer & Van Lavieren 1975, Williamson 1991, Thirgood *et al.* 1992). Variations in both reproduction and population structure occur as a result of natural or artificially induced ecological changes (for example, from the effects of fluctuating seasonal rainfall and hydro-electric impoundments on hydrological regimes) that in turn affect nutrition.

Males are sexually active from about 18 months (all animals weighing more than 55 kg showed active spermatogenesis; Williamson 1992), ♀♀ from about 24 months (Williamson 1991), and later in populations under nutritional stress. However, ♂♂ are unlikely to mate successfully until they acquire territories (from 4–5 years). The gestation period is about 7.5 months (Grimsdell & Bell 1975). Females produce a single calf, weighing about 5 kg; twinning is rare. The parturition interval is about one year. Lactation continues for up to seven months (Robinette 1963), but weaning often extends into a following pregnancy. During the first few months the horns grow straight, but as they grow they gradually curve backwards and outwards. In captivity, they have been known to live for more than 25 years (Weigl 2005).

Mean reproductive rates in ♀♀ are in the order of 73%, with fecundity approaching 100% in healthy female populations between five and ten years old. Southern Lechwes are capable of rapid rates of population increase, and up to 25% per annum has been observed for Red Lechwe in the Busanga Swamps and Black Lechwe in the Bangweulu Swamps. An intrinsic rate of increase was calculated to be 0.265, or a finite rate of increase of 30% per annum (Grimsdell & Bell 1975). Actual rates of increase vary according to population status and condition.

Where population sizes are large, such as in the Kafue and Black Lechwe populations, herds can consist of as many as 5000 individuals of mixed ages and gender. However, adult ♀♀ usually outnumber adult ♂♂, partly because dominant ♂♂ exclude other ♂♂ from these herds, but possibly also because male mortality is higher. Outcast ♂♂ usually congregate in bachelor herds sometimes consisting of more than 1000 individuals. In contrast, population densities of Red Lechwes are much lower, with groups usually containing less than 200 animals.

Colouring in male Southern Lechwe *Kobus leche* (and in other reduncines) emphasizes expression by concentrating white patterns around the mouth, eyes and ears.

Predators, Parasites and Diseases Principal predators include Nile Crocodiles *Crocodylus niloticus*, Lions *Panthera leo*, Leopards *P. pardus*, Spotted Hyenas *Crocuta crocuta*, Cheetahs *Acinonyx jubatus* and African Wild Dogs *Lycaon pictus*, while predation by jackals *Canis* spp. and African Rock Python *Python sebae* has also been recorded.

In their natural environment, Southern Lechwes appear resilient to or tolerant of livestock diseases such as trypanosomiasis. However, bovine tuberculosis (e.g. Gallagher *et al.* 1972, Stafford 1991, Zieger *et al.* 1998c) and heartwater (Pandey *et al.* 1992) have both been recorded from lechwes. Kock *et al.* (2002) examined 22 Kafue Lechwes and diagnosed the following conditions: microscopic granulomatous lesions with prominent giant cells, consistent with tuberculosis, in the lungs of two animals; microscopic hepatic granulomata, presumably caused by schistosomiasis, in eight animals; splenic haemosiderosis in six; splenic extramedullary haematopoiesis in six; acute to subacute perifollicular eosinophilic splenitis and lymphoid hyperplasia in four; periportal hepatitis in seven; myocardial sarcosporidiosis in 11; and pulmonary anthracosis in four. However, other than a case of bronchopneumonia, none of the lesions was considered of clinical importance. Heartwater was not detected, but may be due to the small number of animals sampled.

Parasitic infections include liver flukes, lungworms, nematodes (e.g. *Haemonchus contortus*; Zieger *et al.* 1998a), trematodes (such as *Callicophoron* sp., *Schistosoma* sp. and *Fasciola gigantica*; Gallagher *et al.* 1972, Zieger *et al.* 1998a, Kock *et al.* 2002) and warble flies (particularly *Strobiloestrus vanzyli*; see Stafford 1991, Zieger *et al.* 1998a), particularly where there is regular contact with domestic livestock or under captive conditions when infections may become pathogenic. A survey of helminths in Kafue Lechwe recorded 11 different types of helminths, with amphistomes (100%) and *Oesophagostomum* (60.9%) the most common identified. There was no evidence that infections, in the intensities observed, adversely affected the health of the lechwe, although these animals could serve as a potentially stable source of infection to domestic livestock (Phiri *et al.* 2011). Infections with *Eimeria* spp. were documented in all but one of 22 culled animals examined by Kock *et al.* (2002).

Ixodid ticks collected from Southern Lechwes include *Amblyomma variegatum*, *Boophilus decoloratus*, *Rhipicephalus appendiculatus*, *R. evertsi* and *R. lunulatus* (Stafford 1991, Zieger *et al.* 1998b).

Conservation IUCN Category: Least Concern (*K. l. smithemani* – Vulnerable D2; *K. l. kafuensis* – Vulnerable D2; *K. l. robertsi* – Extinct; *K. l. anelli* – Critically Endangered A2cd; *K. l. leche* – Least Concern). CITES: Appendix II.

The principal populations of Southern Lechwes in southern Africa are distributed amongst wetlands that all enjoy some degree of status as protected areas (excluding captive and game-ranch populations). In spite of this, poaching, encroachment and habitat destruction pose growing threats to the conservation of lechwes. Poaching has been implicated in apparent large-scale changes in the dry season distribution of the Black Lechwe, with a dramatic decrease in the numbers occupying the western end of the main Bangweulu Swamps (East 1999).

In Botswana, Red Lechwes occur in Moremi G. R. and Chobe N. P. but are also widespread outside these protected areas. In Zambia, Red Lechwes occur in Sioma Ngwezi, Liuwa Plains and Kafue

National Parks, and the West Zambezi and Kasonso-Busanga Game Management Areas. In Namibia, small numbers of Red Lechwes occur in Western Caprivi G. R. and Mahango Game Park, but the majority fall outside Namibia's protected areas. In Angola, Red Lechwes occur in Kameia N. P. and Luando, Mavinga and Luiana Game Reserves.

Kafue Lechwes occur only in Lochinvar and Blue Lagoon National Parks, both designated as wetland sites of special importance under the Ramsar Convention, and the Kafue Flats Game Management Area in Zambia. The population appears to be declining due to hunting and the construction of the Iteszi-tezhi dam.

Black Lechwes occur only in Bangweulu Game Management Area, which includes Chikuni Special Conservation Area (also a Ramsar site), and Kalasa-Mukoso Game Management Area in Zambia. The small population reintroduced to the Bwela Flats of the upper Chambeshi has not survived. Black Lechwes no longer occur in any National Parks, and Isangano N. P., established partly to protect this subspecies, is currently encroached and depleted of most wildlife.

In DR Congo, Upemba Lechwes still occur in the western extension of Upemba N. P., where they are highly threatened, mainly by commercial poaching (Cotterill 2005).

Kobus megaceros NILE LECHWE (MRS GRAY'S LECHWE)

Fr. Le Cobe de Madame Gray; Ger. Frau Grays Wasserbocke (Weissnacken-Moorantilope)

Kobus megaceros (Fitzinger, 1855). Sitzb. K. Akad. Wiss. Wien XVII: 247. Sudan, Upper Nile Prov., 'Bahr el abiad' or according to the collector, von Heuglin (Nov. Act. Acad. Caes. Leop. Carol. Germ. Nat. Curios., Abhand. 30, part 2, p. 14 [1863]), 'am Sobat, Bhar ghasál und untern Kir' (Bahr el Abiad or White Nile, Bahr el Ghazal, Kir River or lower Bahr el-Jebel, and Sobat River); restricted to 'Mouth of the Bahr el Ghazal at its junction with the White Nile' (Roosevelt & Heller, 1915: 519).

Nile Lechwe *Kobus megaceros*.

Taxonomy Monotypic. The Austrian naturalist Theodor von Heuglin discovered this antelope in 1853. In 1854, he brought some skins and skulls of this species to Vienna and a living ♀ was kept at the Imperial Menagerie at Schönbrunn. Leopold Fitzinger described von Heuglin's specimens and the environment in which they were captured, thus taking priority for the species' name. He mentioned von Heuglin's intention to name the new species 'Adenota megaceros Heuglin' (a name that emphasizes the size of the horns: Greek *mega* big and *kera* horn), but von Heuglin did not publish a description until 1863. The name *Kobus maria* (Gray, 1859), was established on the basis of specimens collected on the White Nile and in ignorance of Fitzinger's description. Gray named the species in honour of his wife, Maria, and this gave rise to the popular name 'Mrs Gray's Lechwe'. The Nile Lechwe was once subsumed in the genus *Onotragus* (Patrizi 1937). To date there are no known fossils that can be related to this species (Gentry 1978).

Synonyms: *maria*. Chromosome number: $2n = 52$; the X chromosome is a large acrocentric and the Y chromosome is a

Lateral and palatal views of skull of Nile Lechwe *Kobus megaceros*.

small metacentric/submetacentric (Wurster & Benirschke 1968, Kingswood *et al.* 2000). Gray (1972) documents records of hybridization between Defassa Waterbucks *K. ellipsiprymnus defassa* and Nile Lechwes, which produced a fertile ♀, and between Kobs *Kobus kob* and Nile Lechwes, and between Southern Lechwes *Kobus leche* and Nile Lechwes.

Description Medium to large-sized robust antelope, with short face, elongated and slender limbs and long rough hair; the long hindlegs and well-muscled haunches tend to elevate the rump. There is pronounced sexual dimorphism, both in terms of size and patterning. Male pattern and colouring differs greatly according to age and is, perhaps, also under hormonal control. In subadult ♂♂, starting at the age of two, the pelage changes from yellow-ochre to tawny russet eventually reaching the reddish to blackish-brown colour characteristic of adult ♂♂. Mature ♂♂ have a white patch (with or without interruptions) running from the head, between the ears, down the nape to the upper shoulders. This is variable in width and brightness, but generally, at the age of two, the white patch begins as a light-coloured area, gradually becoming bright white and contrasting very strongly with the dark colour of the rest of the body with maturity. Occasionally, the patch is absent and sometimes it can

darken in relation to individual hormonal and social status. Typical facial pattern has white markings strongly contrasting with the blackish forehead and suborbital areas; white supraorbital markings loop incompletely around the eyes; chin, lips and margins of the nostrils white. Inguinal pelage is white. Hair is longer and thicker, like a beard, from the cheeks to the lower throat to the dewlap. Legs are dark, with a light whitish area above the hooves.

Adult ♀♀ are smaller than ♂♂. Pelage from yellowish-ochre to tawny-chestnut brown, with dark patches appearing in some older ♀♀, mainly on the upper forelegs and hindlegs. Throat, belly, shoulders, hindquarters and legs lighter. Cheeks darker brown; area under the eyes blackish, with incomplete white 'spectacles' around the eyes; upper lips and chin bright white; white-lined, pointed ears also conspicuous, but backs of ears are ochre or tawny-chestnut in ♀♀ (and immature ♂♂). Aged ♀♀ have longer and thicker pelage on the throat. In both sexes, the tail is long, sometimes whitish, with a conspicuous terminal black tuft. Young of both sexes are coloured like ♀♀. Calves, until the fourth month, are pale grey-yellowish. Hooves of the species are spread out and very elongate; inner hoof narrow, and outer hoof wide and stubby; back of the pasterns naked. Inguinal glands present; pedal and preorbital glands absent.

Horns, present in ♂♂ only, annulated (from 20 to more than 30 annulations), lyrate, double-curved; the first section broadly curved backwards and outwards, the second section, shorter, varies in shape and direction of the curve (more or less diverging outwards, but in some individuals the tips converge inwards). Horn cores with little mediolateral compression inserted farther behind the orbits than in other reduncines; wide nasals and very strong longitudinal ridges on the basioccipital (Gentry 1978).

Geographic Variation None recorded.

Similar Species

Kobus kob. White-eared Kob (*K. k. leucotis*) occurs sympatrically.

Similar in colouring, but with sleeker pelage, with shorter legs and less measured gait. Kob ♂♂ distinguished by white underside, chin and upper throat.

Distribution Endemic to Sudan and Ethiopia. Once possibly more widespread along the Nile R. and indeed they probably once occurred as far north as Egypt based on evidence of archaeological remains (Osborn & Osbornová 1998). Today, populations occur in S Sudan, in the 'Sudd' swamps and wetlands, along the Bahr el Gazal, at its confluence with the Sobat, along the Bahr el Zeraf, the Bahr el Jebel (White Nile) and in the Machar marshes at the Ethiopian border. More peripheral herds (most likely overspill from the Machar marshes population) have been recorded from the Pibor, Akobo, Gilo and Baro Rivers, and also from near Gambella, in SW Ethiopia (Yalden *et al.* 1984, Hillman 1988a, Hillman & Fryxell 1988, East 1999). Several herds comprising a hundred individuals were observed near the Lakes Nyuborn and Yirol (Hillman & Fryxell 1988). Recent surveys in S Sudan reveal that the Nile Lechwe remains widespread along the Nile R. (Fay *et al.* 2007).

Habitat The primary habitat is swamps and marshes subject to seasonal inundation. They are almost always in shallow waters on the edge of deeper swamps where the water is between 10 and

Kobus megaceros

40 cm deep (Mefit-Babtie 1983). In all areas occupied by the Nile Lechwe, differences between dry and wet seasons are marked but local patterns of flooding have the most influence on the species. In the Sobat system rains begin in Apr, peak in May and by mid-Jun the whole Sobat area is flooded. Rainfall tails off and ceases completely in Nov when the dry season begins. In Mar and Apr temperature reaches 45 °C.

In the Sudd proper, Nile Lechwes are mainly confined to the river-flooded grasslands that lie between deep swamp (dominated by *Cyperus papyrus* and Sudd grass, *Vossia*) and the drier rain-flooded grasslands (dominated by thatch grass, *Hyparrhenia rufa*). This river-flood zone, or *toic* (an ecotype named from a local Dinka term), is dominated by swamp antelope grass (*Echinochloa stagnina*), rice-grass (*Leersia*) and wild rice (*Oryza*) and has numerous pools edged with bulrushes and water-lilies. Within the *toic* the lechwes follow fluctuating margins between shallow floodwaters and drier ground. This involves continuous seasonal drifting up and down the flood tide lines. As floods deepen (about May), the lechwes move further from the river and/or upstream, travelling as far as 30–40 km between high- and low-flood seasonal pastures. Because movement is today severely constrained by dense settlement and livestock herds all around the swamps, the lechwes tend to converge on levees and termite complexes deep within the *toic* until the floods begin to subside in about Oct. By the time fires are burning the flood-plain (Jan–Mar) the lechwes occupy the patchy margins of the permanent swamp where they avoid papyrus, but are commonly found in Sudd grass. At this time competition for grazing is keen and large herds of cattle tend to force the lechwes deeper into the swamps (Howell *et al.* 1988, Kingdon 1997).

The Nile Lechwes' strong preference for river-flooded *toic* and their progressive forcing, by cattle, into deeper swamps during the late dry season was evident in the results of three aerial surveys made in 1981 and 1982. These surveys covered the eastern flood-plains and swamps of the Sudd (about half of the entire range of this species)

Distribution of Nile Lechwe *Kobus megaceros* in a part of the Sudd flood-plains and swamps. Movements indicate that the lechwes' preference is for flood waters that are 10–40 cm deep (from Mefit-Babtie 1983).

and were made during the middle of the wet season, early dry season and then again in the late dry season. The lechwes were virtually free of competition for pasture during the wet season, but put under progressively more pressure during the dry season, suggesting that competition (and occasional hunting) at this time are currently the major constraint on population size (Mefit-Babtie 1983)

Abundance The aerial surveys of Mefit-Babtie (1983) produced an estimated total of 30,000–40,000 individuals, 95% of which were concentrated in the Sudd and the rest scattered between Sudan and Ethiopia. The Machar population was estimated at 900 individuals (Hillman & Fryxell 1988). In Gambela, Duckworth (1974) reported that the species was rare: 'a few hundred of individuals' and may have decreased further (Hillman 1988a). In 1967, Blower (1968) estimated about 150 individuals in Ghilo R. swamps. In 1973, in the same area and season, Duckworth scored only 52 animals (Bolton 1973). In 2001, the population in Fanyikang G. R. in SE Sudan was estimated at 109 individuals in the early dry season and 209 in the late dry, a possible decline, since illegal hunting has accompanied the ongoing civil war (Ogilo 2001). The dry season surveys of Fay *et al.* (2007) estimated the total population along the Nile R. at nearly 4300 animals, particularly in and around Zeraf G. R.

Nile Lechwes are likely to be very strongly constrained by large numbers of cattle that penetrate deep into the Sudd during the dry season and they are commonly very close to dense herds of cattle during the day, but always in water that is too deep for the latter to graze in. It is likely that numbers of lechwes were very much greater and herds much denser before pastoralists developed techniques for exploiting the Sudd (estimated at about 1000 years ago).

Adaptations Long legs and splayed, elongated hooves facilitate life in the shallows; the shape of the hooves is suited to walking in grassy mud without sinking. The lack of pedal and pre-orbital glands is probably connected with the ineffectiveness of scent-secretions in an aquatic environment; in compensation other forms of marking have developed. The conspicuousness of white chins and lips in ♀♀ suggests that chewing movements may have some signal value and may advertise subordination in a social milieu that is dense, with very frequent and close interactions between individuals. Nile Lechwes are also exceptionally vocal and this must also facilitate communication and help regulate social relationships. They make croaks that resemble those of a full-throated frog.

Male colour pattern assumes great importance in social organization. Marked sexual dimorphism in colouration, uncommon among antelopes, facilitates distant recognition within the herds, both for mating, regulating social encounters and priorities in access to food. The male's white nape patch, contrasting with the black of the body, emphasizes the threat display, which consists of rapid lowering of the head, putting the horns into an attack position. Kingdon (1982) suggested that the white colouring on the neck advertises such head movements and helps to provide an easy assessment of the size of the horns; markings are dorsal because the animal's lower surfaces are normally hidden. Age-graded colour-coding has culminated in an extreme visual contrast, which serves to reduce ambiguity and thus limit competition for access to female herds to a relatively small cadre of adult ♂♂ in prime condition. Intimidation displays probably help define temporary boundaries through repetitive stand-offs. Moreover, colour and brightness of the pelage provides a measure of the status and vigour of individual ♂♂. In captivity, the

acquisition of adult patterning by subadult ♂♂ living with dominant ones is delayed, or some individuals may even resume juvenile colouring. Also, ♂♂ that have lost their hierarchical dominance have been observed to revert to the juvenile pattern or lose brightness and contrast in their colouring (Falchetti *et al.* 1994). It seems that these changes, which are probably under hormonal control (with testosterone presumably playing a prominent role) serve to reduce the likelihood of aggressive encounters between strong dominant ♂♂ and the subordinate or temporarily weak or exhausted ones. Colour-coding by age, sex and rank assists social hierarchies while marked differences between ♂♂ and ♀♀ probably enable each sex to pursue independent life-cycles. In predator-rich environments, highly conspicuous animals invite attention but, under normal conditions, the threat to Nile Lechwe ♂♂ from large visual hunters is negligible so they can afford to be conspicuous. It is significant that the one Southern Lechwe population in which the ♂♂ are black and white (Black Lechwe *K. l. smithemani*) also lives on a very wide, flat flood-plain in the Bangweulu basin, Zambia, with few resident predators.

Nile Lechwe *Kobus megaceros* foetus showing elongated hooves and dark pigment around eyes and mouth.

Foraging and Food Predominantly grazers, with food consisting of swamp grass and shoots (generally in water 10–40 cm deep). They graze on growing wild rice *Oryza longistaminata* during the early flood season, but mainly rice grass *Leersia hexandra*, swamp antelope grass *Echinochloa stagnina* and Sudd grass *Vossia cuspidata* as the floods recede (Kingdon 1997). It is not entirely clear whether *Vossia cuspidata* comprises more than one species, but it exists in two very distinct forms. One is tall with multiple inflorescences and urticaceous leaf sheaths. The second, much shorter form is without irritant hairs, has single or double inflorescences and appears to be more attractive to grazers, including Nile Lechwes. Herds often graze in or very close to areas that are dominated by papyrus *Cyperus papyrus* or rushes *Typha domingensis*, but neither of these species is normally eaten, especially in their mature state. However, small patches of *Leersia hexandra* and, perhaps, *Digitaria debilis* and *Paspalum scrobiculatum*, seem to be the dietary attractions. It is uncertain whether aquatic bladderworts, *Utricularia* spp., are eaten but animals have been seen to pull similar vegetation up out of shallow water (J. Kingdon pers. obs.). Likewise,

it is uncertain to what extent the lechwes take common swamp herbs such as *Ipomoea aquatica*, *Hybiscus cannabinus*, *Vallisneria aethiopica* or *Ludwigia leptocarpa*.

Social and Reproductive Behaviour At the present time, Nile Lechwes form loose, temporary herds of 50–100 individuals, sometimes up to a few hundreds, which include adult ♀♀ with calves, young ♂♂ and ♀♀, some adult ♂♂ and marginal groups of bachelors. These split into breeding and bachelor herds in the late wet/early dry season. The size of herds depends on food abundance and availability of resting-places on dry ground, islets or even on the sides of termite mounds. It seems likely that temporary herds of many hundreds would be less rare, were it not for competition from cattle for pasture.

The behaviour of animals in the wild is poorly known; however, observations in the field and in captivity (Falchetti 1997, 1998, Kingdon 1997) reveal a complex social organization, in which ♂♂ and ♀♀ pursue largely independent existences. In 1980–82, J. Kingdon (pers. obs.) observed adult ♂♂ tolerating the presence of several other well-horned ♂♂, but only ones that could be graded by colour. These clearly represented hierarchically ordered age-classes. In captivity, social relationships appear to be based on a strong hierarchical dominance within male and female groups. Among ♂♂ there is a despotic hierarchical order; at the apex there is only one adult, which does not defend any particular area and tolerates the presence of other ♂♂ only if they are subordinate. Dominant ♂♂ have priority in feeding, in space utilization and exclusiveness in mating. Male dominance is not stable but changes according to the outcome of challenges from other ♂♂. Defeated ♂♂ may lose their bright colour and seclude themselves in small 'arenas' away from the herds and deeper within the swamps; alternatively, and more rarely, they stay within a herd and behave as subordinates. Inter-male encounters are characterized and, perhaps, regulated by, displays of threat and dominance. Postures shown by dominant or challenging ♂♂ serve to emphasize size and physical strength. Subordinate ♂♂ display submission through the lowered position of their head, ears and neck and backward-facing horns. These appeasement gestures reduce the frequency and intensity of fights. In contrast, combats between ♂♂ in prime condition are violent and continuous until one of the challengers submits or retreats. Dominant ♂♂ mark themselves, squirting urine forwards onto their own necks and 'beard', rubbing necks and horns on their own faeces. In this way they reinforce their scent in their own home area, presumably advertising their status within the herd.

The female hierarchical organization is strong, stable and based on age and body size. Rank order is expressed in feeding priority, the capacity to defend individual space, in superior exploitation of hiding places for offspring and in more effective defence of calves. The highest-ranking ♀♀ are the most aggressive; they threaten by suddenly lowering the head and neck, and folding back the ears. Head-butting, kicks and bites are frequent. Females are very vocal and groups on the move emit a chorus of frog-like croaking.

Kingdon (1997) reported that in the early dry season single ♂♂ successfully excluded other piebald ♂♂ from herds that can be in excess of 100 individuals. By Mar these ♂♂ were spaced out in a rather linear scatter along the margins of the swamps and there was much sexual activity that would seem to have attained a peak

Nile Lechwe *Kobus megaceros* adult male performing flehmen. The brow and area behind and below eye is white in adult male and serves to emphasize the typically swollen brow and rolling of eye at close quarters. Likewise mouth expressions are enhanced by white outline; ear movements are also advertised by white colour.

around Apr. Males exhibit flehmen and follow oestrous ♀♀ with great persistence, trying to isolate them from the herd. In courtship the ♂ puts his neck on the back of the ♀ and touches her belly or flanks with an upward strike of one of his forelegs (laufs Schlag). This behaviour induces her to accept mounting.

After parturition, captive mothers are observed eating the placenta, cleaning the calf and ingesting its urine and faeces, typical behaviour of all the 'hider' antelopes. Despite their capacity to walk immediately after birth, newborns remain hidden for nearly 30 days in secluded and shady places, and meet the mothers only for nursing. Their fawn pelage optimizes concealment. Outside their hiding places, calves are vulnerable to aggression from other members of the herd; mothers defend them and nudge them actively with the muzzle toward suitable hiding places. Sometimes they vocalize toward their offspring. During their second month, calves gradually join the herd and pass most of the time with calves of the same age. Kingdon (1997) observed young calves gathering for playful chases, circling and jumping about in the shallows.

Reproduction and Population Structure In the wild, the peak of births is reached in the early dry season (Nov–Dec), and calves are observed emerging from lying-up in the reeds in Feb (Kingdon 1997). In captivity, births are scattered throughout the year (Falchetti & Mostacci 1993, Bercovitch *et al.* 2009).

Studies of captive animals show that one calf is born per reproductive cycle, after a gestation period of approximately 33 weeks, and is suckled for 24–32 weeks (Falchetti & Mostacci 1993). Average interval between two births has been given as 47 weeks (Falchetti & Mostacci 1993) and 52 weeks (Bercovitch *et al.* 2009). Ovulation occurs one month after the previous birth. Sexual maturity and the age of first reproduction are reached at 20 months in ♂♂ and 19 months in ♀♀ (Falchetti & Mostacci 1993), although Bercovitch *et al.* (2009) reported the youngest ♀ to bear progeny was 466 days of age. The maximum number of reproductive events per ♀ is ~14 (Falchetti & Mostacci 1993, Bercovitch *et al.* 2009). In captivity, sex ratio at birth is roughly 1 : 1 (Falchetti & Mostacci 1993, Bercovitch *et al.* 2009). Sex and adult–young ratios in wild

Nile Lechwe *Kobus megaceros* adult male in pursuit. At a distance the white nape draws attention to the length of the horns.

herds are known to be very variable, but have yet to be assessed. Studies in captivity have also shown that older female Nile Lechwe were more likely to bear sons than daughters, male calves weighed more than female calves, neonatal mortality was greater among ♂♂ than ♀♀, and neonatal mass was strongly correlated with maternal age (Bercovitch *et al.* 2009). The maximum longevity recorded in captivity is 21 years (Weigl 2005).

Predators, Parasites and Diseases Although there is an influx of predators such as Lions *Panthera leo* and Leopards *P. pardus* into the Sudd following the large herbivore migrations during the dry season, the Nile Lechwe is protected by the inaccessibility of the swamps; moreover, it is an excellent swimmer and, if disturbed, does not hesitate to enter even the deepest channels. Nile Crocodiles *Crocodylus niloticus* and African Rock Pythons *Python sebae* are known predators.

In captivity, Nile Lechwes have been subject to virus infections such as infective bovine rhinotracheitis, herpes virus 1 and to bacterial bovine tuberculosis (A. Croce & P. Alfonsi pers. comm.). Among the parasites recorded from two animals collected in the Sudd were *Oesophagostomum columbianum*, *Gigantocotyle symmeri*, *Carmynerius exoporus*, *Calicophoron phyllerouxi*, *Stephanopharynx compactus* and *Setaria bicornata*. *Haemonchus contortus* was recorded from the abomasum and intestine. All these parasites were common in other Sudd antelopes (Mefit-Babtie 1983). Of special interest was the presence of a fluke species resembling *Schistosoma leiperi*. Extracted from the mesenteric veins, this parasite was previously well known from Southern Lechwes in central Africa. In that region there has been epidemiological evidence of suppression of other schistosomes that are known to be damaging to humans and livestock. Infection with *S. leiperi* appeared to exclude *S. haematobium* and *S. mansoni* in humans and *S. matthei* in cattle (Pitchford 1976). Although domestic stock and other Sudd antelopes had substantial tick burdens, no tick species were found on Nile Lechwes (Mefit-Babtie 1983).

Conservation IUCN Category: Endangered A2a. CITES: Not listed.

Civil war, and the displacement and resettlement of people, have affected the Sudd region in various ways. Hunting by men armed with automatic weapons takes place without any effective control

Nile Lechwe *Kobus megaceros* adult male.

and the shooting of wild animals has reportedly increased, assisted by easy access to modern firearms. The construction of the long-proposed Jonglei Canal has been interrupted by civil war. If ever completed, it could reduce the extent of marshland and change local patterns of flooding. The impact on the Nile Lechwe and its habitat could be significant and certainly would be detrimental to both (Howell *et al.* 1988). Oil exploration and exploitation in the Sudd is a major and immediate threat to the wildlife of these wetlands and the Zeraf Reserve (Fay *et al.* 2007).

In the Sudan, populations of Nile Lechwes occur in three nominal game reserves: Zeraf G. R., extending over 9700 km² along the Bahr el Zeraf; Fanyikang G. R., north of the Bahr el Gazal, which separates them from Zeraf G. R.; and Shambe N. P. over 620 km², along the Bahr el Jebel. However, Nile Lechwes are known to move in and out of these nominally protected areas and most occur in areas that are shared seasonally with vast herds of cattle. In Ethiopia, they occur in Gambella N. P., which is yet to be officially gazetted.

An effective captive-breeding programme aimed at enhancing and conserving viable and self-sustaining populations could help to ensure the survival of viable populations outside their potentially vulnerable natural home-range, but the gene pool is small (320 individuals as of 2005) and problems with inbreeding have been reported (Falchetti

& Mostacci 1993, 1995).

Measurements

Kobus megaceros

HB (♂ ♂): 1600–1800 mm

HB (♀ ♀): 1300–1700 mm

T (♂ ♂): 500 mm

T (♀ ♀): 450 mm

Sh. ht (♂ ♂): 1000–1050 mm

Sh. ht (♀ ♀): 800–850 mm

WT (♂ ♂): 90.0–120.0 kg

WT (♀ ♀): 60.0–90.0 kg

Sudan (Haltenorth & Diller 1980, Kingdon 1997)

Maximum recorded horn length is 87.0 cm for a pair of horns from Yirol, Sudan (Rowland Ward)

Kobus ellipsiprymnus WATERBUCK

Fr. Cobe onctueux; Ger. Wasserbock

Kobus ellipsiprymnus (Ogilby, 1833). Proc. Zool. Soc. Lond. 1833: 47. 'about twenty-five days' journey north of the Orange River between Latakoo and the western coast of Africa'. Since restricted to Gaborone, Botswana, the top reaches of the Ngotwane R.; see Smithers (1971: 233) and Grubb (1999: 25).

Waterbuck *Kobus ellipsiprymnus*.

Taxonomy The Waterbuck is here considered a putative species with two subspecies, Common *K. ellipsiprymnus ellipsiprymnus* and Defassa *K. ellipsiprymnus defassa*. The latter was originally described as a full species by Rüppell (1835), but the two are generally regarded as conspecific (Grubb 1993c, 2005); Ansell (1972) treated these as two distinct superspecies groups, with four subspecies in his *ellipsiprymnus* group and nine in his *defassa* group. Each has a different chromosome number, $2n = 50-52$ ($FN = 61-62$) in *K. e. ellipsiprymnus* and $2n = 53-54$ ($FN = 62$) in *K. e. defassa*, as well as differing Y chromosomes: in Common, the X chromosome is a large metacentric and the Y a small acrocentric, whereas in Defassa the Y is a small submetacentric (Kingswood *et al.* 1998b, 2000). Overlapping is recorded in at least three East African localities, apparently due to allopatric hybridization, zones of intermediate pattern remaining narrow possibly due to reduced fertility of hybrids. DNA analysis revealed that hybrid individuals from Nairobi N. P. (Kenya) have only Common mitochondrial haplotypes, whereas both Defassa and Common haplotypes are found in the Samburu N. P. (Kenya) population, suggesting eastward expansion of Defassa (Lorenzen *et al.* 2006b). Spinage (1982) suggests separation resulting from the last Rift Valley arid phase sometime after 20,000–12,000 BP. The

work of Lorenzen *et al.* (2006b) suggests Defassa and Common were restricted to west and southern African refuges, respectively, and subsequent dispersal northwards of Common from a southern Africa locus could have resulted in contact between previously allopatric groups. Some 80 races described on pelage colour and horn length have been limited to five by morphometric analysis of horn shape by Spinage (1982), as differences in colour and markings can be found within a single population, but genetic variation is insufficient to substantiate races.

The study of Lorenzen *et al.* (2006b), based on variation in 478 nucleotides of the mitochondrial DNA control region and 14 polymorphic microsatellite loci, showed a high degree of genetic differentiation between the subspecies and strongly confirmed hybridization in Kenya's Nairobi N. P. population (which shows an intermediate rump pattern). The data suggest admixture was a recent event, their mitochondrial DNA is not completely separated into two distinct clusters, but chromosomal differences could hinder gene flow between the species providing an emerging reproductive barrier. Isolation by distance was not statistically supported within subspecies, or between all the sampled populations. A population of Common Waterbucks at Matetsi Safari Area in the extreme west of Zimbabwe just south of the Victoria Falls had exclusively private haplotypes and was genetically further apart from East African Common populations than it was from Defassa. Whereas one cannot discount differences in sample size influencing the results, or the Common having been through a population bottleneck, which would decrease its diversity, genetic distances within Defassa were markedly lower than between Defassa and Common, while Common was shown to have a higher level of genetic drift in the period between the original split and the hybridization event, confirming an originally smaller population size of Common. Since hybridization, a population at Samburu N. P. in Kenya and the Nairobi N. P. population have experienced about a 20- to 90-fold increase in drift compared with that of Common and Defassa. The estimated level of genetic input from Common to the Samburu N. P. and Nairobi N. P. populations was 0.58% and 0.32%, respectively, the Nairobi N. P. population being grouped genetically mid-way between Defassa and Common. Although phenotypically Common, the Samburu N. P. population had a high maternal Defassa contribution of 42%. The genetic analysis indicates that hybridization in the Nairobi N. P. and Samburu N. P. populations is very recent, perhaps within the past few centuries, and perhaps is still ongoing. The genetic distance between the Tsavo N. P. and Matetsi Safari Area Common populations is markedly higher than that between the Tsavo N. P. and the hybrid populations. This could suggest introgression into Tsavo N. P., which would have to be historic as there are no Defassa Waterbuck within several hundred kilometres today. The alternative would be that the variable rump patterns identified here (Spinage 1982) were due to natural variability, but such variability has not been identified elsewhere.

That all *Kobus* species are able to hybridize in captivity (see Gray 1972) suggests a recent radiation of the entire genus. A recent phylogenetic analysis (Birungi & Arctander 2001) based on complete mitochondrial cytochrome *b* sequences places the Waterbuck within the Reduncini as a derived paedomorph reduncine, also confirming the subspecies differentiation between Defassa and Common Waterbucks, but identifies them as a sister clade to the Kob *Kobus kob* and Puku *Kobus vardonii*, while the Southern Lechwe *Kobus leche* forms a separate phyletic branch. The Waterbuck is thus supported as a plesiomorph relative to other *Kobus* species. Little indicates the ancestry of the Waterbuck other than that the species is considered to derive from the lower Pleistocene *K. sigmoidalis* from Olduvai 5 mya (Gentry 1978).

Synonyms: *abyssinica*, *adolffriderici*, *albertensis*, *angusticeps*, *annectens*, *avellanifrons*, *breviceps*, *canescens*, *cottoni*, *crawshayi*, *defassa*, *dianae*, *ellipsiprymnos*, *frommi*, *fulvifrons*, *griseotinctus*, *harnieri*, *hawashensis*, *kondensis*, *kulu*, *kuru*, *ladoensis*, *lipuwa*, *matschiei*, *muenzneri*, *nzoiae*, *pallidus*, *penricei*, *powelli*, *raineyi*, *schubotzi*, *senegalensis*, *singsing*, *thikae*, *tjaederi*, *togoensis*, *tshadensis*, *ugandae*, *unctuosus*, *uwendensis*. Chromosome number: see above.

Description One of the heaviest antelopes, and largest of the genus *Kobus*, the two subspecies are distinguished by the distinctive patterning on the rump. Common Waterbucks have a white ellipse on the rump, whereas Defassa Waterbucks are all white. Intermediates exhibit all degrees. Gorget, muzzle, eye surround and inside ear are white. Large ears are tipped black and forehead area tends to black. Pelage shaggy in appearance, especially on the neck, but not dense, generally russet-coloured in Defassa, and grizzled tending to grizzled light grey in Common. Belly is greyish, lower legs shading to black with short white spats. A pale phase once existed in the region of the Lorian Swamp and parts of the Uaso Nyiro, Kenya; and white forms are occasionally reported, but not true albinos. Philtrum is black and hairless. Waterbucks are much heavier in the forequarters than many other antelopes, and the long neck has skin up to 2.5 cm thick in the ♂. Neck girth relates to weight of the long horns, hence hindleg weight is not a good indicator of body weight as it is in other antelopes studied. False hooves are large and conspicuous. Tail, reaching almost to the hocks, terminates in a black tassel. Females are 20% lighter in weight. There are no compound odoriferous glands. A very dark appearance is due to an oily musky skin secretion. This makes the flesh very distasteful to most palates if contaminated by it.

Males bear sharply pointed, long, inwardly curving horns, ridged on the anterior face, first appearing at about eight months and growing at some 16 cm per year to age five, with growth then slowing abruptly to approach an asymptotic level at six years continuing to old age with wear at the tips equalling growth.

Skull is massive, relatively long with large lachrymal vacuities, large auditory bullae and the premaxillae reaching to the long nasal bones. Skull of ♂ is 6% longer than ♀. Adult ♀ has paired rugosities on the frontal bones that bear the horns in the ♂. Teeth are hypsolenodont, arranged in a similar manner to those in *Redunca*. Replacement of deciduous dentition takes place between 3 and 3.5 years. Dental abnormalities are rare, Colyer (1936) recorded only three cases in 57 specimens: one rotated mandibular P₄ and a left and right rotated maxillary P₄. C. Spinage (pers. obs.) observed one left

Lateral view of skull of female Waterbuck *Kobus ellipsiprymnus*.

maxillary rotated P₄ in 46 animals from Akagera N. P., Rwanda, and no abnormalities in 164 animals from W Uganda. Foley & Atkinson (1984) described a type of uneven and excessive tooth wear affecting 50% of Defassa Waterbucks of all ages in Lake Nakuru N. P., Kenya, predominantly affecting P₄ and the molars. Miles & Grigson (1990) suggested the type of wear could be due to an inherited regular pattern of difference in mineralization between individual teeth in the dentitions, perhaps, as Foley & Atkinson (1984) suggest, caused by overcrowding and inbreeding. Kisia *et al.* (2002) demonstrated abnormal bone mineralization due to soil mineral imbalances, undoubtedly also reflected in the teeth.

Geographic Variation

K. e. defassa (Defassa Waterbuck): West, north-east and central Africa.

Lacks the white crescent that characterizes Common subspecies, having an all-white rump. Five Defassa races are recognized by Spinage (1982) according to width between the horn tips in the ♂, which reflects the 'bow' of the horns: West Africa (*unctuosus*), ranging from Senegal and Gambia eastwards to the Semliki Valley and southwards north of the Congo rainforest and the Congo R. to the west coast; Uganda (*ugandae*), from the foot of the Abyssinian highlands through S Sudan, the Bahr el Ghazal basin and southwards through Uganda to W Tanzania; Rwenzori (*avellanifrons*), from the Western Rift from the southern end of the Rwenzori Mts to south of L. Edward; Rhodesia (*crawshayi*), in Zambia and Zimbabwe north of the Zambesi R.; and Angola (*penricei*), from Congo and S Gabon through Angola to the upper Okavango and the eastern end of the Caprivi Strip. Separation on coat colour and pattern is discounted as this is variable within single populations. Due to overlapping measurements, the width between the tips of the horns of each race following a curve of normal distribution, identification of races depends upon the statistical comparison of samples and their geographical origins.

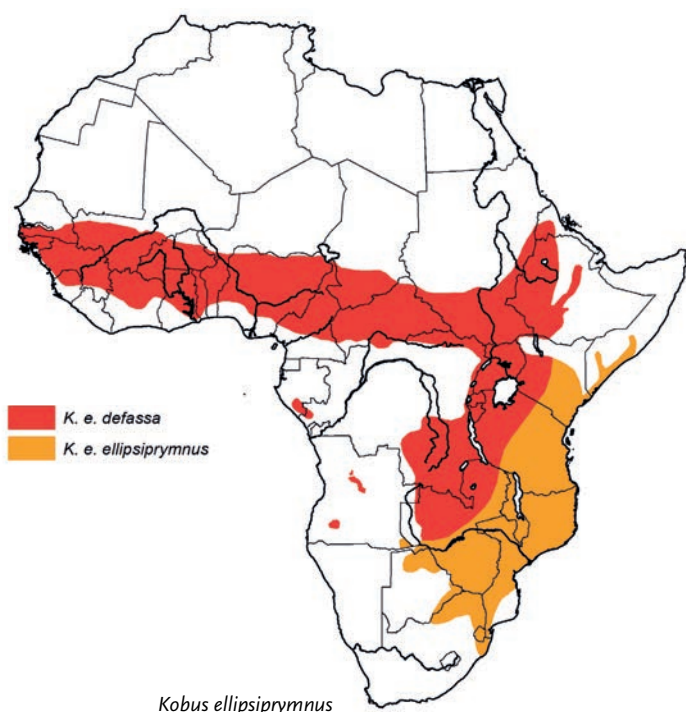

K. e. ellipsiprymnus (Common Waterbuck): south-east Africa, broadly east of the Eastern Rift Valley. Most diagnostic feature is the white ellipse on the rump. No races of the Common subspecies are recognized by Spinage (1982).

Similar Species

Kobus kob. Broadly sympatric south of the Sahel and west of the Rift Valley. Smaller with a bright gold fulvous pelage; male horns short but thick and S-shaped. Inhabits open plains.

K. vardonii. Sympatric across much of the range. Smaller, more similar in size and shape to the Kob. Tends to inhabit the fringes of plains more than open plains.

K. leche. Red Lechwe sympatric, principally in the Busanga Plains of Zambia and the Okavango Delta of Botswana. Smaller, bright

chestnut to blackish pelage with contrasting white underparts; male horns long and lyre-shaped. Very aquatic in habits.

Distribution Endemic to Africa, ranging widely throughout most of sub-Saharan Africa in savanna woodlands and forest–savanna mosaics, although their current distribution is fragmented, having been eliminated from many parts of their former range.

Current Distribution The Waterbuck has been eliminated from many parts within its former range, but still ranges widely. Defassa is found in well-watered savanna west of the Western Rift Valley and south of the Sahel from Eritrea in the east to Guinea-Bissau in the west; its most northerly point of distribution is in S Mali, formerly in Boucle du Baoulé N. P. but not recently confirmed there although still present in Fina Faunal Reserve, 75 km to the south-east (B. Chardonnet pers. comm.). A population still exists in Senegal in Niokolo-Koba N. P. 450 km to the west and 75–125 km south of the most northerly known distribution (A. Galat-Luong & G. Galat pers. comm.). Defassa Waterbucks range eastwards reaching west of the Western Rift Valley and east of the Congo Basin forest, and then spreading west below the basin's southern limit through the western and northern plateaux of Zambia into Angola. Another arm extends north, west of the Congo Basin to the savannas of SW Gabon. East of the Eastern Rift Valley, Defassa is replaced by Common, which extends southwards to just below 28° in Hluhluwe-iMfolozi N. P., KwaZulu–Natal, and west, south of the escarpment in Zambia, and north of the Kalahari, to the Caprivi in Namibia.

Of the 42 African states south of the Sahara, the Defassa Waterbuck occurs in 28 and the Common in 11. Defassa became extinct in Gambia by around 1990 (although they may still occur as vagrants from Niokolo-Koba N. P. in Senegal; see Grubb *et al.* 1998, Jallow *et al.* 2004) and Common is believed extinct in Ethiopia since 1988 (although Defassa remains).

Habitat Waterbucks are a water-dependent species partial to scattered woodland and bush where mean annual rainfall is 400–1600 mm; Defassa generally is limited to areas receiving at least 750 mm annual rainfall, whereas Common persists in drier regimes. Waterbucks are most numerous in fairly humid habitats, with an optimum temperature range of 13–37°C for Defassa. In southern Africa, where mean surface temperature falls to 12°C, Common withstands low winter night temperatures that fall to freezing. Highest densities are in lakeside regions or in well-watered valleys where there is good quality grass. Waterbucks are always limited by distance from permanent water in the dry season; in the wet season female groups are more dispersed and range farther. They have been recorded with certainty to at least 2100 m in Ethiopia, and perhaps to 3000 m (Yalden *et al.* 1996).

Feeding and daily behaviour patterns apparently vary according to latitude and climate. In W Uganda, completely open grassland was not the most favoured habitat, grassland with moderate nearby cover being preferred. In Lake Nakuru N. P., where Lions *Panthera leo* are absent, male preference changed with increasing age from open woodland to dense shrub, open shrub and finally open grassland. Adult ♀♀ were more often in dense shrub than were subadults but all favoured open grassland during rainfall (Wirtz & Kaiser 1988). In other areas the preference is predominantly for riverine woodland, and Hirst (1975) in Mpumalanga, South Africa, found no preference of the Common for open grassland.

Abundance Undisturbed densities range from 0.23/km² (Kruger N. P., South Africa) (Pienaar 1966) to >30 (Lake Nakuru N. P.) (Kutilek 1974), but corrected density estimates from recent aerial surveys, assuming 46% is detected (East 1999), range from 0.1–0.3/km² in many areas where the species is regarded as reasonably common to 0.4–1.8/km² in a few higher density areas. Ground surveys where the species is regarded as common have produced density estimates of the order of 0.4–1.5/km² (East 1999). A conservative corrected continent-wide estimate of numbers based mainly upon aerial surveys is 95,000 Defassa and 105,000 Common (East 1999).

Adaptations Only Defassa physiology has been studied in detail, and in view of the spatial separation between the subspecies and genetic differences, Common possibly exhibits a distinctive physiology, able to withstand lower, but not as high, temperature, and more arid conditions. Defassa is highly water-dependent, lacking almost any ability to conserve water, unable to withstand even short periods of dehydration in a hot environment. Unlike most mammals, Waterbucks do not reduce urine volume when water is restricted, reducing only faecal water, eating less food and digesting it more completely. Maintaining body temperature almost constant at 39.2°C, it does not store heat, and does not drink excess water when available, always forming a nearly maximally concentrated urine. Its high protein intake (see below) results in a high production of urea demanding a high water intake to flush it out. A higher than normal energy intake is required to maintain thermoneutrality at low temperatures, but in southern Africa the cold season is a time of low vegetative quality, which could be the cause of reported high winter mortality.

Measurements indicate the Common Waterbuck from South Africa is possibly larger than the Defassa from W Uganda, which would accord with Bergmann's Rule and the colder seasons experienced in

South Africa or the largest races being found in areas colonized last by the population concerned, but there are insufficient accurate sampling records to confirm an increase in body mass. Also possibly shorter ear and tail lengths conform to Allen's Rule and the colder climate. Although horn length appears greater, the sample is probably biased in favour of the longest horns, compared with the random sampling of adults in W Uganda. Swayne (1895) considered that the Waterbuck in Somalia had shorter horns than Waterbucks further south. Smaller size of northern Waterbucks is tentatively confirmed by considering the greatest length of skull, which in a single Defassa ♂ from Setit (Eritrea) was 7.25% shorter than the mean value of a sample from W Uganda (n = 19). The greatest skull length of Common ♂♂ from Somalia (n = 8) was 9.4–12.7% shorter than two Kenya specimens, and 11.6% shorter than the sample from South Africa (n = 5). Greatest skull length of the ♀ (n = 3) was 12% shorter than one specimen from Kenya and specimens from South Africa (n = 3).

The Waterbuck perhaps owes its success to being a generalist able to exploit the range of habitats to which its congeners are specifically adapted, albeit only to a varying degree, not as aquatic as the Southern Lechwe (although its prominent false hooves allow it to travel over marshy ground), nor as independent of water as the Kob. The ♂ also adapts its behaviour to lessen excessive strife, e.g. to permit other adult ♂♂ access to water where this is in another's territory, and the resource-defence system of the territorial ♂ does not demand a reduction in feeding time. The species does suffer competition in lacustrine or riverine shorelines from Common Hippopotamus *Hippopotamus amphibius*, and in open grassland possibly from herding grazing species where these are numerous. Despite their name, Waterbucks do not spend much time in water, although in southern Africa they sometimes stand belly-deep grazing aquatic emergents, but never bathe, only taking to water to escape predators.

Foraging and Food Waterbucks are classified as grazers according to the classification of Cerling *et al.* (2003), taking 70–95% grass. Studies involving stable carbon isotopes from Waterbuck samples from both East and southern Africa revealed grass dominating in the diet, 92% (Cerling *et al.* 2003), and 97% and 100% (Sponheimer *et al.* 2003b), but these percentages should be viewed as $\pm 15\%$ (M. Sponheimer pers. comm.). In Kruger N. P., isotopic analysis of Waterbuck faeces suggests seasonal differences in diet, but at the same time supports the idea that Waterbucks in that region are, on average, fairly dedicated grazers. With the exception of the late dry and early wet season, where there is evidence for over 20% browsing, the Waterbuck samples were nearly identical to those of Common Wildebeest *Connochaetus taurinus* (M. Sponheimer pers. comm.). Carbon isotope analyses of teeth from eight male and 22 female Defassa Waterbucks collected in Queen Elizabeth N. P. in Uganda 1964–67 (Copeland *et al.* 2008) confirmed that the species consumed on average 98% C₄ grass with some C₃ browse, indistinguishable from most other grazers studied, including the African Buffalo *Syncerus caffer*; however, variation was as much as 28% between individuals.

In taking some browse, Defassa Waterbucks are not opportunistic browsers, browse being essential to boost their protein intake. The empirical studies of Taylor *et al.* (1969) demonstrated that Defassa Waterbucks require a protein diet four times higher than that of other grazing bovids studied (domesticated Hereford steer, African Buffalo *Syncerus caffer* and Beisa Oryx *Oryx beisa*), necessitating

feeding them lucerne in place of hay; however, Cerling *et al.* (2003) show both the African Buffalo and oryx taking much more browse than the Waterbuck. From observations of continuous 12-hour periods, Spinage (1982) found that an adult ♂ in the dry season spent 11.1% of feeding time on browse, and at night 20.7%, giving an estimated total for the 24 hours of 31.8%. In the wet season, no time was spent browsing either during the day or at night. The adult ♀ spent only 10.2% of time in the day browsing, so assuming the same increase in rate of feeding at night, she would spend 19% of time browsing, which added to the day's total would approximate to 29.2%. It is questionable whether a Waterbuck could survive the dry season on 97% or 100% graze, or even on 92% graze, and the similarity to Common Wildebeest feeding found in Kruger N. P. is puzzling. However, where stable carbon isotope sampling is from P4 tooth enamel, the food intake refers only to a period between 10 and 25 months in the animal's life when the enamel is laid down prior to tooth eruption, and the animal is subadult, which may reflect anabolic feeding, the diet changing to one of maintenance when the animal is adult (or the Waterbuck may be a structurally very selective feeder).

Waterbucks eat both medium-height and pyrophilous protein-rich short grasses with a high ratio of leaf to stem (Chloridae, Paniceae and Sporobolidae), taking the greatest range of species in the wet season. Variability in choice of grass species is dependent upon location rather than frequency of occurrence. In W Uganda, where 20 different grass species were taken, *Sporobolus pyramidalis* was favoured in some areas, *Themeda triandra* in others (Field 1972). In one area of South Africa, Common Waterbucks favoured *Heteropogon contortus* (third choice by Defassa in W Uganda), and the creeping, protein-rich *Cynodon dactylon* was also highly favoured, compared with only 50% by Defassa (Wilson & Hirst 1977). Annuals seem to be avoided. In southern Africa, feeding on *Typha* and *Phragmites* aquatic emergents has been observed (Child & von Richter 1969, Herbert 1972, Tomlinson 1980a, 1981), but riparian topography and drought conditions could determine such behaviour, which was not witnessed in W Uganda. Dry season protein deficiency in graze was supplemented in W Uganda by browsing, especially *Capparis tomentosa*, particularly the heavily scented inflorescences, and *Acacia sieberiana*.

Defassa ♀♀ in W Uganda spend some 64% of daylight hours feeding in the dry season, ♂♂ 43.5%, with only slightly more time in the wet. In ♂♂ feeding at night falls to some 38% of time, the difference being spent in ruminating. Only some four minutes are spent in deep sleep. Anything from as little as 3% to as much as 18% of time is spent in resting and light dozing, with the longer times in the wet season. Tomlinson (1980a) in Zimbabwe recorded almost identical percentages of feeding time for ♂♂, but diurnal feeding of ♀♀ in the hot dry season was 35%. Wirtz & Oldekop (1991) in Lake Nakuru N. P. recorded only 27% of time spent by adult ♂♂ in feeding, and 40% for ♀♀. But the results are not comparable as a grazing animal moving forward to the next bite was recorded as 'walking'. If anything, they show that the animal moves about more when feeding, confirmed by three times as much time occupied in 'walking and other activities' in W Uganda (21% compared with 7%). They also show ♀♀ spent more time feeding than ♂♂, 32.5% more compared with 29% in Uganda. Only 1.1% of time was spent in browsing but the seasons of observation were excessively wet, perhaps leading to more abundant food requiring less searching time.

Oxygen isotope ratios from the teeth of subadult ♀♀ in Queen Elizabeth N. P., which reflects the composition of drinking water and water in plant foods, showed greater variability than did those of subadult ♂♂, which may be a reflection of larger home-ranges (Copeland *et al.* 2008).

Social and Reproductive Behaviour Females are sedentary with overlapping home-ranges of 200–600 ha in W Uganda. Within these ranges, sedentary and strongly territorial adult ♂♂ defend territories of from 4 to 146 ha depending upon population density, suitability of habitat regarding food resources and age of holder. As soon as horns begin to appear, subadult ♂♂ are chased from the dam's side by territorial ♂♂. Such ♂♂ associate in bachelor groups within the female home-ranges where they are tolerated by territorial ♂♂. Males indicate submissiveness by holding the head low, neck stretched out, horns directed backwards. Females respond with a similar submissive posture accompanied with jaw champing to signify rejection. Outside the equatorial regime, bachelors may be excluded from territories during part of the year. At extremely high (and probably unnatural) densities of 72–106/km² as in Lake Nakuru N. P., territory holders may tolerate adult satellite ♂♂, which also defend the territory, appearing to 'assist' the dominant territory holder (Wirtz 1981, 1982). Territories are marked by presence and the strong pungent odour. Dung is dropped randomly and it is unlikely it serves as a territorial marker.

Males are territorial for up to five years, the largest territories being occupied between occupier ages six and nine, when ♂♂ are in their prime. Territory seeking begins at the age of about five years and is usually always successful by age seven. Largest territories have the most female visits and ♀♀ stay from a few hours to three months. Although ♂♂ attempt to herd ♀♀ to prevent leaving, this is never successful. Males do not remain throughout life on the first territory obtained, but graduate to bigger ones, not enlarging an existing one, even when a neighbour is killed in combat. After nine years of age a ♂ is in decline and once over ten usually loses out to a younger ♂. Such

♂♂ do not rejoin bachelor groups, but continue a solitary existence in a small, undefended area (Spinage 1982).

When an adult ♂ is approached by another ♂ of subadult or adult age, it adopts a display attitude typical of the Bovidae, standing in lateral view with the neck arched stiffly, variously referred to as the 'lateral-present', 'present-threat' or 'proud-posture', tail held out stiffly in line with the body. When displaying strongly, the penis is extruded and the urethral process extended. If the other ♂ continues the approach, the horns are inclined stiffly towards him. He makes no attempt to look taller by raising his hackles as the ♀ does when alarmed. Horn size is not a mark of rank; those with the longest horns are often the most timid in conflict situations. If the approaching ♂ does not lower the head in submission then he is faced and the horns can be engaged. Tomlinson (1980b) studied the behavioural display of Common Waterbucks in Zimbabwe in detail, noting some differences with Defassa Waterbucks in Uganda, but lack of a behavioural observation in Defassa does not mean it does not occur.

Territorial ♂♂ (and bachelor ♂♂ if they have the chance), examine chosen ♀♀ that enter the territory, nuzzling the hindquarters to induce tail-lifting and urination. Urine is sampled exhibiting typical lip-curling (flehmen). Females leave the group about two days prior to calving, returning to the same spot each time. Birth takes place early in the morning, the dam ingests the placenta and the calf stands and suckles after about 30 minutes. A 'hider', the calf remains concealed for three weeks, the mother remaining in the vicinity. She reacts to alarm bleats of her calf by attempting to chase off intruders using head-butts. After parturition, territory holders follow the ♀ closely until she comes into oestrus again 21 days later, when she is willing to receive the ♂. Males play no part in defence of the calf. Producing a concentrated milk, the dam visits the calf once during the day for suckling, which takes 10 min or more. The calf plays during the visit of an hour or so, scampering around the dam. When she walks off it hides itself. In the early stages the mother licks the calf's perianal region to induce defecation, which she ingests to remove traces of the calf's presence. The calf's scent does not develop until about 14 weeks, but some scent is transferred from the dam at birth and during visits. Once the calf starts to walk about the dam leads it to a new hiding place and prompts the calf to follow her by holding the tail stiffly erect (Spinage 1982).

Some dams drive their female young away from their side. At the age of 18 months these ♀♀ form spinster groups, perhaps remaining in the group until four years of age, while others emigrate up to 30 km. These spinster groups undergo a phase of wandering and emigration, until individuals settle into a home-range when they first come into oestrus and are temporarily attended by a territorial ♂. Female dispersal is unusual among bovines. Female groups run to greet each other, but no mutual sniffing or bodily contact occurs. Groups are dynamic within the home-range, with numbers ranging from one to 70, forming randomly. Mean group size in W Uganda was 5.3, but ♀♀ were most commonly found alone or in twos. Increases in group size are related to population density and were the same in wet and dry seasons in W Uganda's relatively benign habitat, where there was a tendency for larger groups to form in the morning (or during the night) that broke up later in the day. Juveniles making too close contact with adult ♀♀ are rebuffed vigorously (Spinage 1982).

The young ♂, becoming sexually mature at 3–4 years, is unable to obtain a territory and mate until 6–7 years. Before this he is too light

Waterbuck *Kobus ellipsiprymnus* detail of adult male exhibiting 'flehmen'.

Waterbuck *Kobus ellipsiprymnus*.

in weight to defeat a territory-holding adult. In the unnaturally high and restricted densities of Lake Nakuru N. P., Wirtz (1982) suggested dominant bachelor herd ♂♂ could be as successful as territory holders in the number of copulations achieved. Young ♂♂ join a 'home' bachelor group, which does not readily accept young ♂♂ from other areas. Bachelor groups are essentially random associations, their home-ranges of 30–340 ha being roughly co-incident with that of local ♀♀. Frequent sparring or dominance contests occur between bachelors of similar age and emigration, which can extend outside of the local territory mosaic, follows when there are too many of a similar older age group. Emigrants tend to form their own groups, but can sometimes join others. When old enough to quit the group the ♂ must fight a territory holder to obtain a place of his own and adopts different ruses, such as stationing himself where three territories meet, and running into another's territory if approached.

Waterbucks normally appear to be silent animals, but the dam calls her calf with low, penetrating bleats. Calves bleat when alarmed.

Reproduction and Population Structure Females first give birth at just under 2.5 years and can be reproductively active for ten years. Equatorial breeding takes place throughout the year, with most conceptions in May, Jun and Nov, producing births in Apr, May and Aug. There are conflicting reports whether distinct breeding seasons occur in the latitudes, but it appears calving peaks in the wet season (Spinage 1982).

A single calf is born after a gestation of 40 weeks (Heinroth 1908), weighing about 13.6 kg (Spinage 1982). Twins have been recorded, even triplets (Frechkop 1954), but such records are exceptional. Where breeding is continuous there is a calving interval of 325 days (Spinage 1982). Weaning takes place at about 40 weeks, and young ♀♀ are ready to conceive at 20 months. Mortality up to weaning is greater than 50% (Spinage 1982).

Recorded sex ratios range from 1 : 0.5 to 1 : 4.3 (Bourlière & Verschuren 1960, Foster & Kearney 1967, Hanks *et al.* 1969, Mentis 1970, Herbert 1972, Kutilek 1974, Elliott 1976, Wirtz 1978, Spinage 1982). They can live to 18 years in the wild (and 30 years in captivity; Weigl 2005), but mean life expectation at birth is four, with mean length of life in ♂♂ under five. During fights among adult ♂♂ it is not uncommon for deaths to occur from abdominal or chest puncture wounds; battles can last up to 30 min.

Predators, Parasites and Diseases Lions *Panthera leo* are the main natural predators on adults, but Leopards *P. pardus*, Cheetahs *Acinonyx jubatus*, African Wild Dogs *Lycaon pictus* and Nile Crocodiles *Crocodilus niloticus* are also known to take adults. Leopards and Spotted Hyenas *Crocuta crocuta* are important predators on calves.

Waterbucks are known to suffer ulcers (including perforated), pleuritic lungs probably resulting from lungworm infection, and kidney stones (Spinage 1982). Positive responses are reported for foot-and-mouth disease, bluetongue and bovine virus diarrhoea (Fay 1972) as well as for several mosquito-borne arboviruses: Group A (Sindbis), Group B (Yellow Fever, West Nile, Uganda S, Zika, Wesselbron) and ungrouped Zinga (Thal 1972), several of which are fatal to man. Deaths have been reported from anthrax (Pienaar 1967) and one positive brucellosis isolation was made in South Africa (Herbert 1972). They are relatively resistant to rinderpest virus (Carmichael 1938). Fairly heavy trypanosome infections of *Trypanosoma vivax* and

T. congolense–*T. brucei* are recorded (Wenyon 1926), although the vectors, tsetse flies *Glossina* spp., feed on Waterbucks least of all. Reactions to tick-borne protozoa *Theileria parva* (causing East Coast Fever in cattle), *Anaplasma marginale* (gall-sickness in cattle) and *Babesia bigemina* (redwater in cattle) have been identified (Fay 1972).

Internal parasites include tapeworms *Moniezia benedeti* (Spinage 1982) and *Stilesia hepatica* (Baer & Fain 1955), the liver-fluke *Fasciola gigantica* (Stunkard 1929) and stomach-flukes *Paramphistomum phillierouxi*, *P. microbothrium*, *Calicophoron calicophorum* and *Carymerius* sp. (Herbert 1972, Spinage 1982). Other helminths recorded include: *Linguatula nuttali* (Thal 1972), *Dictyocaulus* sp. (Zieger *et al.* 1998a), and *Haemonchus bedfordi*, *Cooperia yoshidai*, *C. hungi*, *C. fuelleborni*, *Impalalia tuberculata*, *Oesophagostomum columbianum* and *Parabronema* sp. (Boomker *et al.* 1986). In the faeces, larvae and eggs of the coccidian *Eimeria aubumensis*, the hookworm *Bunostomum trigonocephalum* and the whipworm *Trichiuris ovis* have been found (Elliott 1976). All appear superficially identical to those found in domestic animals, but could be host-specific. *Haemonchus* sp. in Common Wildebeest, for example, does not infect bovine calves. Boomker *et al.* (1986) noted cross-infection among antelopes of a number of helminths. Perhaps a first stage to determining host specificity would be DNA analyses.

A total of 27 species of ixodid ticks has been found on Waterbucks, and a healthy animal has been estimated to be carrying more than 4000 ticks mainly in their nymph and larval stages (the commonest being *Amblyomma cohaerens* and *Rhipicephalus tricuspis*) (Spinage 1982). Impaired calf survival due to apparently high, but unquantified, levels of *R. appendiculatus* infestation in the iMfolozi G. R., South Africa, has not been proved (Melton 1987). The large numbers of ticks suggest the Waterbuck's prolific oily secretion is not a deterrent and unlike many other ungulates, Waterbucks only rarely tolerate oxpeckers *Buphagus* spp. The Biting Louse *Damalinea (Bovicola) hilli* is not uncommon, while in W Uganda the ear mite *Railletia hopkinsi* causes considerable discomfort, large, scab-covered swellings under the ears frequently resulting from repeated scratching. Bloodsucking flies *Siphona minuta* and *S. latifrons* were often seen around the head in W Uganda. The ectoparasitic hippoboscid fly *Hippobosca hirsuta* also occurs, particularly in the long hair on the neck (Spinage 1982).

Conservation IUCN Category: Least Concern (*K. e. defassa* – Near Threatened; *K. e. ellipsiprymnus* – Least Concern). CITES: Not listed.

Waterbucks are particularly susceptible to poaching because of their sedentary nature and fondness for cultivation. Of the 36 countries in which Waterbucks are known to occur, the population trend is considered to be decreasing in half (with the status in four not known); only in South Africa is the species regarded as 'increasing' (East 1999).

About 60% of Defassa Waterbucks occur in protected areas, with important populations including: Niokolo-Koba N. P. (Senegal), Comoé N. P. (Côte d'Ivoire), the complex of 'W' N. P. (quite rare in Niger), Arly-Singou Faunal Reserve and Pendjari N. P. (Burkina Faso, Benin, Niger), Mole N. P. (Ghana), Gashaka-Gumti N. P. (Nigeria), Zakouma N. P. (Chad), Awash N. P. and Omo-Mago-Murale (Ethiopia), Murchison Falls N. P. and Queen Elizabeth N. P. (Uganda), Serengeti N. P. and Katavi N. P. (Tanzania) and Kafue N. P. (Zambia). Of the 105,000 Common Waterbucks estimated to survive in Africa, more than 50% are in protected areas, with the particular strongholds including: Tsavo N. P. and Lake Nakuru N. P. (Kenya), Tarangire N. P. and Selous G. R.–Mikumi N. P. (Tanzania), North and South Luangwa

N. P. (Zambia) and Kruger N. P. and Hluhluwe-iMfolozi G. R. (South Africa) (East 1999, Chardonnet & Chardonnet 2004).

Although the species is relatively well represented in protected areas, population declines have been reported even within protected areas: 59% between 1977 and 1995 in Queen Elizabeth N. P., and 67% between 1967 and 1995 in Murchison Falls N. P. (von Richter *et al.* 1997); 91% between 1979 and 1993 in Lake Nakuru N. P. (Butynski *et al.* 1997a), the latter largely due to natural mortality; and 75% between 1978 and 1998 in Comoe N. P. (Fischer & Linsenmair 2001a). Discounting Lake Nakuru N. P., this represents an average loss of 3.2% per year. The disappearance of Waterbucks from the flood-plain areas around Waza N. P. in N Cameroon, where they used to occur only in small numbers, can be attributed to the construction of the upstream Maga Dam in 1979 and subsequent low rainfall. Its subsequent return to the area may be associated with the re-flooding that took place from 1994 onwards (Scholte 2005, Scholte *et al.* 2007). In 1997, the 300 km² Mutara reserve, and northern and western sections of Rwanda's Akagera N. P., were degazetted; fortunately, recent surveys suggest that numbers of Waterbuck in the new Park (estimated at 1640) have recovered to a level higher than that reported for the period 1997/98 (Apio & Wronski 2011).

Measurements

Kobus ellipsiprymnus

K. e. ellipsiprymnus

HB (♂): 2080 mm, n = 1

Tribe OREOTRAGINI

Klipspringer

Oreotragini Pocock, 1910. Proc. Zool. Soc. Lond. 1910: 885.

The Klipspringer *Oreotragus oreotragus* has always been recognized as an anomalous and highly specialized species, but with the advent of molecular phylogeny the species has become recognized as the survivor of a unique type of basal antelope, deriving directly from the earliest Antilopinae and deserving recognition as the monospecific representative of a singular lineage, the Oreotragini.

The previous allocation of the Klipspringer to the former Neotragini 'waste-paper basket', grouped *Oreotragus* with other small antelopes such as the dwarf antelopes (genera *Neotragus* and *Nesotragus*) and grysboks, *Raphicerus* spp., which have also been shown to be ancient, but separate, basal lineages. However, *Oreotragus* is clearly distant from other neotragine genera; molecular data (Hassanin & Douzery 1999, Matthee & Robinson 1999a, Hassanin *et al.* 2012) even concluded that the Klipspringer was closest to duikers Cephalophini (but see Matthee & Davis 2001). Grubb (2005), who provisionally retained *Oreotragus* in a traditional Neotragini, remarked that *Oreotragus* was not shown to share any synapomorphies with *Cephalophus*, and that *Oreotragus* should perhaps be restored to tribe Oreotragini (originally erected by Haltenorth 1963), which is the approach followed here (and see Bronner *et al.* 2003).

Characteristics of the tribe include: the presence of horns in ♂♂ only, except in ♀♀ in parts of East Africa; the presence of false hooves; preorbital and preputial gland present, but no interdigital and inguinal glands; and the presence of preorbital fossae (to accommodate the preorbital glands) and an ethmoid fissure. Relative to other antelopes, there are some unique changes to the digital bones that enable the Klipspringer to move quickly over slippery rocky surfaces. A remarkable feature of the Klipspringer, unique amongst African antelopes, is the hollow nature of the hairs, which provides an insulating layer of air to deal with temperature extremes (Norton 1980). Of some fifteen named subspecies some might merit specific status, given the likelihood of ancient and prolonged isolation on widely separate massifs. However, Robinson *et al.* (1996) were unable to find any genetic differences in the regional specimens that they sampled.

Klipspringer

Oreotragus A. Smith, 1834. S. Afr. Quart. J. 2: 212.

Oreotragus is a monotypic genus including only the Klipspringer *O. oreotragus*, widely distributed in the savanna and arid zones in precipitous rocky habitats. *Oreotragus major*, recorded as late as 0.7 mya in South Africa (Vrba 1995), has recently been regarded as conspecific with the living species (Watson & Plug 1995).

Klipspringers are small antelopes (shoulder height about 60 cm, mass up to about 16 kg) adapted to a life among rocks and distinguished

from all other antelopes by stance on short hooves and short limbs, very short muzzle, and peculiar pelage. Unique aspects of its morphology have led to its placement here in a distinct tribe following Haltenorth (1963).

Peter Grubb

Oreotragus oreotragus KLIPSPRINGER

Fr. L'Oréotrague; Ger. Klippspringer

Oreotragus oreotragus (Zimmermann, 1783). Geogr. Gesch. Mensch. Vierf. Thiere 3: 269. 'Die Caffern'; now known to be South Africa, Western Cape Prov., Cape Dist., False Bay (Grubb 1999).

Klipspringer *Oreotragus oreotragus schillingsii*.

Taxonomy Ansell (1972) listed 11 subspecies from different parts of the geographic range, based mainly upon the treatment of Haltenorth (1963), the most notable being the isolated western race, *O. o. porteousi*, from Nigeria, and the East African *O. o. schillingsii*, the only subspecies in which ♀♀ are horned (Roosevelt & Heller 1915, Kingdon 1982). We provisionally list these subspecies here, noting that Kingdon (1997) reduced the list to seven subspecies without comment, though earlier (1982) he implied that *stevensoni*, *transvaalensis* and *tyleri* are synonymous with the nominate form (and *aureus* with *schillingsii*). Robinson *et al.* (1996a) demonstrated the apparent lack of any regional cytotypes within the species. Synonyms: *aceratos*, *aureus*, *centralis*, *cunenensis*, *hyatti*, *klipspringer*, *porteousi*, *saltator*, *saltatrixoides*, *schillingsii*, *somalicus*, *steinhardti*, *stevensoni*, *transvaalensis*, *tyleri*. Chromosome number: $2n = 60$; all chromosomes, including X and Y, are acrocentric (Robinson *et al.* 1996a).

Description A small and stocky antelope, yet supremely agile in its rocky habitat. Pelage is sandy-yellow to grey, with white undersides and, in some populations (e.g. *O. o. centralis* in SW Tanzania), a russetting around the shoulders. Black skin on the insides of the ears partially covered by white hair, giving rise to a black-and-white pattern that can aid individual identification. Pelage coarse and pithy as in some deer. Hooves short and unusually shaped so that the animal appears to walk on tip-toes – this provides good purchase on slippery rocky surfaces. The tips are oval in shape and leave characteristic tracks in moist ground. The false hooves on the forelimbs are much better developed than those on the hind. Tail short and untufted. Distinct,

Lateral, palatal and dorsal views of skull of Klipspringer *Oreotragus oreotragus*.

black preorbital glands are present in both sexes, but are larger in ♂♂. A preputial gland is present; interdigital and inguinal glands are absent. Females have two pairs of inguinal nipples. Females are usually about 10% larger than ♂♂.

Males have straight, sharp, spike-like horns, reaching up to 16 cm but averaging about 9 cm (S. C. Roberts & R. I. M. Dunbar unpubl.); ♀♀ are horned in parts of Kenya, NE Tanzania and E Uganda. Horns have no more than six annulations (sometimes less or none). Norton (1980) recorded that horn growth started at about four months of age, and that horns protruded above the hair at 5.5–6 months. They then grow rapidly up to 12 months attaining adult size at about 17–18 months.

The rostrum is short, even more so than in *Raphicerus*, and an ethmoid vacuity is present. The preorbital fossae are very much larger than in *Raphicerus*, with sharply ridged posterior and dorsal margins; there is no secondary bony growth on the frontal and parietal. Lower incisiform teeth are relatively small, median pair broader; cheekteeth are relatively larger than in *Raphicerus*, with large premolars.

Geographic Variation

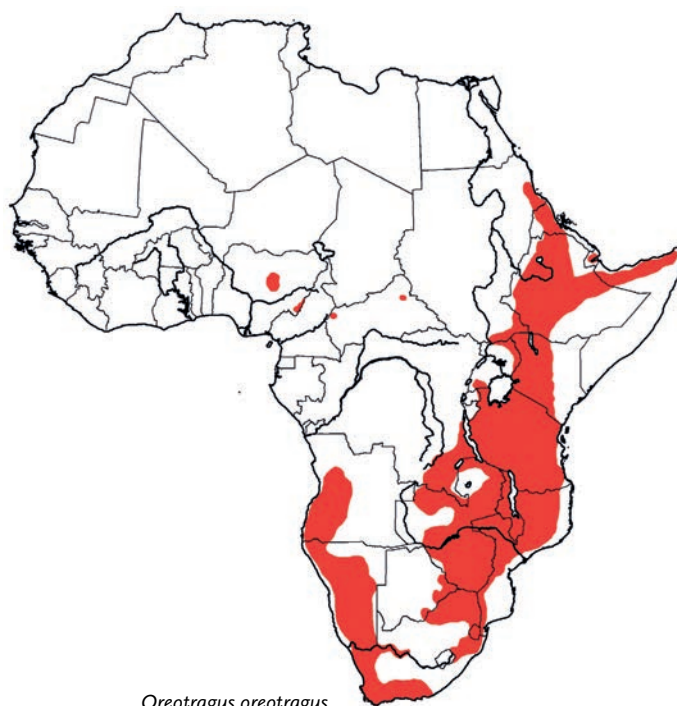

- O. o. oreotragus*: South Africa, in the Cape and E Free State.
O. o. transvaalensis: N and E South Africa, possibly into S Mozambique.
O. o. tyleri: Namibia and SW Angola. Exact limits and degree of intergradation with *oreotragus* unclear.
O. o. stervensoni: Zimbabwe and E Botswana.
O. o. aceratos: south-east Africa between the Rufiji and Zambezi Rivers.
O. o. centralis: Zambia, SE DR Congo, SW Tanzania, N Malawi; also ranges south into Zimbabwe (Ansell 1978).
O. o. schillingsii: Tanzania (except the south-east where replaced by *aceratos* and south-west where replaced by *centralis*), S Kenya, SW Uganda and presumably Rwanda and formerly Burundi. Females often have well-developed horns (averaging 7 cm in length, $n = 5$; S. C. Roberts pers. obs.).
O. o. aureus: N Kenya, NE Uganda and S Ethiopia; distinguished from *schillingsii* only by hornless ♀♀.
O. o. saltatrixoides: Ethiopian Highlands, Eritrea and Sudan.
O. o. somalicus: N Somalia and Djibouti (see Künzel *et al.* 2000).
O. o. porteousi (Western Klipspringer): isolated populations in suitable habitat in Nigeria (particularly around the Jos Plateau) and Central African Republic.

Similar Species

- Raphicerus* spp. More slender build; ears larger; pedal glands present.
Ourebia ourebia. Sympatric in much of East and south-eastern Africa. More slender build, with a distinctive black patch below the ears; inguinal glands present.
Sylvicapra grimmia. Broadly sympatric. Similar in outline, though taller and heavier, and has much smaller, backward-pointing horns.

Distribution Endemic to Africa. Klipspringers have a wide distribution from NE and SE Sudan, Eritrea, N Somalia and the Ethiopian Highlands southwards through East and southern Africa to the Western Cape in South Africa, and along the west coast in Namibia and SW Angola. More isolated populations occur in Central African Republic (two separate areas in the north-eastern and north-western uplands) and Nigeria, where they occur in and around the Jos Plateau (East 1999), and also in the east in Gashaka–Gumti N. P. (Nicholas 2004a); there are no records from Cameroon (Lamarque *et al.* 1990). They are confined to suitable rocky or mountainous areas, including largely contiguous habitat (e.g. the Rift and Zambezi Valleys, and the southern African escarpment) and isolated kopjes in savanna and scrublands. The current distribution is probably very similar to its historical one, as their dependence on mountainous terrain and browsing feeding habits protects them from loss of habitat to agriculture and from competition with cattle. The only country in which they formerly occurred, but are now probably extinct, is Burundi, while in Rwanda they are now confined entirely to Akagera N. P. (East 1999).

Habitat As its name implies (Klipspringer means ‘cliff-jumper’ in Afrikaans), Klipspringers are dependent on rocky and mountainous terrain, occurring up to 4380 m in the Ethiopian Highlands (Yalden *et al.* 1996). With this crucial exception, they are adaptable and have a wide climatic range. In the Kuiseb Canyon in Namibia, for example, mean annual rainfall is only 17 mm and is highly seasonal, and mean monthly temperatures vary from 10 to 33 °C (Tilson

Oreotragus oreotragus

1980). In contrast, the Ethiopian Highlands have an annual rainfall of 1385 mm falling over half of the year, and monthly temperatures of only 2–8 °C (Dunbar 1979). Klipspringers are common in both areas, and in other parts of Africa with intermediate conditions. Since there is wide botanical variation associated with these environmental conditions, there is no specific vegetation type that can be associated with Klipspringer abundance.

Klipspringers often have two main habitat types within their territories: (i) rocky slopes, outcrops or cliffs, and (ii) flat, often sandy, scrubland at the base of the slopes. They typically feed at the base of the cliffs where suitable plants are abundant, and then seek suitable resting sites high up on the slopes to rest and ruminate. There are usually two or three favoured resting sites in each territory, where family groups may spend the entire mid-day period. Such sites are often rocky ledges under overhangs, providing both shade and excellent vantage points over the slopes below.

Abundance Klipspringers are locally abundant in suitable habitat, reaching high densities (e.g. an estimated 10–14/km² in the Simien Mts in Ethiopia; Dunbar 1978). Abundance is closely related to the extent of suitable rocky terrain, and overall population density is more typically in the range of 0.01–0.1/km² in restricted areas of suitable habitat, to 0.15–0.30/km² in areas with more extensive habitat (East 1999). Based on these average population densities, East (1999) estimated a total population of about 42,000 animals, but which is almost certainly an underestimate. The species occurs in substantial numbers on private farmland in Namibia.

The numbers of the Western Klipspringer in Nigeria and Central African Republic are unknown, but are unlikely to exceed a few thousand at most, and are probably declining.

Adaptations Unique changes to the digital bones have occurred, relative to other antelopes, to provide the Klipspringer with the traction necessary to move quickly over slippery rocky surfaces.

Klipspringer *Oreotragus oreotragus* vertical leap (from film). Note bunching of forefeet.

The third phalangeal bone has rotated about 30 degrees posteriorly so that, in effect, the animal actually walks on the anterior tips of the hooves, which wear down as youngsters mature (Norton 1980). The hairs, which range in length from 15 to 28 mm, are springy in texture and hollow, another feature unique amongst African antelopes, providing an insulating layer of air to deal with both upper and lower extremes of temperature (Norton 1980).

Klipspringers are unique in that ♀♀ are horned in some high-density areas in eastern Africa and hornless elsewhere. Involvement of the ♀♀ in territory defence has led to the suggestion that ♀♀ may be the primarily territorial sex, rather than ♂♂ defending territorial food resources for the ♀ (Roberts & Dunbar 2000). Females initiate up to 90% of scent-marking bouts, choosing where and when to carry out this important territorial advertisement. In contrast, ♂♂ follow ♀♀ and over-mark every one of the female's scent marks, perhaps a form of mate-guarding. In between-pair encounters, ♀♀ also engage other ♀♀ in bouts of violent head-butting, even where they are hornless. Further evidence for this suggestion comes from comparisons of the ecology and social behaviour of horned and hornless female populations (Roberts 1996, S. C. Roberts & R. I. M. Dunbar unpubl.). Female horned populations in East Africa have by far the smallest territories, where the highest rates of physical encounters are expected. High aggression rates between ♀♀ may thus have led to horn expression, but because horns make fighting more dangerous, ♀♀ appear to avoid fights. Since ♀♀ initiate group movements, this also reduces the number of male intra-sexual encounters, theoretically driving reduced selection for large male horns in East African populations (S. C. Roberts & R. I. M. Dunbar unpubl.).

Foraging and Food Klipspringers are browsers, preferring food of high energetic and protein content. This includes young leaves, flowers, flower buds, seeds and fruits. Between 4 and 13 (mean = 8) plant species are eaten per day in South Africa (Norton 1984), with up to 90% of feeding records being of fruit and flowers in the wet

season (as low as 19% in the dry season). While browse forms the bulk of their diet, they have also been found to include up to 30% of new, green grass growth in Ethiopia where there is high rainfall. However, this appears to be exceptional, and in drier areas grazing is less common: less than 10% of the diet in Zambia (Wilson & Child 1965), 1.5% in Kenya (Qvortrup & Blankenship 1974) and only one observation in 1000 in the Cape (Norton 1984). Indeed, studies involving stable carbon isotope analysis in East African Klipspringers found that their diet includes only 4% grass (Cerling *et al.* 2003).

Favoured food in Zambia (Wilson & Child 1965) included leaves of *Diplorhynchus mossambicensis*, *Pseudolachnostylis maprouneifolia* and *Lannea edulis*, and fruit of *P. maprouneifolia* and *Dicrostachys cinerea*. Some of the same items were also eaten in a Zimbabwe study (Smithers & Wilson 1979), as well as the fruit and leaves of *Ziziphus mucronata* and flowers of *Aloe chabaudii* and *Diospyros mespiliformis*. In the far south of Zimbabwe, the same items crop up, in addition to fruits of *Hexalobus monopetalus*, fruits and leaves of *Grewia bicolor* and *G. flava*, and leaves of *Croton pseudopulchellus* and the herb *Tephrosia rhodesica*, as well as the succulent *Sansevieria pearsonii* (Roberts 1994). Norton (1984) recorded very selective seasonal feeding of *Aspalathus hirta* flowers and fruits of *Maytenus oleoides*, *Rhus undulata*, *Indigofera spinescens* and *Euphorbia mauritanica*, often stripping shrubs entirely of their fruit.

During the dry season in Zimbabwe, ♀♀ have been observed to rear up on their hindlegs to reach food items out of reach, and measurements taken later show that this confers a maximum range of 106 cm above the ground (S. C. Roberts pers. obs.). This behaviour is different from that commonly observed in Gerenuk *Litocranius walleri*, as they do not rest their forelegs against branches for support while feeding in this way. Under the most extreme conditions in Namibia, Klipspringers have even been known to climb ana trees *Acacia albidia*, up to a height of 5.4 m, in order to reach their favoured food (Kok & Van Wyk 1982) and have been seen to take refuge in trees in Tanzania (Kingdon 1982). Norton (1980) recorded osteophagia and geophagia from termitaria.

Klipspringers have been thought to obtain all their water requirements from their food, a conclusion based on observations of groups living far from water (Wilson & Child 1965). However, in the dry season in Zimbabwe, Klipspringers cross several neighbouring territories to visit permanent springs and they have even been observed drinking from small pools in the sandy bed of the seasonally flooding Limpopo R. (S. C. Roberts pers. obs.). Such excursions are risky, taking them up to several hundred metres away from the safety of the cliffline across difficult, sandy terrain. Notably, all excursions away from the rocks were made during the hottest, middle hours of the day, when predation risk is lowest. They also regularly drink from rock-pools after rainfall. These observations suggest that Klipspringers in some areas are not tolerant of water-deprivation.

Social and Reproductive Behaviour The basic social unit is an adult male–female pair, often accompanied by one or sometimes two offspring (Dunbar & Dunbar 1974a, Tilson 1980, Roberts 1994). Short-term observations can overestimate the proportion of single individuals, while the size of female offspring can lead to the conclusion that some ♂♂ are accompanied by two adult ♀♀. Although up to nine animals have been seen together (Kingdon 1982), these instances appear to be temporary and formed by two

Klipspringer *Oreotragus oreotragus*.

or more groups meeting. Subadult offspring are driven away by the same-sexed adult, young ♂♂ being expelled earlier than ♀♀ (Norton 1980).

Adult pairs occupy territories that adjoin those of 2–4 neighbouring pairs. Territory size varies across Africa and is inversely related to annual rainfall (S. C. Roberts & R. I. M. Dunbar unpubl.). The smallest recorded territories (about 1.4 ha) are in Tsavo N. P. in Kenya (annual rainfall 750 mm), increasing to 5.5 ha in Matobo N. P. in Zimbabwe (558 mm), 8 ha in Ethiopia (1385 mm), 10 ha in the Drakensberg Mts, South Africa (941 mm), 15 ha at Gamka in South Africa (400 mm), 20 ha in the Limpopo Valley, Zimbabwe (332 mm), 49 ha at Springbok in South Africa (160 mm) and 90 ha in the Kuiseb Canyon, Namibia (18 mm).

Territories are defended throughout the year. The most common form of territory delineation is by scent-marking at latrine sites and on vegetation. All family members defecate and urinate in the same visit to dung middens (up to 2 m across), of which there are 5–10 dotted around the territory, often along boundaries (Dunbar & Dunbar 1974a). Scent-marking on vegetation is done by depositing secretion from the preorbital glands onto twigs and leaves. The same twigs are used repeatedly, leading to a visible accumulation of secretion that resembles a black bead. The secretion contains a number of ketones and esters, which are considerably more volatile than those found in the preorbital secretions of other antelopes (Burger *et al.* 1997). Over 50% is protein, which probably acts as a controlled release system for the volatiles. Marking is often preceded by licking the old marks, probably to release volatiles to check who marked there last (Roberts 1998). Very fresh marks are detectable by humans, the smell resembling aniseed (S. C. Roberts pers. obs.). Three territories in the Limpopo Valley, Zimbabwe, which were mapped in detail (Roberts & Lowen 1997), contained 403, 644 and 836 discrete scent-marking sites. Half of all the surveyed sites contained either one or two marked twigs, but up to 22 different twigs could be marked within one site. The number of these sites marked in a 24-hour period varied seasonally between 60 and 140, increasing during the mating season and towards the end of the dry season (Roberts 1994). Most marks were revisited at least every 5–7 days, and some marks every two days. Visit rates to marking sites appear to coincide with the length of time over which scent is detectable: an experiment with captive Klipspringers indicated that marks retain efficacy for seven days but not ten days (Roberts 1998). To increase chances of being detected by territorial intruders, pairs scent-mark in highly predictable spots (even to human observers), above bare rock surfaces in elevated areas, especially in areas with good vantage points. Food plants are also marked more often than unpalatable species (Roberts 1997). Marks are placed throughout the territory, not just at boundaries, although boundaries with neighbours are marked more than boundaries not directly adjoining another territory (Roberts & Lowen 1997; see also Kruger *et al.* 2002).

Physical territory defence between neighbouring pairs occurs at a much lower frequency, which is predicted by both rainfall and territory size. Fights and chases are more common in areas with high rainfall and small territory size (S. C. Roberts & R. I. M. Dunbar unpubl.). The highest rates of physical aggression are about 1 per 12 h at Sankaber in Ethiopia (Dunbar & Dunbar 1980), while in the Kuiseb Canyon in Namibia, in the largest territories recorded, no

encounters were observed in over 900 hours of observation time (R. L. Tilson pers. comm.). Both sexes are involved. Of 21 encounters observed in various studies, ♂♂ were involved in 18 (86%) and ♀♀ in eight (38%); in three cases both sexes confronted the same-sex members of another pair (Roberts 1994). Klipspringers do not have ritualized 'air-cushion' fights (common in the related dik-dik), in which actual contact is avoided. However, physical contact is rare and was made in seven cases (33%; female–female physical contact in two), the rest were chases without observed contact. Males have been known to die from horn-jab wounds sustained in fights (Norton 1980). Female territorial defence, the possibility that ♀♀ may be the primarily territorial sex, and the correspondence between high densities and the appearance of horns in ♀♀ have been discussed above in the Adaptations section.

Pair bonds between adult ♂♂ and ♀♀ are remarkably strong and stable. Behavioural synchrony is high, with pair members engaged in the same activity for between 50 and 80% of the time (Dunbar & Dunbar 1980, Norton 1980). Distances between pair members are usually 5 m or less, but more when feeding. This cohesiveness is apparently not seasonally variable, even though the ♀ is only receptive for a fraction of the year. Pairs are thought to last until one of the pair dies and the longest recorded pairing is nine years (Norton 1987). Since ♀♀ can (at least partly) defend their own food resources, this raises the question of why Klipspringers maintain such well-maintained pair bonds. These pair bonds persist outside the breeding season and so are unlikely to be solely due to mate-guarding by ♂♂ (Roberts & Dunbar 2000). The reason may be that ♂♂ provide a vigilance service against predators while ♀♀ are feeding: pairs alternately take turns to stand guard from an elevated vantage point while the other feeds in the bushes below. Males spend more time being vigilant and are more likely to detect a threat than ♀♀. By guarding the ♀ and offspring, ♂♂ thus increase their own reproductive success (Dunbar & Dunbar 1980), in addition to benefits gained by mate-guarding.

When a predator is observed, a brief alarm call is given by the first to spot the danger. The group flees 30–50 m to an elevated vantage point, then turns to keep the predator in view. They may then give further alarm calls. About 64% of encounters with predators elicited such calling. In Namibia, the adult ♂ and ♀ may continue to call every 3 sec for up to 20 min (average 5 min) in what has been termed 'alarm duetting' (Tilson 1977a). These calls are audible up to 700 m away and appear to act as a pursuit deterrent signal to the predator (Tilson & Norton 1981).

Courtship is typified by the ♂ sniffing the female's rear, performing flehmen and tapping the female's hindlegs with his forelegs (laufschiag). Observations in captivity suggest that oestrus appears to last about a week and that 4–6 copulations occur during this time. Young are born in the shelter of rocks or in thick vegetation in the rocky habitat and remain hidden for up to three months before joining the pair. At least during the very early part of their lives, the young, if approached, lay their heads flat on the ground, with their ears flat and make no attempt to move off. Their cryptic colouration makes them very difficult to see when lying up in shelter (Skinner & Chimimba 2005).

Reproduction and Population Structure Breeding seasonality varies across the range. In Zimbabwe, mating was observed

Klipspringer *Oreotragus oreotragus*.

in three pairs and courtship behaviour in another; all cases were in Jul and no mating or courtship occurred during the rest of the year. Lambing would then be timed to coincide with the wet season (Roberts 1994). In Ethiopia, the mating season is probably in Aug–Sep (Dunbar & Dunbar 1974a). However, in Zambia, pregnant ♀♀ were recorded in all months except Dec–Jan, and small lambs were found in Apr, Jun and Nov (Wilson & Child 1965). A late foetus was found in an animal taken in Jul in Angola (Hill & Carter 1941). Fecundity varies across populations and is related to temperature: it is lowest in colder areas at high altitude (Dunbar 1990).

Gestation has been estimated at five months (Norton 1980) and weaning at four months (Cuneo 1965, Norton 1980). Birth-weight of a female lamb was 1.13 kg (Wilson & Child 1965). No genetic studies have been carried out to investigate the possibility or extent of extra-pair paternity. However, an observation in Namibia (R. L. Tilson pers. comm.) indicates that extra-pair copulations can occur: a neighbouring or transient ♂ copulated with a mated ♀ while her mate was further down a canyon, busy alarm-calling at a jackal. The other ♂ had disappeared by the time he returned to the ♀, but he spent the next few minutes sniffing the ♀ and scent-marking, so it is possible that he was aware of the other male's visit.

Of 44 completely sexed groups at Sankaber, Ethiopia, 33 were male–female pairs and 11 were trios of one ♂ and two ♀♀ (Dunbar & Dunbar 1974a). The same authors recorded the following group compositions at Geech in Ethiopia: 12 male–female pairs, three two-female trios and one two-male trio at Geech (they reported similar findings at a third site, Bole, but this area was subject to regular hunting, which would reduce male numbers). Dunbar & Dunbar (1974a) conclude that a typical group (roughly three-quarters of all groups) consists of an adult pair, with a quarter consisting of two

♀♀. Other studies agree with this estimate, though group sizes of up to five can occur in exceptional cases (Norton 1980). Based on this information, an adult sex ratio can be estimated at about 1 ♂ to 1.2 ♀♀, although the sex ratio at birth may well be at parity.

Predators, Parasites and Diseases The major predator of adult Klipspringers is probably the Leopard *Panthera pardus*, which favours similar rocky habitat and is present across almost all of its range. In Matobo N. P., Klipspringers appeared in 9–13% of 449 leopard scats and an adult ♂ killed by a Leopard was also found (Smith 1977). Similarly Klipspringers were the most common prey item (with Rock Hyrax *Procavia capensis*) in the Cedarberg Mts of South Africa (Martins *et al.* 2011). Klipspringer remains have also been found in Caracal *Caracal caracal* scats (Stuart & Hickman 1991). Both adult and young Klipspringers may occasionally be killed by African Rock Pythons *Python sebae* and large raptors (Roberts 1994), and baboons *Papio* spp. and Black-backed Jackals *Canis mesomelas* have been observed taking young lambs (Tilson 1980, Davies & Cowlshaw 1996). Attempts to reintroduce Klipspringers in the Free State in South Africa have been unsuccessful mainly due to healthy populations of predators such as Black-backed Jackals and Caracals (S. Vrahimis pers. comm.).

Klipspringers are hosts to an unusual parasite. While all ungulates pick up ticks on the legs and body from vegetation, one tick species aggregates specifically on branches scent-marked by Klipspringers, using this as a means of crawling onto the face of Klipspringers when they return to scent-mark again (Rechav *et al.* 1978, Spickett *et al.* 1981). The ticks appear to locate marks by following the aqueous scent trail formed by rainwater washing scent down the bush. The tick, *Ixodes matopi*, is named after Matobo

N. P. where it was first observed. It would be interesting to learn how widespread this host–parasite relationship is, because it was not present on marks in the Limpopo Valley, only 300 km away, despite careful daily search of 2000 marks, including after rain (Roberts 1995). The tick completes its life-cycle on Jameson's Red Rock Rabbit *Pronolagus randensis*.

Klipspringers are also host to other tick species (e.g. *Rhipicephalus* spp. in the Limpopo Valley), and these are gleaned, with the apparent acceptance of Klipspringers, by at least four passerine birds: Pale-winged Starlings *Onychognathus nabouroup*, Red-winged Starlings *Onychognathus morio*, Yellow-bellied Greenbul *Chlorocichla flaviventris* and Familiar Chats *Cercomela familiaris* (Tilson 1977b, Steyn & Hosking 1988, Roberts 1993, 1995, Anderson 2006). There is some evidence that these birds may also specifically ingest proteinaceous preorbital gland secretion direct from the glands (Roberts 1995). Klipspringers also self-groom, combing pelage through the incisors to tease out ticks (Hart, L.A. *et al.* 1996).

Conservation IUCN Category: Least Concern (*O. o. porteousi* – Endangered C2a(i)). CITES: Not listed.

Klipspringer populations often persist in areas devoid of other ungulates, because their preference for rocky habitat does not conflict with agricultural needs. The population currently is believed to be stable, or slightly declining. However, recent information on the status of populations in several countries is lacking, including Sudan, Somalia and Angola. Roughly one-quarter of the total population is estimated to occur in protected areas, including strongholds such as Simien and Bale Mountains National Parks (Ethiopia), Tsavo N. P. (Kenya), North and South Luangwa N. P. (Zambia), Nyika N. P. (Malawi), Niassa G. R. (Mozambique), Matobo N. P. (Zimbabwe), Hester Malan N. R. and Augrabies Falls N. P. (South Africa) and Namib–Naukluft N. P. (Namibia) (East 1999).

The status of the Western Klipspringer *O. o. porteousi* is an exception to the above, with this subspecies occurring in fragmented populations in Nigeria and the Central African Republic. It is known to occur in Lamé G. R. (East 1999) and in Gashaka–Gumti N. P., which is thought to represent a stronghold for this isolated subspecies (Nicholas 2004a). There is a need for close monitoring of the population status of this subspecies.

Measurements

Oreotragus oreotragus

HB (♂ ♂): 862 (820–920) mm, n = 13

HB (♀ ♀): 905 (883–1000) mm, n = 10

T (♂ ♂): 76 (65–90) mm, n = 13

T (♀ ♀): 84 (65–103) mm, n = 10

HF c.u. (♂ ♂): 223 (215–230) mm, n = 13

HF c.u. (♀ ♀): 224 (215–240) mm, n = 10

E (♂ ♂): 93 (87–100) mm, n = 13

E (♀ ♀): 92 (85–99) mm, n = 10

WT (♂ ♂): 10.6 (9.1–11.6) kg, n = 13

WT (♀ ♀): 13.2 (10.5–15.9) kg, n = 10

Southern Africa (Smithers 1983)

Maximum recorded horn length is 16.2 cm for a pair of horns from Gravelotte, Limpopo Province, South Africa (Rowland Ward)

Tribe AEPYCEROTINI

Impala

Aepycerotini Gray, 1872. Cat. Ruminant Mamm. Brit. Mus. p. 4, 42.

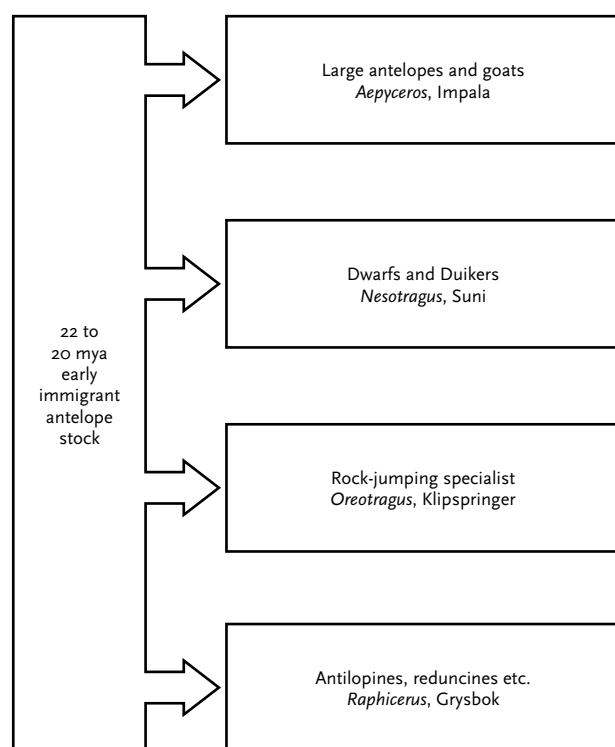

A taxonomic puzzle for many years, the Impala *Aepyceros melampus* has been recognized as a distinct evolutionary lineage by some authors (e.g. Ansell 1972, Vrba 1979, Gentry 1992). It had previously been linked to the gazelline antelopes (Simpson 1945, in his tribe Antilopini), on the basis of its proportions approximating to various gazelles, and to the reduncines (Ellerman *et al.* 1953) based on even closer superficial resemblances with *Kobus* and *Redunca*. A less obvious relationship with the Alcelaphini was first proposed by Gentry (1966, 1978) on the basis of many cranial resemblances between living and fossil forms (both lineages showing elongation of the skull and hollowing at the base of the horns). Gentry's placement of the Impala in Alcelaphini was followed by Kingdon (1982, 1997) and Vrba (1984). A molecular association with Alcelaphini was also proposed by Lowenstein (1986), and Essop *et al.* (1997) found some weak support for sister status between *Aepyceros* and *Alcelaphus* on the basis of restriction sites of mtDNA. Gatesy *et al.* (1997) noted that while the precise phylogenetic affinity of *Aepyceros* was not clear, the Impala placed as the sister group to Hippotragini, Alcelaphini, Caprini and *Pantholops* (the Chiru or Tibetan Antelope).

On the basis of molecular work, the Impala is here included as the sole member of its own tribe (Hassanin & Douzery 1999, 2003, Matthee & Robinson 1999a, Matthee & Davis 2001). These molecular analyses generally agree with Georgiadis *et al.* (1990) that the Impala represents the sole survivor of a basal lineage with a proposed lineage ancestry of about 21.5 million years (Hernández Fernández & Vrba

2005). In agreement with Gatesy *et al.* (1997), the phylogenetic supertree by Hernández Fernández & Vrba (2005) aligned the Impala as sister species of a clade containing caprines, hippotragines and alcelaphines (contra Vrba & Schaller 2000).

However, basal positions have invited further analysis or speculation on the Impala's possible relationship with other basal groups as well as its position in regard to later, secondary radiations. Hernández Fernández & Vrba (2005) envisaged the earliest bovids splitting three-ways into 'Bovinae', 'Aepycerotinae' and 'Antilopinae', with many subsequent derivatives, but omitted behavioural or ecological arguments for the bovid radiation. Exploring molecular relationships among bovids, others (Matthee & Robinson 1999a, Hassanin & Douzery 1999, Hassanin *et al.* 2012) found the Impala clustering with the Suni *Nesotragus moschatus*, another basal antelope (but see Matthee & Davis 2001). This is of special interest as both the Suni and Impala share the peculiarity of a vacuity between the maxilla and premaxilla. The resemblance has been noted by many authors and has generally been assumed to be due to convergence, but demonstration of at least some genetic linkage forces a reappraisal of this common peculiarity.

In both instances the significance of the vacuity seems to lie in a phylogenetic elongation of both nasals and premaxilla to create a solid joint between the side and top of the muzzle. In structural terms this looks like improvised 'casing' that helps elongate the muzzle. This implies that both species had an ancestor with reduced nasals and premaxilla, but was this ancestor common to both? An open 'nasal bellows' mechanism for sophisticated heat-control by nasal panting is found in many gazelline desert antelopes (Antilopini), the Beira *Dorcotragus megalotis* and, most extremely, in the Saiga Antelope *Saiga tatarica* and in the dik-diks (Madoquini) (Kingdon 1982). All these antelopes have ancient pedigrees (for example, the Saiga has been estimated to have diverged from other Antilopini about 20 mya; Hernández Fernández & Vrba 2005). There are important

Four antelope radiations over last 20 million years and most conservative surviving genus.

Diagram of Impala *Aepyceros melampus* skull compared with hypothetical and more generalized antelope. Distinctive evolutionary traits/trends/peculiarities in structure suggested by arrows.

Top left: symmetrical grid imposed on skull outline of hypothetical ancestral antelope. Below left: cartesian co-ordinates imposed on Suni *Nesotragus moschatus* skull. Below right: cartesian co-ordinates imposed on Impala *Aepyceros melampus* skull. Top right: cartesian co-ordinates used to construct a skull intermediate between the previous three.

evolutionary implications for a more heat-adapted precursor to both the Suni and Impala. For a start, such a conclusion is consistent with the putative adaptive difference that separated and distinguished ancestral Antilopinae from ancestral Bovinae (Kingdon 1982). It is also consistent with the Bovinae/Antilopinae split first taking place along the hot, dry interface between Eurasia and Africa. It follows from this that the predominantly southern and eastern African ranges of Impalas and Sunis are consistent with a long-established, but essentially secondary, preference for cooler, well-shaded habitats. Because these regions are more distant from the putative centre of origin for Antilopinae it seems likely that both Aepycerotini and Neotragini represent very early branching into founding lineages, the former larger, longer in the legs and emphatically gregarious, the latter remaining small, short-legged, solitary and territorial. Lengthening of the legs can be correlated with lengthening of the skull in the Impala but not, of course, with the Suni.

Although Impalas have no facial, pedal or inguinal glands, the backs of the lower hindlegs have thick oval tufts of black hairs that

cover metatarsal glands, a feature unique among Bovidae, and that presumably plays an important role in scent communication. Other characteristics of the tribe besides those already mentioned include the presence of lyrate, strongly ridged horns in males only, and the absence of preorbital fossae or an ethmoid fissure in the skull.

Survival of the Impala lineage in an unstable ecotone between woody bushlands (mainly in the dry season) and more open grassland and savanna (in the wet season) is probably partly due to a browse/graze dietary adaptation (Harrison 1936) and partly to exceptional versatility in its social relations (Schenkel 1966, Jarman, P. J. & Jarman, M. V. 1973, Monfort *et al.* 1973, Warren 1974). Individuals have no lasting attachments and can disperse or assemble easily. The laying of scent-trails and very loud calls assist this easy coming and going and the morphological adaptations associated with these behaviours are described in the species and generic profiles.

Gregariousness in the earliest Aepycerotini and increases in body size, leg-length and spatial range were probably the key adaptations that ensured survival of the Impala lineage. Perhaps it was their early acquisition of sociality, physical enlargement and an ability to escape predators that ensured that it was this branch of the earliest Antilopinae that subsequently gave rise to the majority of larger-bodied antelopes, goats and sheep. If, as suggested by others (e.g. Gentry 1978, Vrba 1984, Lowenstein 1986, Gatesy *et al.* 1992, 1997), Alcelaphini share a common ancestry with Aepycerotini, their relationship, though distant, is manifest in such shared characteristics as elongation of the legs and face and an ability to live at higher densities. Other supposedly related groups may also share different permutations of characteristics such as hollow foreheads and exceptional agility in caprines, grass-eating and still larger body sizes in the hippotragines. In any event, future molecular techniques can be expected to greatly refine our understanding of the relationship of Aepycerotini to other antelopes in the near future.

GENUS *Aepyceros*

Impala

Aepyceros Sundevall, 1847. Kongl. Svenska Vet.-Akad. Handl. Stockholm 1845: 271 (1847).

The Impala is the only representative of the tribe Aepycerotini and the only species in the genus *Aepyceros*. Impalas superficially resemble many medium-sized antelopes in their general proportions and, in their colouring, have an even closer resemblance to the Gerenuk *Litocranius walleri* (except that Impalas have prominent dark thigh stripes that seem to mimic the black genital cleft and serve to widen the angle at which an attractive, species-specific rump signal can be transmitted). Impalas also resemble some gazelle, kob and reedbuck species, resemblances that formerly led to suggestions of affinity with the gazelles (Simpson 1945) and with reduncines (Ellerman *et al.* 1953), and display some less obvious resemblances with the Hartbeest *Alcelaphus buselaphus* that led Vrba (1984) to consider the Impala as a sister-clade to the alcephalines (Hartbeest, wildebeest), and Gentry (1978) to include *Aepyceros* in Alcelaphini.

A striking conclusion of the study by Vrba (1984) is that Impalas have been unchanged in their basic form for at least 5 million years (the oldest fossil Impala is smaller but otherwise unchanged from the modern representative), whereas in that same time period the alcelaphine common ancestor has diverged at least 18 times in various forms of hartbeest and wildebeest of quite diverse morphology. The greatest change that can be observed in modern Impalas is between the isolated population of Black-faced Impalas *A. m. petersi* in Namibia and the Common Impalas *A. m. melampus* found everywhere else throughout its range, and even here the differences between the subspecies are modest (though several authors have proposed treating *petersi* as distinct; Shortridge 1934, Oboussier 1965, Cotterill 2003a). The implication is that Impalas were and are superbly adapted to their environment, and thus there has not been selection for any major changes in morphology or behaviour. These adaptations include a mixed feeding strategy, the ability to straddle both sides of an ecological frontier between wooded and grassy habitats, high population growth rate, gregarious habit with weak social bonds (see below), flexible territorial system, excellent anti-predator behaviour, and a unique system of tick-defence adaptations that includes an 'antelope toothcomb', reciprocal allogrooming and tolerance of and cooperation with tick-eating oxpeckers (see species account).

A particularly outstanding peculiarity of Impalas is their ability to form and to break up into loose aggregations of very variable size without any obvious attachment to other individuals or to permanent territories. Linked to their ability to disperse and then assemble in groups is their ability to transmit very effective visual, olfactory and auditory signals; notably 'empty-kicking' and 'tongue-flashing' displays, energetic modes of laying glandular scent trails by means of the metatarsal glands, and extraordinarily loud roars, in all of which they are unlike any other antelope.

Impala *Aepyceros melampus* tongue-flashing while roaring.

The horns of the Impala are unusual in being circular in section and hollow at their bases. For their strength and flexibility they rely as much on the thickness of the horn layer as on their relatively slender bone cores. They consist of two inverted arches so that blows can be delivered, caught or interlocked in a light wrestling technique that seeks to throw the opponent off balance. Their very wide span arcs through an extended catchment volume so that clashing horn surfaces dull the impact of blows and keep potential damage well away from the cranium. This favours the locking of horns rather than the ramming through of bruising blows.

Aepyceros melampus IMPALA

Fr. Impala; Ger. Schwarzfersenantilope

Aepyceros melampus (Lichtenstein, 1812). Reisen Sudl. Africa 2, pl. 4 opp. p. 544. Khosis, Kuruman, South Africa.

ABOVE: Lateral, palatal and dorsal views of skull of Impala *Aepyceros melampus*.
LEFT: Impala *Aepyceros melampus*.

Taxonomy Ansell (1972), largely following Haltenorth (1963), provisionally listed six subspecies, noting that the limits and intergradation between the subspecies are not well defined. Recent classifications, supported by molecular data (Nersting & Arctander 2001, Lorenzen *et al.* 2006a), recognize two subspecies: the nominate form, the Common Impala *A. m. melampus*, and the Black-faced Impala *A. m. petersi*. The Black-faced Impala has been considered a distinct species (Shortridge 1934, Oboussier 1965), and the two are highly genetically differentiated (Lorenzen & Siegmund 2004). Lorenzen *et al.* (2006a) also split the Common Impala subspecies into two genetically distinct groups, conforming with regional geographic affiliation to southern or East Africa, and also revealed the genetic distinctiveness of the Samburu population in Kenya, possibly indicative of a population bottleneck. More recently, Bastos-Silveira & Lister (2007) have examined morphometric data in more detail and have proposed four subspecies: *A. m. melampus* in South Africa; *A. m. petersi* in SW Angola and Namibia; *A. m. johnstoni* in Malawi and Zambia; and *A. m. suara* (including *rendilis*) in East Africa. Until these regional forms have been described in more detail and the exact boundaries of their ranges have been drawn we provisionally retain the conservative division into two subspecies. Synonyms: *holubi*, *johnstoni*, *katangae*, *pallah*, *petersi*, *rendilis*, *suara*. Chromosome number: $2n = 58-60$; these differences are due to fusion metacentrics (Wallace & Fairall 1967b).

Description A medium-sized antelope with long, thin legs, slender body and clear sexual dimorphism. Easily identified by its marked two-tone, short-haired coat: back, nape and upper flanks are reddish-brown and have a distinct sheen – although in *A. m. petersi* upperparts

are duller, lacking distinct reddish-brown colour – while limbs and lower flanks are paler. Ventral pelage white. Hair is closely pressed to the body and averages 12 mm in length on the top of the shoulders, being slightly longer on the underparts (about 15 mm). Hairs are off-white at the base and broader and reddish-brown at the tip, though duller at the tip in *A. m. petersi*. Most of head is reddish-brown with white patches above eyes and around mouth. Chin and throat white. Crown, between the ears, is black. Ears large, inside white with tip black. On each buttock and upper thigh there is one vertical and distinct black band (surrounded by patches of pale brown hairs) running from the level of the tail to the upper hindleg. Paler patches occur on insides of legs, while on back of lower hindleg there are thick oval tufts of black hairs that cover metatarsal glands, unique to the Bovidae. Tuft of tail is black and continues in a thin black line that runs up to the rump. Underparts of the tail are white, and the white hairs are long (~100 mm). Preorbital, pedal and inguinal glands are absent. Females have two pairs of inguinal nipples. In adults, the cloven hooves have an average length of 47 mm (40–52 mm); there are no false hooves. Sexual dimorphism is distinct: ♂♂ are taller and heavier than ♀♀ in all age groups.

Only ♂♂ carry horns, which are deeply ridged for most of their length, but smooth towards the tips: in juveniles the horns are straight, vertical and short (<150 mm). They become curved like upright brackets (<250 mm long) when individuals are 12–18 months old. With age, the horns curve backwards in a lyrate shape, with an average length of 500 mm (365–820 mm) for adult ♂♂. The skull is characterized by the absence of preorbital fossae or ethmoid fissure and a premaxillo-maxillary vacuity is present, which is known otherwise only in Bates' Pygmy Antelope *Neotragus batesi* (albeit vestigially) and

the Suni *Nesotragus moschatus* (Ansell 1972). Tooth eruption has been used as a means of estimating age up to 2.5 years, after which age can only be estimated based on tooth wear (Lane *et al.* 1994).

Geographic Variation

A. m. melampus (Common Impala): C Kenya to South Africa and west to SE Angola. Description mainly as above.

A. m. petersi (Black-faced Impala): NW Namibia and SW Angola. Larger and darker than Common Impala; a dark, nearly black band extends from the nostrils to between the eyes, and continues in a thinner band to the top of the head (these black facial markings are variable, and the thinner band is sometimes missing); black ear tip is larger and the tail almost 30% longer and much bushier than in the Common Impala.

There is a black colour variant of the Common Impala, which is recessive to the common red colour of the pelage. Individuals are totally black and farmers in southern Africa have isolated individuals in large paddocks resulting in pure black populations (J. D. Skinner pers. comm.).

Similar Species

Litocranius walleri. Sympatric only in East Africa. Of similar colouring, but with elongated legs and neck. Males with very robust horns that are shorter than in the Impala.

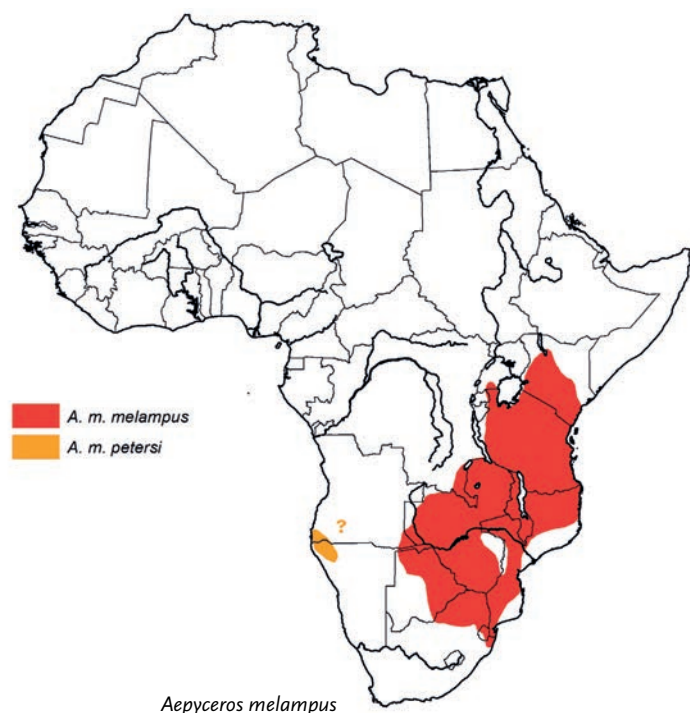

Distribution Endemic to Africa. Widespread in both the eastern and southern parts of the continent from Kenya to South Africa in savanna and woodland habitats close to water. The distribution range of Impalas remains largely unchanged from their historical range, although they have been eliminated from some parts through hunting and human settlement (East 1999). The northern extent of their range is the dry central and southern regions of Kenya, particularly in Kajiado and Laikipia Districts. Their range includes SW Uganda,

mainly in Lake Mburo N. P., although they formerly also occurred in the north-east of the country. They still occur in Rwanda where they are confined to Akagera N. P., but they have been extirpated from Burundi. Their range extends southwards throughout Tanzania, Zambia (except parts of the country west of the Zambezi R.), and Malawi, where they are confined mainly to protected areas. They formerly occurred marginally in extreme SE DR Congo, but there is no recent information on their status (East 1999).

In Mozambique, they occurred throughout much of the country, except apparently much of Nampula and Zambezia Provinces, but the civil war had a detrimental impact on their populations and they survive mainly in protected areas such as Gorongosa and Zinhave National Parks, Niassa G. R. and in W Gaza province; ongoing efforts to rehabilitate wildlife populations in this country will no doubt benefit this species. In Zimbabwe, they occur nearly throughout (although herds have been decimated by poachers since 2000), but are naturally absent from the miombo-*Brachystegia* woodland in the north-east. In Botswana, they are confined to the northern, north-eastern and eastern parts, particularly around the Okavango Delta (occasionally turning up in the eastern parts of the Kalahari), while the western part of their range extends to extreme SE Angola and NE Namibia in the E Caprivi Strip. The southern natural limit of the range of the species includes the Limpopo, North West and Gauteng Provinces of South Africa, E Swaziland and N KwaZulu-Natal as far as the Mhlatuze R. (East 1999, Skinner & Chimimba 2005).

In the last four decades, Impalas have been introduced to numerous privately owned game ranches and small reserves throughout southern Africa, such as Free State Province and much of KwaZulu-Natal in South Africa, Namibia and Zimbabwe and widely in Namibia (East 1999). Today Impalas also occur in Gabon, central Africa, where they have been introduced into two protected areas, though they are now in decline (P. Chardonnet pers. comm.). It has been noted that Impalas easily colonize new areas, such as the south-eastern part of Hwange N. P. in Zimbabwe, providing that a regular supply of surface water is available (Matson 2003).

In NW Namibia, the Black-faced Impala is naturally confined to Kaokoland and neighbouring SW Angola. Kaokoland was set aside as a protected area in 1928, when it formed part of Etosha N. P., Namibia, but lost its protection status in 1970. To guard against extinction, Black-faced Impalas were translocated to SW Etosha N. P. on the edge of the historic Black-faced Impala range (Green & Rothstein 1998). Today, this subspecies occurs between the Otjimborombonga area (ca 12°45'E) and Swartbooisdrift on the Cunene R., southward to the Kaoko Otavi area in the south-western part of Etosha N. P., and Kamanjab District just south of the Park (see also Conservation). There is no information on the current status of this subspecies in Angola, but they survive in Iona N. P. and may still occur in Bikuar and Mupa National Parks (East 1999, Crawford-Cabral & Veríssimo 2005). Historically, the two subspecies were separated in Namibia by Ovamboland, an old geographical barrier stretching over a distance of more than 300 km, with *A. m. petersi* occupying the Cunene R. area and *A. m. melampus* the Okavango R. area (though see Crawford-Cabral & Veríssimo 2005). Migration from the latter area would have been possible to Botswana and South Africa provided there was availability of suitable surface water (and see later) (Skinner & Chimimba 2005).

Habitat Throughout its range, the Impala is water dependent and a typical ecotone species, associated with light woodlands and savannas (see Estes 1991a, Skinner & Chimimba 2005 for reviews), selecting open *Acacia* savannas with nutrient-rich soils providing good-quality grass, and high-quality browse in the dry season (Pettifer & Stumpf 1981, Dunham 1982, Skinner *et al.* 1984, Fritz *et al.* 1996). In southern Africa, Impalas are sometimes found in association with mopane *Colophospermum mopane* woodlands (Jarman & Jarman 1974, Dunham 1982). Interestingly, both bachelor and breeding herds use the same habitat selection criteria, lightly wooded grassland and open woodlands, with ♂♂ tending to be more opportunistic in the dry season (Bourgarel 2004, H. Fritz & W. Crosmayr unpubl.); these ecological criteria appear to be robust as they do not vary with changes in density (Gaidet 2005). Impalas often concentrate on areas of short grass, particularly close to lakes, or on post-fire flushes of grass (Monro 1978). In their semi-arid environment, Black-faced Impalas also select the interface between wooded savanna and open grassy vleis (Joubert 1971, Matson *et al.* 2005).

Impalas require canopy cover for shade and thermoregulation as they are not well adapted to dry heat (Klein & Fairall 1984, 1986; and see Matson *et al.* 2005), but their most important requirement is surface water, perhaps associated with a physiological need to eliminate nitrogenous waste imposed by a high crude protein intake (Fairall & Klein 1984). They were rarely found further than 5 km from water in Tsavo N. P. (Kenya) during the dry season (Ayeni 1975), and less than 8 km from water in Kruger N. P. (Young 1972) or 2 km from the Chobe R. in Botswana (Omphile 1997). Impalas are thus rarely recorded in arid regions, except where they can use artificial man-made supplies such as spillage from wells and boreholes, as in Botswana. In Hwange N. P., the range expansion of the Impala population was probably favoured by the introduction of permanent waterholes, and in Etosha N. P. Impalas are restricted to areas close to waterholes, being found on average within 3.5 km around waterholes (Matson *et al.* 2006). Impalas have been noted to go for 2–3 days without drinking water in Serengeti N. P., Tanzania, provided there is sufficient succulent food available (Jarman, M. V. & Jarman, P. J. 1973), while in the Zambezi valley marked individuals drank at 3–4 day intervals in the dry season (Gaidet 2005). This water-dependency, coupled with fairly strong territorial behaviour, often leads to clumped distributions. Impalas are absent from montane ecosystems, recorded to about 1700 m on the slopes of Mt Kilimanjaro (Grimshaw *et al.* 1995).

Abundance East (1999) details population estimates for most of the Impala's current range states, giving a total population of around 1,600,000 Common Impalas, with more than half in South Africa, and 2200 Black-faced Impalas. However, East (1999) cautions that the former does not account for undercounting in aerial surveys or areas for which population estimates are lacking. The latter estimate for Black-faced Impalas is slightly lower than that estimated by Green & Rothstein (1998), who estimated the population in Etosha N. P. at around 1500 individuals, with an additional 1200 on private land; the total population in Kaokoland was estimated at around 500. The number of Black-faced Impalas is currently estimated at more than 3200 individuals in Etosha, with a further 50–100 on communal conservancies and perhaps 1000 individuals in the north-west (J. Jackson pers. comm.). Correcting for undercounting biases, East

(1999) provides a crude estimate of nearly 2,000,000 Impalas, of which about half are on private land and one-quarter in protected areas.

The recorded densities of Impalas vary greatly, from less than 1/km² (Mkomazi N. P., Tanzania) to as many as 135/km² on the shores of L. Kariba, Zimbabwe (Bourgarel 1998) and 214/km² in the wooded savanna of the old (i.e. including areas later degazetted) Akagera N. P. in Rwanda (Monfort 1972). The average density in Kruger N. P., where they are a dominant ungulate, is around 7/km² (calculated from Owen-Smith & Ogutu 2003). In Lake Mburo N. P. and adjacent ranches in SW Uganda, highest population densities of 53.1/km² were found inside the park, while outside the protected area densities varied between 20.7 and 24.6/km² (Averbeck 2002). Such variation also exists within sites and between seasons, reflecting the heterogeneity of habitats and the availability of surface water (Dunham 1994, Jarman 1972b). These differences may also reflect difference in census techniques (and see East 1999).

Adaptations The 'metatarsal glands' on the hindlegs are covered by tufts of black hair. Kingdon (1982) noted that these glands give the appearance of expanding at precisely the moment in which jumping Impalas make their characteristic 'empty kicks'. In behaviour that is unique to Impalas, they kick their hindlegs almost vertically while landing on their forelegs, rebound, and bring their hindlegs down before landing again. This action probably emits trails of scent that Kingdon supposes assist animals to regroup after frequent dispersals. The chemical constituents of the metatarsal glands have been analysed by Wood (1997a).

The Impala appears to be the only ungulate to perform, in addition to self-grooming, 'allogrooming', i.e. reciprocal grooming to get rid of ticks and other ectoparasites on the head or neck (Hart *et al.* 1988, McKenzie 1990, Hart & Hart 1992, Mooring & Hart 1992, 1993). Like many small- and medium-sized antelopes, the Impala has a set of lateral incisor teeth that have been morphologically modified to form grooming tools. The second and third incisors, and the incisiform canine, are thin and needle-like, and arranged in the form of a comb on both sides of the lower jaw. These teeth are loose to facilitate see-saw action and are spaced to assist in the removal of parasites (McKenzie & Weber 1993) (see also Social and Reproductive Behaviour).

Foraging and Food Impalas are mixed feeders, consuming both grass and woody plants. The proportion of these food types in their diet varies greatly with season and location. A recent synthesis and attempt to classify the diet of African bovids has classified the Impala as a 'mixed-feeder, browser-grazer intermediate', with an average diet composition of 45% dicotyledon, 45% monocotyledon and 10% fruit (Gagnon & Chew 2000). This classification is in agreement with dietary classifications based on stomach morphology (Hofmann 1973), dental mesowear (Franz-Odenaal & Kaiser 2003) and stable carbon isotopes (Cerling *et al.* 2003, Sponheimer *et al.* 2003b). Even their digestive physiology, such as the rate of fermentation, seems to be adapted to their principal food (Giesecke & van Gylswyk 1975, Hoppe *et al.* 1977, Gordon & Illius 1994).

When succulent palatable green grass is available, Impalas graze: just after the first major rains, the proportion of grass in the diet peaked around Jan at 75% in Sengwa, Zimbabwe, while it decreased to less than 10% in the dry season (Jun/Jul) (Dunham 1980). Similarly, in Serengeti N. P. the proportion of browse in the diet increased as the

dry season progressed (Jarman & Sinclair 1979), and these patterns are mirrored in other studies (e.g. Van Rooyen 1992, Meissner *et al.* 1996). In the Midlands of Zimbabwe, dominated by miombo and mopane dry woodlands where primary productivity of grasses was poor, Impalas mostly browsed, even during the wet season (Fritz *et al.* 1996). The peak of browsing is often in the middle of the dry season, as some grass may be available at the end of the dry season, due to early sprouting of species like *Cynodon dactylon*, or post-burn re-growth (Moe *et al.* 1990, Wisley 1996). In the open areas of Hwange N. P., around waterholes, the re-growth of grass (particularly *Cynodon dactylon*) in the middle of the dry season induces Impalas to graze. Similar observations were made in Lake Mburo N. P. where regular fires changed the foraging behaviour of Impalas from predominantly browsing to pronounced grazing in the dry season (Wronski 2003). The timing of fires and the possibility of early showers may occasionally allow Impalas to graze throughout the year (Underwood 1982). Impalas can also vary their habitat use to ensure the availability of green grass, as in Serengeti N. P. where they move up and down the catena, switching from the upper slopes in the wet season to drainage-line greenbelts during the dry season (Jarman 1979). A wide variety of grass species is eaten by Impalas, 13 in Hwange N. P. (Wilson 1975) and 23 in Nylsvley, South Africa (Monro 1979). Preferred species include *Cynodon dactylon*, *Themeda triandra*, *Digitaria eriantha*, *Sporobolus* spp., *Panicum maximum*, *Eragrostis* spp. and *Urochloa* spp. Impalas exhibit a strong selectivity for green parts, across all heights (from 0 to >21 cm; Arsenault & Owen-Smith 2008). Short grasses are often used, but taller swards are also well utilized.

A wide variety of browse species is eaten, with *Acacia* leaves and twigs commonly found in the diet, along with *Combretum* spp., *Dichrostachys cinerea*, *Grewia* spp., *Boscia* spp., *Maytenus* spp. and *Commiphora* spp. Wilson (1975) listed 28 browse species eaten in Hwange N. P., and Monro (1979) 46 species eaten in Nylsvley. Fallen leaves of mopane may contribute the bulk of their diet during the dry season in the woodlands of southern Africa. Impalas also eat fruit, particularly pods, with those of *Acacia tortilis* and *Acacia nilotica* being actively sought for their high protein content. These feeding observations explain why most feeding is at ground level (Dunham 1982, du Toit 1990a). The high browsing pressure on *Acacia* spp. by Impalas is thought to be responsible for the low regeneration rate of these trees in some ecosystems (Prins & Van der Jeugd 1993, Moe *et al.* 2009). Joubert (1971) listed 21 browse plants and 12 grasses utilized by Black-faced Impalas in N Namibia.

The ratio of dicotyledons to monocotyledons in the diet may also vary with sex and social status (Van Rooyen & Skinner 1989). Territorial ♂♂ eat less dicotyledons (31% of diet) than ♀♀ (48%) or bachelor ♂♂ (49%). This difference between the sexes was also noted at L. Mburo, Uganda (Wronski 1999, 2002) and in a study in Kruger N. P. using stable carbon isotopes (Sponheimer *et al.* 2003a). It may reflect the fact that dominant ♂♂ monopolize habitat where the grass layer is of prime quality, but probably reflects the fact that the time devoted to holding a territory prevents a ♂ seeking the dispersed, high-quality dicotyledons, as suggested by the greater proportion of dicotyledons in the diet of ♀♀ that share the home-ranges of dominant ♂♂.

Social and Reproductive Behaviour Impalas are gregarious, forming herds of various sizes depending on the season and the

quality of habitat. In Hwange N. P., group size varies from 4 to 150 individuals with the largest herds found in open habitats (mean group size 15.4 in bush/grassland habitats, 12.2 in grassland and 7.3 in bushland; Bourgarel 2004). It is generally during the wet season, or the beginning of the dry season, that the biggest herds occur (Murray 1981). In N Namibia, Black-faced Impala herds range from 3 to 15 individuals, occasionally up to about 20, with aggregations of larger herds formed during or after the birth season (Joubert 1971).

Impala social organization consists of territorial adult ♂♂ during the rut, bachelor groups and breeding herds. In the Sengwa area, ♀♀ seemed to be in separate, stable clans of 30–120 individuals, occupying discrete home-ranges of 80–180 ha depending on the season (Murray 1982a). Bachelor groups comprise juvenile, subadult and adult ♂♂ that are potentially territorial. An age-based hierarchy exists within bachelor groups. Highly mobile (in Hwange N. P., some marked subadults and adults moved 30 km from where they were born [M. Bourgarel pers. obs.]), bachelor groups tend to occur in lower-quality habitats where intra-specific competition and disturbance are less (especially during the rut). Cohesion within bachelor herds is poor, particularly when adult ♂♂ intending to become territorial become aggressive. After the rut, bachelor ♂♂ often mix with breeding herds. Breeding herds comprise adult, subadult and juvenile ♀♀, and subadult and juvenile ♂♂ that form cohesive herds (average spacing between individuals <1 m) without a true hierarchical structure (Jarman 1979). Except during the rut, breeding herds often include several adult and subadult ♂♂ (mixed herds). Studies of marked individuals in Hwange N. P. and the mid-Zambezi valley showed that daily changes in herd size and composition, and in individual association, are frequent throughout the year (Bourgarel 2004, Gaidet 2005). Big herds may split during the day into smaller groups, and individuals from neighbouring herds can join other herds for a few days. Temporary nursery herds have been frequently observed, especially during months following birth periods.

Herd activities are closely synchronized, especially within a breeding herd. Impalas are primarily diurnal (with some nocturnal activity), spending most of the night lying down generally in an open area, mostly ruminating. During the day, when they are not feeding or moving or disturbed, they rest, ruminate and groom themselves in the shade. Due to fairly tight group structure, local competition between individuals may also contribute to the strong group effect on foraging (Fritz & de Garine-Wichatitsky 1996, Blanchard *et al.* 2008).

Impalas display a frequent and highly reciprocal allogrooming system between adults (♂♂ and ♀♀), but also between adults and young and between young individuals, regardless of sex, kinship or dominance status (Mooring & Hart 1992, 1993, 1997b). However, short self-grooming bouts occur more frequently than allogrooming (Mooring 1995, Mooring & Hart 1995a). For many years, the Impala was the primary model organism for testing the predictions of the 'programmed grooming hypothesis', which postulates that tick-removal grooming by Impalas (and other ungulates, see comparative study by Mooring *et al.* 2004) is regulated by an internal timing mechanism that elicits a grooming action before the tick is able to engorge and cause cutaneous irritation. The programmed grooming model makes a number of predictions known as the vigilance, habitat, body size and tick challenge principles. These predict that breeding ♂♂ will groom more frequently than ♀♀ (vigilance principle), smaller individuals will groom at a higher rate than larger individuals

Impala *Aepyceros melampus*. The illustrations on the right show horn-wrestling postures among males (from photographs).

(body size principle), inhabitants of environments with a high density of ticks will groom more frequently (habitat principle), and seasonal increases in tick threat will result in more frequent grooming (tick challenge principle). All these predictions have been supported in studies on Impalas. The rate of grooming varies both seasonally and by region: Impalas increase their rate of grooming during the wet season when tick density is high (Mooring 1995), and populations in tick-dense habitat groom more frequently compared with those in habitats where ticks occur at lower densities (Hart *et al.* 1992, Mooring & Hart 1997a, b). Maternal allogrooming occurs during nursing bouts, but its frequency declines rapidly after the first week. Young Impalas oral-groom more than adults, and consequently harbour a lower density of ticks than adults (Gallivan *et al.* 1995, Mooring & Hart 1997a, b). On the other hand, territorial ♂♂ groom themselves the least, probably related to the need for vigilance and territorial defence, and carry a higher density of ticks as a result (Mooring & Hart 1995a, b, Mooring *et al.* 1996) (see also Predators, Parasites and Diseases).

Just before the rut, adult members of bachelor herds become aggressive and sensitive to even slight movements and changes of posture in others. Dominant ♂♂ assert their position by walking stiffly in the arrogant posture, displaying their thicker neck and horn development (Jarman 1979). In addition, they occasionally fold the ears back and lift the tail, or face their challengers with head turned away, yawning or tongue flicking. Threat can also be expressed by high, medial or low horn presentation, head-tossing, head-dipping, vegetation-horning or (rarely) ground-horning and by mouthing their own penis. During confrontation, with the high horn presentation posture, the dominant ♂ invites his opponent to sniff his forehead. By sniffing and walking away with the low head attitude, the subordinate confirms his submissive position, which can

also be displayed by walking away while grazing, or by sniffing the under-tail of the dominant ♂ (uncommon).

With equal assertions of dominance between two rivals, the confrontation may end in combat. Whilst rare, a fight more often occurs between two territorial ♂♂ than between ♂♂ with different status. Fatal wounds are rare owing to the presence of a dermal shield of thickened skin that protects the neck and head, those parts of the body exposed during fights or pushing contests (Jarman 1972a). Dominant ♂♂ mark their territory with olfactory and auditory advertising. Sebaceous glands are concentrated on the forehead of dominant ♂♂ and the strong-smelling secretion is used to mark vegetation by frontal-rubbing, thereby contributing to scent-marking of territories. This is particularly common during the rut, and is not practised by ♀♀ (Jarman & Jarman 1974). Urine and faeces seem to have a smaller olfactory function even though urination and defecation are often performed in a ritualized fashion (Jarman 1979). Roaring is the most far-reaching display (up to 2 km) of dominant ♂♂, making rutting Impalas one of the noisiest ungulates. Roaring is used when intruders approach and it is occasionally followed by chasing. Roaring increases in intensity as the peak in the rut approaches.

The intensity of territorial behaviour depends on climatic conditions influencing the breeding season. In East Africa, nearer the Equator, an extended breeding season leads to a very long territorial period covering nearly the full year. However, mating generally occurs during the peak of territoriality at the end of the wet season (Jan–Feb in Serengeti N. P.; Jarman 1979). In southern Africa, the determining proximate factor initiating territorial behaviour and the onset of the oestrous cycle is shortening daylength (Skinner 1971, Skinner *et al.* 1974, Skinner & Van Jaarsveld 1987, Oliver *et al.* 2007). Murray (1982b) found that, during the rut, roaring by ♂♂ is also influenced by the lunar cycle; however, Moe *et al.* (2007) found

no consistent pattern to link conceptions with the lunar cycle in 17 years of data from South Africa and Botswana combined. In southern Africa, the rut occurs only during a short period (two months or less) (Fairall 1983) of the cold/dry season (Apr–Jun). Murray (1982b) found that in Zimbabwe the peak of the rut (centred in May) varied across a 20-day interval in five years.

The body condition and fat reserves of territorial ♂♂ decrease during the rut (Monro & Skinner 1979, Dunham & Murray 1982, Van Rooyen 1993) and so the number of territorial ♂♂, the duration of territorial period and territory size are a function of the seasons, population density, individual aptitude (age) and habitat quality. Generally, the number of territorial ♂♂ is greatest at the beginning of the rut and decreases progressively as food resources and intensity of territorial behaviour decline. At higher population densities, or at the beginning of the rut when competition between ♂♂ is greatest, territories are generally smaller. In Sengwa, where the density was 50–68 ind/km², territory sizes were between 8.5 and 13 ha during the peak with an average annual home-range from 49 to 90 ha according to their age (Murray 1982a), but in Serengeti N. P., where the density was 32 ind/km², mean territory size was 17 ha during maximum territorial activity and 58 ha during the dry season (Jarman 1979). In Limpopo Province, South Africa, Oliver *et al.* (2007) found mean territorial tenure was 67 days (range 23–99 days), compared with 82.5 days (range 5–267) in East Africa (Jarman 1979). Good-quality habitats increase mating opportunities by permitting long-lasting territorial periods and by allowing a territorial ♂ to keep more ♀♀ on his territory.

Compared with results of other studies, the home-ranges of Impalas in Lake Mburo N. P. were larger, and long-distance movements of young ♂♂ and ♀♀ occurred. Mean annual home-range size of female breeding herds was 168 ha, whereas home-ranges of up to 590 ha in young ♀♀ were observed (Averbeck 2002). Mean home-range size in adult ♂♂ varied between 70 and 110 ha, and exceeded values found by Murray (1982a) considerably. In NW Namibia, the home-ranges reported for female Black-faced Impalas (using minimum convex polygon) are the largest recorded for Impalas anywhere, at 33.3 ± 3.2 km², perhaps a reflection of the considerable distances that Black-faced Impala ♀♀ must travel between patches of suitable foraging habitat compared with Common Impalas, which inhabit less arid environments (Matson *et al.* 2007).

The home-range of breeding herds (mean area 297 ha in Serengeti N. P. and 80–180 ha in Sengwa; Jarman 1979, Murray 1982a) is bigger than male territories, and so can overlap several territories. As soon as a territorial ♂ has acquired a breeding herd, he checks intermittently to detect ♀♀ in oestrus by genital smelling and licking, or by smelling their urine on the ground. This act is generally followed by display of flehmen. Pre-mating behaviour is variable (Jarman 1979). Generally, the ♂ approaches and follows oestrous ♀♀ with head lowered and nose held forward. With receptive ♀♀ copulation often occurs after perineal licking. Mounting lasts up to 10 sec, and many consecutive mountings will follow at variable intervals (few seconds to one or two minutes). After successful copulation, ♂♂ frequently snort, roar, or chase bachelors and herd ♀♀. After successful copulation, a ♂ does not display any further interest in that ♀ even if she remains sexually receptive.

The Impala ewe and neonate exhibit behaviour that is between the pure 'hider' and pure 'follower' (Jarman 1976): several hours before parturition the pregnant ♀ isolates and conceals herself (in tall grass or

thick bush). The mother eats the afterbirth (Jarman 1976). How long the young stay hidden is uncertain, but after a day or two, they follow their mothers back to the herds during the day. At night, neonates (less than a week old) stay concealed in cover far from the adults. Often several young stay hidden in the same area. When disturbed, these 2–3-day-old young try to make themselves less conspicuous by laying with their head on the ground, but seven-day-olds are vigilant and run away if a potential threat comes too close (M. Bourgarel pers. obs.). After a week, young are no longer isolated from the herd and display anti-predator behaviour, including the formation of nursery groups, especially where there is a marked annual birth season. The weakness of mother–young bonds is illustrated by the rapid decline of the proximity between mother and young and the formation of groups of juveniles (Mooring & Rubin 1991). At 4–6 months of age, offspring preferentially associate with age-mates, forming crèche groups, which are characteristic for Impala young (Jarman 1979, Estes 1991a). Females remain in the breeding herd for life, while weaned ♂♂ are subjected to aggressive behaviour by dominant ♂♂ and are eventually driven out of the breeding herds. Dispersal distances appear to be fairly low (less than 10 km), although male subadults have been recorded dispersing up to 40 km in Hwange N. P. (M. Bourgarel pers. obs.).

Reproduction and Population Structure Females become sexually mature at age 18 months, whereas ♂♂ are fertile as yearlings, but mate only when they become behaviourally mature and territorial in their fourth year (Kerr 1965). In southern Africa, the ♀ has a maximum of two cycles during the reproductive period, but normally conceives during her first oestrus. The fecundity rate is normally 95% in fully mature ♀♀ (>2 years old) but lower in two-year-olds (Fairall 1983). There is no sign of reproductive senility in animals up to 14–15 years old (Skinner 1969).

The relatively short parturition season takes place at the beginning of the wet season (Nov–Jan) in southern Africa (Skinner & Chimimba 2005); in Chobe N. P. Impala parturition is highly synchronized, with 90% of young born within two weeks in mid-Nov, shortly after the first rains (Moe *et al.* 2007). However, in eastern Africa there is no marked reproductive seasonality, as a consequence of little change of daylength near the Equator and the bimodal rainfall pattern (Jarman 1979). Moe *et al.* (2007) posited that Impalas synchronize births in areas with a highly seasonal food supply, and temporally space births in less seasonal (equatorial) areas to reduce predation risks.

Gestation lasts 27–28 weeks (Fairall 1972), and a single young is born (although twins have been recorded; Kayanja 1969, Joubert 1971). At birth, the lamb has an average mass of about 5 kg, but smaller lambs (3.5 kg) have been captured in Hwange N. P. (Bourgarel 2004). Young grow quickly and weaning occurs between 17 and 25 weeks of age. The asymptotic mass is achieved at 4–5 years, but 75% of mature mass is reached by two years of age (Howells & Hanks 1975, Hanks *et al.* 1976, Brooks 1978, Fairall 1983).

At birth and during the first year, the sex ratio is equal, but at adulthood it is biased towards ♀♀ (65% of adults were ♀♀ in Kruger and Hwange National Parks). In breeding herds in Hwange N. P., 88% of adults are ♀♀. Overall, the age composition is 23% juveniles and this figure increases during the birth season to over 30% (M. Bourgarel pers. obs.). Recruitment appears highly variable, and the juvenile to female ratio seems to change strongly (0.47–0.81) with variations in density-dependent competition for resources

(Gaidet 2005). Averbeck (2002) observed an average ♂ : ♀ sex ratio of 1 : 1.5 in Lake Mburo N. P., while the percentage of adult ♀♀ (38–45%) in the population was greater than that of ♂♂ (21–27%). The proportion of juvenile and subadult Impalas remained almost unchanged throughout the study period, at a level of 5–10%. The ratio of sexually mature to sexually immature animals was 2 : 1, and the ratio of adult to subadult ♀♀ was on average 1 : 1.1 (Averbeck 2002).

The survival rate depends on the environment, sex and age (Ginsberg & Milner-Gulland 1994): the probability of survival is 0.6 during the first year for both sexes, but mortality occurs mainly during the first month of life (Bourgarel 2004) and reaches 0.95–0.97 at three years old. For ♀♀, the probability stays the same up to 8–9 years old, whereas for ♂♂ it starts to decrease after six years of age to reach zero at 9–10 years of age. Female longevity is 12–14 years in the wild, compared with ten years for ♂♂. Captives have lived to 25 years (Weigl 2005).

Predators, Parasites and Diseases Impalas are prey to all larger predators (including jackals *Canis* spp. and baboons *Papio* spp.), and are often considered as preferred prey for African Wild Dogs *Lycaon pictus*, Leopards *Panthera pardus* and Cheetahs *Acinonyx jubatus* (e.g. Pienaar 1969a, Pole *et al.* 2004, Hayward *et al.* 2006a, b, c). However, as the Impalas taken by predators are on average in poorer condition than the average in the population (Pole *et al.* 2003), it is possible that the rank of the Impala in the prey list of large predators

is density-dependent: when at high density, the proportion of weaker individuals would increase and Impalas would then become the main prey of most large carnivores. As medium-sized predators such as large eagles also prey on young Impalas (see, for example, Mooring 1993), the mortality of newborn Impalas is high, ranging from 15–60% in a study population at Hwange N. P. (H. Fritz pers. obs.). One pack of seven African Wild Dogs in Hwange N. P. ate 4–5 newborns daily for a week (M. Bourgarel pers. obs.). Cheetahs seem also to specialize on young Impalas in the large game ranches in Namibia (Matson 2003).

In woodland (their favourite habitat), Impalas are more vulnerable to predation and so they are extremely alert and prompt to flee. They tend to use more open habitats preferentially when predators such as Lions are in the vicinity (Valeix *et al.* 2009). When disturbed by an intruder that is beyond their flight distance, they snort and move off slowly, but if the intruder is within their flight distance, they often run and leap in all directions, bounding up to 12 m. It is at such times that they commonly kick their hindlegs up, rebounding before landing again (see Adaptations). Seasonal parturition and nursery groups reduce predation risk by diluting the risk among newborns and enhancing vigilance, although this strategy is only likely to be effective against specialist predators (Ims 1990, Moe *et al.* 2007). In general, grooming increases predation risk (Mooring & Hart 1995a).

Ectoparasites of Impalas include ticks, which are also vectors of blood parasites, and lice. Durden & Horak (2004) list five species

Impala *Aepyceros melampus*.

of lice known to parasitize Impalas, including the recently described *Linognathus weisseri*, while numerous studies have investigated tick burdens in Impalas (e.g. Horak 1982, Horak *et al.* 1995b, 2003). The intensity of infestation by ticks depends on the season and Impala density, and varies between individuals: the infestation is greater in subadults and adults than in juveniles, and in adult ♂♂ than in adult ♀♀ (Gallivan *et al.* 1995). Males on their territories harboured six times more adult ticks than did ♀♀, showing the cost of decreased grooming activity (Mooring & Hart 1995a, b). Impalas frequently associate with oxpeckers, *Buphagus* spp., which concentrate their time foraging around the ears, head and neck of Impala, which are the regions supporting the highest density of ticks (Mooring & Mundy 1996, Mooring *et al.* 1996). When oxpeckers are in attendance, Impalas noticeably reduce their own grooming efforts (Mooring & Mundy 1996).

Impalas also harbour numerous endoparasites, and again numerous studies have investigated prevalence, host specificity and seasonal incidence in Impalas (e.g. Horak 1978a, 1981a). In Zimbabwe, 26 nematode, eight cestode and three trematode species have been recovered from Impalas (Jooste 1987). Some of these are definitive Impala parasites and others are occasional. In Zimbabwe, on 20 farms where causes of Impala mortality were studied, 34% of natural deaths were due to predation and 10% to disease (acute fascioliasis, verminous aneurysm/*E. coli* septicaemia or clostridial infection). Endoparasites did not cause death among Impalas and losses associated with ticks and tick-borne diseases were rare (Knottenbelt 1990). Mortality due to anthrax has also been recorded (e.g. Prins & Weyerhaeuser 1987).

Conservation IUCN Category: Least Concern (*A. m. melampus* – Least Concern; *A. m. petersi* – Vulnerable D1). CITES: Not listed.

Although Impalas seem to have been eliminated from some parts of their range (such as Burundi), they are still relatively widespread and common and abundant in numerous protected areas across their range. Owing to its high rate of reproduction and great adaptability, the Impala has become of prime interest for meat production (e.g. Fairall 1983, Bothma 1989), not only on wildlife ranches but also in remote communal areas (e.g. Feron *et al.* 1998, Auerbeck 2001, 2002, Bourgairel *et al.* 2001).

The main threat to Common Impala seems to be active poaching at the edge of, and within, protected areas (with strong influence on densities as well as population structure) combined with agro-pastoral development (Setsaasa *et al.* 2007, Auerbeck *et al.* 2009b). However, the type of hunting may skew sex and age ratios in the population very differently (Setsaasa *et al.* 2007, Auerbeck *et al.* 2009b). Hunting risk is also likely to affect Impala behaviour, such as change in habitat selection or waterhole attendance (Crosmary *et al.* 2012).

Poaching, livestock development and severe drought are considered the main factors for the decline of *A. m. petersi* (Green & Rothstein 1998, East 1999). The introduction of 180 individuals of *A. m. petersi* from Kaokoland to the west of Etosha N. P. between 1968 and 1971 helped promote the conservation of the subspecies, and a few were translocated from Etosha N. P. to private game farms in Namibia. Matson *et al.* (2004) analysed 21 translocations of Black-faced Impalas to 20 Namibian game farms that occurred between 1970 and 2001, with the aim of identifying characteristics of the translocated populations

and the release sites that significantly correlated with the success of the translocations (determined by whether the population had a positive growth rate). Initial population size was paramount to the success of translocations, and populations of over 15 individuals were more successful, while the presence of Cheetahs also influenced the success of translocated populations; in the presence of this predator, smaller translocated populations of Black-faced Impalas were less likely to be viable than larger populations.

The introduction of *A. m. melampus* to ranches and conservancies neighbouring Etosha N. P. may contribute a threat to *A. m. petersi* through hybridization. Green & Rothstein (1998) estimated that about one-quarter of all privately owned Black-faced Impalas occur in mixed herds with Common Impalas. In a recent study, Lorenzen & Siegmund (2004) analysed 127 Black-faced Impala individuals from five subpopulations in Etosha N. P. to determine whether any hybridization had taken place within the park, but could not find any evidence for hybridization between the two subspecies.

Measurements

Aepyceros melampus

A. m. melampus

HB (♂♂): 1402 (1271–1504) mm, n = 5

HB (♀♀): 1352 (1173–1506) mm, n = 55

T (♂♂): 280 (220–340) mm, n = 33

T (♀♀): 258 (205–300) mm, n = 23

HF c.u. (♂♂): 855 (820–905) mm, n = 5

HF c.u. (♀♀): 767 (672–860) mm, n = 55

E (♂♂): 145 (130–157) mm, n = 33

E (♀♀): 140 (130–155) mm, n = 23

WT (♂♂): 45.7 (31.3–61.5) kg, n = 32

WT (♀♀): 38.5 (23.2–60.5) kg, n = 81

Zambezi Valley and Hwange N. P., Zimbabwe (H. Fritz & M. Bourgairel pers. obs.; V. Wilson pers. comm.)

Sh. ht (♂♂): 873 (785–925) mm, n = 28

Sh. ht (♀♀): 800 (790–810) mm, n = 12

WT (♂♂): 56.9 (46.0–64.4) kg, n = 28

WT (♀♀): 42.1 (38.93–45.69) kg, n = 12

Serengeti N. P., Tanzania (Sachs 1967, with slightly different body measurements)

Maximum recorded horn length is 91.7 cm for a pair of horns from the Masai Mara National Reserve, Kenya (Rowland Ward)

A. m. petersi

HB (♂♂): 1350 (1240–1450) mm, n = 7

WT (♂♂): 63.0 kg, n = 10*

WT (♀♀): 50.4 kg, n = 9*

N Namibia (Joubert 1971)

*Range not available

Maximum recorded horn length is 68.0 cm for a pair of horns from Grootfontein, Namibia (Rowland Ward)

Tribe ALCELAPHINI

Alcelaphines

Lichtenstein's Hartebeest
Alcelaphus buselaphus lichtensteinii.

Alcelaphini Brooke, 1876. In: Wallace. Geog. Distr. Anim. p. 224.

The Alcelaphini are a very well-defined and distinctive group of large, long-faced, heavily horned animals. Molecular clocks have suggested that ancestral Alcelaphini might have first diverged from ancestral Hippotragini about 17 mya and from an aepycerotine basal lineage some 20 mya (Hernández Fernández & Vrba 2005). Living genera in this tribe include *Alcelaphus*, *Damaliscus*, *Connochaetes* and *Beatragus*. The Impala *Aepyceros melampus* was once regarded as an early alcelaphine (Gentry 1978, Vrba 1984), an inclusion that has been rendered obsolete by molecular studies that show *Aepyceros* occupies a basal position within the Antilopinae, its ancestral stock having evolved substantially earlier than the supposed emergence of the earliest alcelaphines. Therefore, while the Impala and alcelaphines do share a very ancient common ancestry this does not merit a common taxon.

There are several fossil genera and, judging from their abundance in the fossil record, the group has been ecologically successful for some 8 million years and even spread to India (where they later became extinct). A giant form, *Megalotragus*, was larger than any living species and carried horns that were over a metre long, of an undulating, convex/concave structure and with a wide span. Alcelaphines have very peculiar cranial morphology and radical remodelling of faces and horns has been assisted by horn pedicels and foreheads being hollow. Fossils reveal that the hammer-shaped head of *Alcelaphus* evolved after the formation of a pedicel, a strong downward turn in the muzzle and an extraordinary phylogenetic upward and sideways twisting of the horn axes. For a discussion of the elaboration of horn shapes in Alcelaphini, see Kingdon (1982).

Alcelaphines are nearly always specialist grazers, inhabitants of the African savanna habitat and its fringes and are classified as roughage feeders (Hofmann 1973). The genera have radiated to occupy distinct ecological niches, notably broad, open grassy valleys (*Alcelaphus*); seasonally inundated valley bottoms with rank grass (*Damaliscus lunatus*); flat open pastures with short grass (*Connochaetes*); and dry open savannas (*Beatragus*). Alcelaphines seem to have specialized on the growth form of grasses typical for one part of the wet-dry seasonal cycle: wildebeest (*Connochaetes* spp.), which have no second lower premolar in adults (Attwell 1980), have very broad flat incisors and are adapted for unselective cropping of short grass swards: the population of Common

Tentative phylogenetic tree for Alcelaphini (modified after Arctander *et al.* 1999 and Hassanin *et al.* 2012).

Wildebeest *Connochaetes taurinus* that resides on the short-grass plains of the Serengeti ecosystem is a classic case. *Damaliscus lunatus* feeds most efficiently from medium-length grasses and in doing so selects a high proportion of leaf blades. Hartebeest, with a long pointed muzzle and narrow toothrow, excel at selecting leaf blades and sheaths from long senescent swards in the dry season. At less favoured times of year, all are forced to eat less preferred growth stages (for example, all graze on green flushes at the start of the rains and all will eat senescent swards in times of drought). However, differences in dietary preferences help explain the coexistence of these genera.

Feeding specializations also explain broad differences in migratory habits and distribution. Thus, wildebeest depend heavily on short green swards, which help fuel the costs of reproduction. Costs are greatest when ♀♀ are lactating and at this time of their reproductive cycle they seek actively growing, short-grass areas where seasonal rainfall has boosted productivity. In the dry season they have to find other reserves of food, so that seasonal pastures are often some distance apart. Spectacular, large-scale migrations such as those of the Serengeti ecosystem are the result. Common Wildebeest and Topis *D. l. jimela* are both dependent on high levels of rainfall with Topis, in particular, relying on sumplands, which, in turn, dictate much of their geographical distribution. By contrast, the feeding style of Hartebeest allows them to select a high-quality diet (in relation to what is available) in the same general area throughout the year: they thus tend to be relatively sedentary. As dry season specialists, Hartebeest can survive in more arid areas, as shown by the existence of Hartebeest in Ethiopia and Eritrea and (until exterminated by modern humans) in North Africa and the Middle East.

Keys to alcelaphine success lie in their adoption of a grass diet out on open valleys and plains, where they withstand intense solar radiation so long as they have access to water. In such habitats their exceptional speed and stamina mitigates their increased exposure to predators. Elongation of the legs (as an anti-predator and enlarged range adaptation) has been matched by elongation of the skull, but not the neck (see figures in Kingdon 1982).

There is little sexual dimorphism although ♂♂ are slightly taller and more heavily muscled, particularly in the neck and shoulders. Females have one pair of inguinal nipples. Both sexes have horns. The shape is similar in the two sexes but those of ♂♂ are heavier and stronger.

Lelwel Hartbeest *Alcelaphus buselaphus lelwel* myology.

Lelwel Hartbeest *Alcelaphus buselaphus lelwel* skeleton.

Males fight by springing forward into a 'clash' of the horns while falling downwards onto their 'knees'. Horn clashes are followed by vigorous 'wrestling' in which ♂♂ try to force the head of the opponent to one side and then hook into its unprotected side using the sharp horn tips. Males may fight for hours and deaths have been recorded.

All alcelaphines have strongly polygynous mating systems, which are shaped by the feeding and reproductive ecology of ♀♀ (Gosling 1986). Females try to maximize food intake and quality for reproduction (the high metabolic costs of lactation are their main problem) by seeking high-quality food. During movements between pastures they minimize the chances of being killed by scanning for predators and by joining groups. Group membership is usually labile although ♀♀ may be accompanied by their offspring for several years. In a few cases group membership is more constant (as in those Topi populations where the territories of ♂♂ are sufficiently large to encompass the entire home-range of female groups and their young). Male mating tactics are determined by the predictability of female movements and the most common outcome, for all alcelaphines, is 'resource-defence polygyny' (Emlen & Oring 1977): ♂♂, therefore, defend areas of grassland that ♀♀ need for food and attempt to mate with them as they arrive. Such territories may be occupied for long periods or only briefly (as in the case of rutting migratory wildebeest, where territories are established for only a few hours or days in the path of the annual migration).

'Lekking', where ♂♂ join clusters and give every appearance of displaying to attract ♀♀, occurs in Topis under quite specific conditions, but has not been seen in any other alcelaphine species. The Topi ♂♂ that achieve the most matings appear to do so because they occupy territories that are preferred by ♀♀, and not because of any individual display characteristics; thus ♀♀ appear to drive this system. However, the lek-like clusters result in highly skewed mating success for the ♂♂. Interestingly, antelopes of the genera *Damaliscus* and *Alcelaphus* do not perform flehmen, and lack the incisive papilla and ducts that constitute the oral connection to the vomeronasal organs (Hart *et al.* 1988).

Scent-marking is well developed in all living alcelaphines. All possess preorbital glands, but these are less prominent than in groups such as the gazelles or Oribi *Ourebia ourebi*. Some species such as the

Topi leave visible deposits of secretion on the tips of grass stems, but most do not have invaginated glands and instead rub the surface of the gland onto twigs, on the ground or on themselves. Pedal glands are well developed on the forefeet of all species, although some have rudimentary glands on the hindfeet; inguinal glands are absent. The most developed expression of marking is piles of dung, which are deposited throughout territories but are largest and most conspicuous where ♂♂ regularly meet their neighbours along boundaries. These encounters are a mixture of agonistic behaviour and scent-marking behaviour with each ♂ sniffing, kneeling, head rubbing and defecating in turn. Boundary dung piles are made even in the tiny lek territories of Topis. Territorial male alcelaphines also 'self-anoint', rubbing the substances used to mark their territories onto their own bodies. Thus, ♂♂ rub preorbital gland secretions onto their shoulders, leaving conspicuous smears, or lie on or even roll in their dung piles. This behaviour may be linked to 'scent-matching', a mechanism that is thought to reduce the cost of territory defence by allowing intruders to match the smell of defenders to that of their territory so that they are more likely to withdraw without risking dangerous combat (Gosling 1982). Territorial ♂♂ also use visual advertisement of their status, including standing on small elevations such as termite mounds.

Over centuries the great biological success of Alcelaphini has been undermined by the intrusion of livestock, especially intensive cattle pastoralism. The survival of alcelaphines, therefore, lies at the heart of the development/conservation debate because livestock compete directly for pasture and alcelaphines are generally displaced once cattle numbers have reached critical levels. Migratory populations have also suffered massive losses when fencing, introduced to enclose stock or control disease, has cut off migration routes. These factors, combined with habitat loss and overhunting, have led to overall decline in alcelaphine populations throughout most of Africa. The only exceptions are in some eastern and southern African localities, where some form of sustainable commercial use has resulted in stable or even locally increased populations.

L. Morris Gosling & Jonathan Kingdon

GENUS *Beatragus*

Hirola

Beatragus Heller, 1912. Smithsonian Misc. Coll. 60 (8): 8.

Hirola *Beatragus hunteri* head myology.

Beatragus is a monotypic genus endemic to SE Kenya and SW Somalia. The generic status of the Hirola has been controversial but it is now recognized as a lineage very distinct from *Damaliscus* and *Alcelaphus*, yet filling an ecological niche similar to *Alcelaphus* (Kingdon 1982, Kumamoto *et al.* 1996, Pitra *et al.* 1998, Grubb 2005). *Beatragus* probably pre-dates the common ancestor of *Damaliscus* and *Alcelaphus* (an alcelaphine that would have closely resembled the extinct genus *Parmularius*) (Gentry 1978). Karyological work supports this conclusion by showing that *Beatragus* is the sister-group of *Damaliscus* + *Alcelaphus*, branching off from the lineage before the latter two genera differentiated. *Damaliscus* + *Beatragus* would be a parapatric and, therefore, unacceptable entity. It now seems that all parties would agree to the treatment of *Beatragus* as a distinct genus.

Beatragus represents a long-lasting phylogenetic lineage dating to ca. 3.1 mya (mid-Pliocene; Kumamoto *et al.* 1996, Pitra *et al.* 1998). The fossil record dates to the early Pleistocene (Gentry 1974, 1978, 1990). *Beatragus* is represented in the fossil record by a larger bodied species, *B. antiquus* (Leakey 1965), which might have approached twice the body weight of *B. hunteri*. Fossils of *Beatragus* have been found at Olduvai, Tanzania (Leakey 1965, Gentry & Gentry 1978), Omo R., Ethiopia (Gentry 1985), Gobaad, Djibouti (Thomas *et al.* 1984), and Elandsfontein, South Africa (Gentry 1974, Gentry & Gentry 1978, Kingdon 1982).

The fossils of *Beatragus* indicate that this genus was widely distributed and probably occupied a tall-grass grazing niche comparable to the one now occupied by *Alcelaphus*. This likely evolutionary history has considerable implications for understanding the biology and management of Hirola. These implications are discussed in the species profile.

Gentry (1974) suggested that *B. antiquus* might be the direct ancestor to *B. hunteri*. As such, *B. hunteri* may represent a somewhat dwarfed

Hirola *Beatragus hunteri* adult male frontal and rear views.

species living in a small, ecologically impoverished area on the fringe of the former range of *B. antiquus*. If so, the exceptionally heavy and disproportionately robust horns of *B. hunteri* (compared with antelopes of similar shoulder height (e.g. Blesbok *Damaliscus pygargus phillipsi* or Addax *Addax nasomaculatus*) might owe as much to larger ancestors as to any current adaptive advantage for hefty horn stems.

Thomas M. Butynski & Jonathan Kingdon

Hirola *Beatragus hunteri* adult male.

Beatragus hunteri HIROLA

Fr. Antilope Hirola; Ger. Hunters Leierantilope

Beatragus hunteri (P. L. Sclater, 1889). Proc. Zool. Soc. Lond. 1889: 58. 'Africam orientalem, in ripis fl. Tana' (East bank of Tana R., Kenya).

Hirola *Beatragus hunteri*.

See Butynski (2000) for discussion concerning use of the common name Hirola instead of Herola. The vernacular name 'Hunter's Hartebeest' (in honor of H.C.V. Hunter, who collected the type specimen in 1887) is not acceptable as this species is not a Hartebeest *Alcelaphus buselaphus*.

Taxonomy Monotypic. Originally named *Cobus hunteri*. Renamed *Damaliscus hunteri*, and even considered conspecific with the Topi *Damaliscus lunatus* (Haltenorth 1963), but fossil and DNA evidence indicate *Beatragus* has been distinct from *Damaliscus* for ca. 3.1 million years (Pitra *et al.* 1998; and see Kumamoto *et al.* 1996); inclusion in *Beatragus* is now generally supported (Kingdon 1982, Gentry 1990, Grubb 2005). Synonyms: none. Chromosome number: $2n = 44$ (FN = 60). Eight metacentric/submetacentric and 13 acrocentric/telocentric pairs of autosomes; the X and Y chromosomes are acrocentric (Kumamoto *et al.* 1996).

Description Medium-sized antelope similar in appearance to a Hartebeest or Topi, but colour paler, build lighter and more graceful, face less elongated, withers much less elevated above hindquarters, and horns lacking a basal pedicle. Has inverted chevron between the eyes and 'spectacles' around the eyes. Inner ears white. Eyes, nostrils, lips, and tips of the ears black. Overall pelage uniform rufous-tawny becoming slaty-grey with age. Ventrums and insides of legs whitish-

Lateral view of skull of Hirola *Beatragus hunteri*.

tawny. Udder and hooves black. Tail white. Preorbital glands very large. Pedal glands on the forefeet. Inguinal glands absent. Females smaller than ♂♂.

Horns are long, lyrate, sharp-tipped, Impala-like, but much thicker at the base. Dental formula: $I^{0/3}, C^{0/1}, P^{3/2}, M^{3/3} = 30$, with the second lower premolar absent (as in *Connochaetes*).

Geographic Variation None recorded.

Similar Species

Damaliscus lunatus. Reddish-brown to purplish-brown pelage; black patches on outer thigh; tail blackish; lacks inverted white chevron between eyes and white 'spectacles' around eyes. Sympatric (*D. l. topi*) over south-eastern half of Hirola range (Butynski 2000).

Distribution Endemic to Africa. The Hirola has a very restricted natural geographic range, being endemic to SE Kenya and SW Somalia. Confined to a region of grassland, light shrub and woodland that lies parallel to the Indian Ocean and which is bounded by dry *Acacia* scrub to the north-west and by coastal forest and tsetse fly to the south-east (Bunderson 1981).

Historical Distribution The Hirola formerly occurred over a region 40–200 km inland from, and parallel to, the Indian Ocean from Garsen and Bura on the lower Tana R. in SE Kenya north-east to Lag Dere in SW Somalia. The historic geographical distribution covered ca. 17,900 km² in Kenya and ca. 20,500 km² in Somalia. The geographical distribution probably did not change greatly between the time of discovery (1887) and the 1970s (Bunderson 1981, East 1999, Butynski 2000).

Current Distribution In Kenya, the Hirola now occurs between Garsen, Bura and Galma Galla/Kolbio over an area of ca. 8000 km² (Butynski 2000). The current status in Somalia is not known. The small population in Tsavo East N. P., Kenya (not mapped), originated from a translocation of 30 animals from Garissa District conducted in 1963. It is thought that most of these perished soon after release and that the size of the

‘effective founder population’ was only 11–19 animals (Butynski 2000). The extent of occurrence of this population was ca. 500 km² in 2011 (Probert 2011). In this profile, the population in SE Kenya and SW Somalia is referred to as the ‘natural population’, whereas the one in Tsavo East N. P. is referred to as the ‘Tsavo population’.

Habitat Hirola inhabit a flat and gently undulating coastal strip where the mean annual rainfall ranges from 350 mm (north-west) to 600 mm (south-east), and the altitude ranges from 220 m (north-west) to 40 m (south-east). The climate is hot throughout the year, with annual minimum and maximum temperatures averaging ca. 21 °C and ca. 33 °C, respectively. Vegetation varies from waterless dry thorn bush (north-west), to open bushed grassland, to light woodland, to lush savanna grassland (south-east). The preferred habitat is seasonally flooded, open grassland with scattered small shrubs and trees on well-drained white sand soils where the mean annual rainfall is 400–500 mm. Highest densities (7.14 ind/km²) occur where there is a good cover (30–50% cover) of green grass (*Chloris mossambicensis*, *Chloris roxburghiana*, *Dactyloctenium aegyptium*, *Digitaria milanjiana*, *Enteropogon somalensis*, *Sporobolus ioclados* and *Sporobolus pellucidus*) of short to intermediate height (10–50 cm). Hirola prefer short leafy swards of grass formed by fire, or by the combined grazing pressure of wildlife and domestic livestock (Bunderson 1981). Highest densities are attained in areas heavily used by domestic livestock where traditional Somali herding practices are maintained and livestock are highly mobile. However, Hirola avoid herds of livestock, areas of overgrazing, tall dense stands of grass and herbaceous vegetation, thick woodland, and forest. During the dry seasons (Jan–Mar, Jul–Sep) the distribution of Hirola in Kenya is compressed and concentrated in two areas of high-quality forage; one near the Tana R. between Masalani and Bura, and the other in the Galma Galla/Kolbio region (Bunderson 1981).

Competition with livestock and habitat degradation appear to be major problems for the Hirola as the range is presently seriously

overstocked and unsustainably grazed. A survey in 2011 of the entire current natural range of the Hirola found more than 100,000 livestock (sheep, goats, cattle, camels), or 232 livestock per individual Hirola (King *et al.* 2011a).

Abundance The natural population in Kenya during the 1970s was ca. 16,000 animals (Bunderson 1981). The population was estimated at 10,000–15,000 animals from 1973 to 1984, followed by a drastic decline (85–90%) between 1983 and 1985 (Butynski 2000). Ground surveys suggested the population was between 500 and 2000 Hirola in Kenya in 1995/96 (Andanje & Ottichilo 1999, Butynski 2000, Dahiye & Aman 2002). An intensive aerial survey was conducted in January 2011 over a 12,000 km² area that probably included the entire present natural range of the Hirola. A total of 245 individuals were observed, yielding a population estimate of 434 animals (S.D. = 30.2; King *et al.* 2011a). As such, Kenya’s population of Hirola has declined ca. 97% since the 1970s. Probably extinct in Somalia, but small numbers may occur north of Bushbush N. P. and at Lag Dere.

Tsavo East N. P. holds a translocated population that was estimated at 56–76 animals in 1995–96 (Andanje & Ottichilo 1999), 77 animals in 2000 (Andanje 2002), 105 animals in 2006 (S. A. Andanje pers. comm.), 100 animals in 2010 (Kock *et al.* 2010b) and 67 animals in 2011 (Probert 2011).

Adaptations Kingdon (1982) does not consider Hirola to have unusual ecological requirements, suggesting that it derives from a more generalized antelope than either *Alcelaphus* or *Damaliscus*. Since Hirola and *Alcelaphus* are allopatric, he further suggests that survival of the present relict population is due to absence of competition from *Alcelaphus*. *Alcelaphus* is a relatively recently evolved genus, the members of which have probably been kept out of the geographical range of the Hirola by sub-desert to the north, the Indian Ocean to the south-east and the Tana R. to the west.

Hirola *Beatragus hunteri* dorsal view of horns and skin fold on nape.

The structure of the gastrointestinal tract indicates that the Hirola is extremely well adapted to eat dry and coarse grasses, and has an excellent ability to preserve water (Hofmann 1996). Hirola drink water (J. King pers. comm.), but this appears to be a rare event (Butynski 2000). Foraging is concentrated in the post-dawn and pre-dusk hours in order to avoid the hot mid-day temperatures. During the heat of the day, Hirola generally rest in the shade of a shrub or small tree.

The nape skin of the adult ♂ is exceptionally thick, rolling up into a prominent fold behind the horns when the head is erect and ears pricked. This probably serves as a dermal shield during male horn-fighting. Kingdon (1982) observed that this fold is an accommodation of tough, inflexible skin to the demand for movement of the ears, which, as with many other bovids, are important signalling devices.

Foraging and Food Primarily grazers, Hirola browse on forbs when grass is scarce (Bunderson 1981, Cerling *et al.* 2003). They select short green grass with a high ratio of leaf to stem (Andanje & Ottichilo 1999). The most important grasses in the diet on the natural range probably include *Chloris myristachya*, *Cenchrus ciliaris* and *Digitaria* spp. (Kingdon 1982). In Tsavo, Hirola eat grasses that average 17 cm in height, cropping them at 4–16 cm above the ground. The plant species eaten most frequently here are *Digitaria rivae*, *D. macroblepora*, *Chloris barbaa*, *Sporobolus helvolus* and *Latipes senegalensis* (Andanje & Ottichilo 1999).

Social and Reproductive Behaviour Adult ♂ ♂ vigorously defend territories of good quality pasture. There is no information on size of territories held by ♂ ♂ except that they appear to be several square kilometres in area. Males mark their territory (mainly in the evenings) by kneeling on forelegs and rubbing their preorbital glands on vegetation and soil while slashing vegetation with their horns. This is followed by scratching the ground with the forefeet and by depositing dung. Non-territorial ♂ ♂ may live in bachelor groups of 2–38 animals (Bunderson 1981), sometimes in the company of Coastal Topis *D. lunatus topi*, Plains Zebras *Equus quagga*, Gerenuks *Litocranius walleri* and Giraffes *Giraffa camelopardalis* (Bunderson 1981, Kingdon 1982).

In the natural population, adult ♀ ♀ and their young form stable breeding groups of 5–40 individuals (mean = 8) (Bunderson 1981). In Tsavo, breeding groups ranged in size from 5 to 11 (mean = 7.5, $n = 8$) in one study (Andanje & Ottichilo 1999) and 6–14 (mean = 9.8, $n = 5$) in a later study (Probert 2011). Home-ranges of breeding groups in Tsavo overlap with the territories of 2–3 adult ♂ ♂ and vary in size from 12 to 40 km² (mean = 21 km², $n = 8$; S. A. Andanje pers. comm.). These groups are usually accompanied by one adult ♂ and led by either the adult ♂ or the dominant ♀. The adult ♂ is presumed to be the holder of the territory on which the breeding group is resident. Breeding groups move from one adult male territory to another in search of food.

In Tsavo, two breeding groups moved 3.5–4.5 km/day (S. A. Andanje pers. comm.). However, these groups were probably much more sedentary than groups in the natural population. Subadults leave the breeding group soon after weaning (ca. 9 months of age) when they are chased out by adult ♀ ♀ (S. A. Andanje pers. comm.). They then occupy areas peripheral to breeding groups where they live alone or in small mixed- or single-sex groups of up to three individuals (Andanje & Ottichilo 1999). Mixed aggregations of

Hirola *Beatragus hunteri*.

breeding groups and bachelor groups up to 300 animals have been observed in the natural population at the end of the dry season when isolated showers produce patches of green forage (Bunderson 1981).

Males perform flehmen during mating (Butynski 2000). Flehmen has not been recorded in either *Alcelaphus* or *Damaliscus*. This is probably of considerable taxonomic significance as it supports the concept that the Hirola is an ancient alcelaphine that, like wildebeest, retains the urine testing behaviour found (as far as it is known) in all other bovids (Estes 1991a). Females leave the group, either alone or with an adult ♂, just prior to calving. Calves do not join groups until 1–2 months of age.

On the natural range, Hirola associate most frequently with Beisa Oryxes *Oryx beisa*, Gerenuks and Giraffes (Bunderson 1981). In Tsavo, S. A. Andanje (pers. comm.) found breeding groups of Hirola alone 33% of the time, in association with Peter's Gazelles *Nanger (granti) petersii* 67% of the time, with Common Warthogs *Phacochoerus africanus* 8% of the time, and with Beisa Oryxes 8% of the time. Probert (2011) found Hirola in association with other species 92% of the time ($n = 38$ encounters); association with Peters' Gazelles was most common (28% of encounters), followed by Plains Zebras (12%).

Reproduction and Population Structure Polygamous. Mating takes place primarily from Feb to Mar at the start of the long wet season. Births occur from Aug to Feb during the short wet season (Sep–Nov) and short dry season (Dec–Jan). The birth peak is Oct–Nov (Kingdon 1982, S. A. Andanje pers. comm.). The timing of the birth season means that optimal grazing is available from Nov to Jan for lactating ♀ ♀ and growing calves. In captivity, single calves were born after a gestation of 227–242 days (Smielowski 1987). Each year, about half of the adult ♀ ♀ in Tsavo give birth (S. A. Andanje pers. comm.).

Data on age at sexual maturity in the wild are not available, but captive ♀ ♀ mated successfully at 1.4 and 1.7 months of age (Smielowski 1987). Female Hartbeest are sexually mature at 1.5–2 years of age and generally give birth to their first young at 2–3 years of age. Male Hartbeest are adult-sized at three years of age but probably take at least four years to establish territories and mate (Kingdon 1982). These parameters probably also apply to the Hirola.

There are no data on the age/sex ratios of Hirola on the natural range. In Tsavo, the population of 76 Hirola in 1996 comprised 30 (39%) immatures and 46 (61%) adults. The sex ratio among adults

was 13 (28%) ♂♂ to 33 (72%) ♀♀. For this population as a whole, 45 (59%) of the animals were ♀♀. Of these 76 Hirola, 60 lived in eight herds, while 16 lived alone (five adult ♂♂ and 11 subadult ♂♂ and ♀♀; Andanje 2002). A 2011 study in Tsavo found a population comprising 21 (31%) immatures and 46 (69%) adults, an overall sex ratio of 24 (44%) ♂♂ to 30 (56%) ♀♀, and an adult sex ratio of 16 (35%) ♂♂ to 30 (65%) ♀♀. Of the 24 ♂♂, six were with nursery herds and 16 were either alone or in bachelor herds (Probert 2011).

In Tsavo, there is high mortality among calves 2–4 weeks of age, with about half of the calves dying during their first month (S. A. Andanje pers. comm.). Likewise, in captivity, 32% of 19 calves died before they were three months of age (Smielowski 1987). A captive animal born at Gladys Porter Zoo, Texas, survived 15.2 years (Weigl 2005).

Predators, Parasites and Diseases There is little information on predation of Hirola. Lions *Panthera leo*, Leopards *P. pardus*, Cheetahs *Acinonyx jubatus*, African Wild Dogs *Lycaon pictus* and Spotted Hyenas *Crocuta crocuta* are known predators (Gibbon 2010, King *et al.* 2011b) and jackals *Canis* spp., Yellow Baboons *Papio cynocephalus*, African Rock Pythons *Python sebae* and large eagles probably prey on newborns. Preliminary data suggest that Lions are the main predators of Hirola on the natural range as well as in Tsavo (Gibbon 2010, S. A. Andanje pers. comm.). During 2010, on the 40 km² Ishaqbini Conservancy (see below), almost 15% of the known Hirola were lost to predation, mainly by Lions and African Wild Dogs, but also to Leopards (King *et al.* 2011b). Predation is believed to be one of the primary factors currently suppressing the recovery of the greatly reduced natural population (Gibbon 2010, Kock *et al.* 2010a).

Almost nothing is known concerning diseases. However, like other African bovids, Hirola are susceptible to rinderpest (Kock *et al.* 1999, Butynski 2000). It is not unusual for rinderpest to cause more than 50% mortality in populations of wild ungulates. Confirmed epidemics of rinderpest occurred among cattle in the natural range of the Hirola in 1962–63 and in 1982–83, with a probable epidemic in 1972–74. During 1983–85 the Hirola population experienced a major crash from which it has not recovered. There was severe drought and rinderpest during this period. It is suspected that this combination of factors was responsible for the crash (East 1999, Butynski 2000). Of particular concern is the likelihood that Hirola are susceptible to diseases harboured by domestic livestock, especially goats and cattle; outbreaks of contagious bovine pleuropneumonia, haemorrhagic septicaemia and tuberculosis occur among livestock within the natural range of the Hirola (Magin 1996). In captivity, Hirola have suffered from acidosis, bloat, tuberculosis and mycobacterioses (Smielowski 1987).

No blood parasites were found in samples collected from 40 Hirola in 1996 (R. Kock pers. comm.). There is no information on ectoparasites.

Conservation IUCN Category: Critically Endangered A2acd. CITES: Not listed.

This is one of Africa's most threatened large mammals and perhaps its most threatened antelope; low numbers are due to a combination of poaching, disease, drought, habitat loss, predation and competition with livestock (East 1999, Butynski 2000, Kock *et al.* 2010a, King *et al.* 2011b). In 1979, the natural population in Kenya comprised

ca. 16,000 animals on ca. 17,900 km². By 1995–96, there were only 500–2000 animals on ca. 8000 km². Today, the estimate is 402–466 animals (King *et al.* 2011a). Somalia had ca. 2000 Hirola in 1979, but has few, if any, today (Butynski 2000, King *et al.* 2011a). The introduced population in Tsavo East N. P. is currently fairly static at ca. 75–100 individuals (Kock *et al.* 2010b, Probert 2011).

The situation for the Hirola is grave, given its extremely rapid decline and the severe political and environmental problems that currently prevail over the natural range. The extinction of the Hirola would represent the first extinction in historic times of a genus of mammal endemic to the African continent. There is an urgent need to improve the level of management and protection of the one natural population of Hirola, particularly in Arawale National Reserve and in the Masalani and Galma Galla/Kolbio regions of Kenya, and in the Bushbush N. P. and Lag Dere region of SW Somalia. Community conservation and anti-poaching activities must be established over a large portion of the Hirola's remaining range. However, insecurity for conservation workers is a serious problem, making conservation efforts in this region both risky and expensive.

Consideration should be given to establishing protected areas at Galma Galla and Lag Dere, and to expanding the Tana River Primate National Reserve east to include at least 300 km² of prime habitat for Hirola. Recently, the Ishaqbini Hirola Community Conservancy established the Ishaqbini Conservancy (190 km²), which is contiguous with the Tana River Primate National Reserve to the west. The primary goal of the Ishaqbini Conservancy is to conserve the Hirola. There are ca. 150 Hirola on the Ishaqbini Conservancy, or roughly 25% of the natural population. A priority conservation action at this time is the construction of a 27.7 km² predator-proof sanctuary near the Ishaqbini Conservancy from which all large predators will be removed and within which Hirola numbers can increase. Hirola from this site (the 'Ishaqbini Sanctuary') will be released to supplement the contiguous natural population (Kock *et al.* 2010a).

The population in Tsavo East N. P. should be encouraged to expand at a faster rate. To this end, a predator-proof sanctuary (60–80 km²) is under consideration (King *et al.* 2011b, Probert 2011). New populations need to be founded on at least four additional sites in Kenya, including private ranches. A self-sustaining captive population must also be established among the better zoos of Europe and North America (the last Hirola in captivity died in 2002; Probert 2011). The current research programme on the Hirola needs to move its focus from Tsavo to the natural range. The priorities for research are: (1) to determine what factors are limiting the size of this population, and (2) to find additional ways to promote the growth of this population.

In Kenya, these and other recommendations for the long-term conservation of the Hirola have been put forth in a conservation action plan (Magin 1996) and in a conservation evaluation report (Butynski 2000). These recommendations are now part of the current conservation and management plan for the Hirola in Kenya (Hirola Management Committee 2004) and some of them are being acted upon by the Kenya Wildlife Service in conjunction with the Hirola Management Committee and local conservation NGOs.

Hirolo *Beatragus hunteri*.

GENUS *Damaliscus*

Damalisks

Damaliscus Sclater & Thomas, 1894. Book of Antelopes 1 (part 1): 3, 51.

Two species are recognized, *Damaliscus lunatus* and *D. pygargus*, which are medium-sized antelopes, although the tropical *D. lunatus* are twice as heavy as the southern *D. pygargus*. Within each species there are subspecies that are so distinct that a case could be made for classifying them as different species, and indeed they have been treated as such by several authors (Allen 1939, Grubb 2005; and see Cotterill 2003a). The Tsessebe (*D. l. lunatus*), for example, has quite different horns from the northern Coastal Topi (*D. l. topi*) and Tiang (*D. l. tiang*), and Blesbok (*D. p. philippi*) have much less colour contrast compared with Bontebok (*D. p. pygargus*). Both these 'bastard hartebeests' have characteristic raised shoulders like their close relative the Hartebeest *Alcelaphus buselaphus*.

The pelage of all species is basically brown, chestnut in the north to chocolate in the south, and they have black patches on the head, shoulders and hindquarters. The pelage is characterized by a striking, shiny hue not found in other ungulates. This appears to be an adaptation to reduce heat stress when there is no shade available, as in the treeless Highveld regions of South Africa, and the open grasslands and wetlands of Jonglei District (Sudan). Their colouration is made even more striking by their yellow or white lower limbs, especially in the Bontebok. These adaptations strengthen the visual impact of their ritualized agonistic and sexual displays (see species profiles).

The genus *Damaliscus* evolved in Africa from an ancestor that resembled the Hirolo *Beatragus hunteri* and Impala *Aepyceros melampus*. They are water-dependent grazers that specialize in high-quality grasslands (flood-plains for *D. lunatus* and 'sweetgrass' Highveld for *D. pygargus*). Hartebeest, in contrast, are specialized grazers of low-quality forage: they have lower metabolic rates and are less water-dependent.

Along with the Hartebeest, the genus *Damaliscus* was until recently the most widely distributed of African antelopes and occupied the grasslands and savannas from Senegal to Somalia and the Cape. They are a component of all the major migratory grazing systems,

Topi *Damaliscus lunatus jimela* dissection of nasal cartilage and nostrils. Cartilaginous modelling is shown in white (left).

and dominate the one in the S Sudan. Their mouths are narrow, which gives their head a sharp appearance, and their incisor arcade is narrower relative to their body size than that of the short-grass grazing wildebeest (*Connochaetes* spp.); none the less, they retain the typical bovid dentition of 32 teeth (cf. 30 in *Connochaetes* and *Beatragus*). The adaptations of *Damaliscus* allow them to extract diets of high quality (with a large proportion of green leaf) from senescent swards when that is all that is available: in the southern African winters, *D. pygargus* can survive on senescent sourveld, and in the tropical dry seasons *D. lunatus* survive, and breed, on medium to tall, mature grasslands. Comparing the two *Damaliscus* clusters, Capellini (2006) found that mean annual rainfall was the best predictor of body-size: the rich, sumpland pastures favoured by the larger-bodied *D. lunatus* complex contrasted with the less productive veld and Cape pastures that sustain the smaller-bodied *D. pygargus*. The mouth shape of wildebeest allows them to achieve higher rates of grass intake on short green lawns, from which they can exclude *Damaliscus*: when

they coexist, competition with wildebeest is likely to be a major process determining the abundance of *Damaliscus* species.

The usual mating system of *Damaliscus* is resource territories that ♀♀ use in a transient manner, though in some low-density populations a group of ♀♀ may remain on the same territory for a year or more. In high-density populations, where the scale of the habitats allows the formation of large herds (e.g. in East African flood-plains), most of the animals live in a few large mixed-sex herds, up to 1500 animals. In such circumstances, leks may appear, with ♂♂ spaced as close as

25 m apart on knolls, which the ♀♀ visit when in oestrus. Leks may evolve from groups of successful resource territories, with weaker ♂♂ establishing themselves around the territories of successful ones. The function of these leks is debated: they may result from mate choice by the ♀♀; oestrous ♀♀ may also use the leks to avoid harassment in the mixed-sex herds (Gosling & Petrie 1990, Clutton-Brock *et al.* 1993, Bro-Jørgensen 2003a).

Patrick Duncan

Damaliscus pygargus BONTBOK / BLESBOK

Fr. Bontebok (Blesbok); Ger. Buntbock (Blessbock)

Damaliscus pygargus (Pallas, 1767). Spicil. Zool. 1: 10. No locality. Since restricted to South Africa, Western Cape Prov., Caledon, Swart River (Bigalke 1948).

Bontebok *Damaliscus pygargus pygargus*.

Taxonomy The Bontebok *D. p. pygargus* and the Blesbok *D. p. phillipsi* have been considered as separate species in the past (e.g. Allen 1939; and see Essop *et al.* 1991), but are currently regarded as conspecific (Meester *et al.* 1986, Grubb 2005). The scientific name has been the subject of some confusion, as it has been argued that since a type specimen 'which is indeed a Bontebok' does not exist, the former name *Damaliscus dorcas*, which was used for more than half a century, is invalid (Rookmaaker 1989, 1991). The major reason for the confusion is the fact that the similarly marked Blesbok was discovered on the inland plains of the Free State some 100 years after the Bontebok, and separated by a belt at least 320 km wide at its narrowest from the range of the latter (Bigalke 1955, Skead 1958). The colonists did not distinguish between the two animals. Grubb (1999, 2004, 2005) attributed the original description to Pallas (1766), in which the author redescribed the Bontebok, because of perceived confusion, as *Antelope pygargus*. Grubb (1999) implies, however, that despite the nomenclatural and other problems, Pallas clearly had the Bontebok in mind when he first described *Antelope dorcas* in 1766.

The nomenclatural history of the Blesbok, although also complex, is a little more straightforward. Burchell (1823) wrote of the Blesbok that he had 'taken the liberty of' in effect naming it '*albifrons*', but in Burchell (1836) he synonymized his *Antelope albifrons* with *A.*

pygargus, stating that the species was 'the Blesbok of the Colonists, and sometimes Bontebok'. Harper (1939) recognized that Burchell did not differentiate between the two variations and went ahead and described the Blesbok as *D. phillipsi*. Synonyms: *albifrons*, *dorcas*. Chromosome number: $2n = 38$ (FN = 60); karyotypes have 11 metacentric/submetacentric and seven acrocentric/teleocentric pairs of autosomes, a large acrocentric X and a smaller acrocentric Y (Wurster & Benirschke 1968, Claro *et al.* 1995, Kumamoto *et al.* 1996). Hybrids of *D. p. phillipsi* and the Hartbeest *Alcelaphus buselaphus* have a diploid number of $2n = 39$, and are sterile (Robinson *et al.* 1991). Fabricius *et al.* (1989) used discriminant function analysis to show that the two subspecies and their hybrids can be separated on the basis of colour pattern.

Description Bonteboks and Blesboks are medium-sized antelopes, smaller but similar to the Tsessebe *Damaliscus lunatus lunatus*, although generally considerably darker in colour, standing approximately 0.90–0.95 m at the shoulder. According to Bigalke (1955), the general body colour of the Bontebok 'is a rich dark brown, darker on the sides of the head, the flanks and upperparts of the limbs' (with a purple gloss) compared with the Blesbok with a general body colour of 'a reddish-brown' (without a purplish gloss). Both are white or nearly so on the underparts. Generally, the white blaze on the Bontebok is not divided between the eyes, whereas that of the Blesbok usually is, thus forming a brown bar across the face. However, this character is somewhat variable, as in Bontebok N. P., David (1970) recorded 19% of both sexes with a divided face blaze in a sample of 68 ♀♀ and 47 ♂♂. Whereas the rump patch on the Bontebok is clearly white and extends above the tail, that of the Blesbok is far less extensive and simply paler in colour, but never white. The limbs of the Bontebok, apart from dark stripes on the front of the forelimbs, and occasionally hindlimbs, are white from the knee downwards, whereas on the outer surfaces those of the Blesbok are brown. The precocial young are initially light brown, but develop full adult colouration at approximately eight months. There is little evident colour variation within the area of distribution of the species. There is also little sexual dimorphism, but adult ♂♂ are generally darker in colour and have a conspicuous white scrotum. Both Bontebok and Blesbok have prominent preorbital glands (larger in ♂ than ♀; David 1973,

Blesbok *Damaliscus pygargus phillipsi*.

Lynch 1974), with pedal glands only on the forefeet; there are no inguinal glands.

Both sexes have ridged horns that rise from the top of the head, curve backward and outward and then forward towards the unridged tips; horns of ♀ tend to be more slender than ♂. The horns of Bontebok tend to be dark whereas those of Blesbok are considerably lighter (straw-coloured). In Blesboks, horn annuli first appear at eight months of age (Rowe-Rowe & Bigalke 1972), and Watson *et al.* (1991) noted that horns started curving from 15 months onwards. In animals younger than 18 months, horn shape, horn length and horn base circumference can be used to estimate age of subadults fairly accurately.

The first permanent molar is fully erupted and functional at six months and at nine months the second molars erupt with M₂ preceding M². The same tendency occurs with the third molars. The first lower incisor is fully erupted at 18 months, although the deciduous premolars are not yet replaced (Watson *et al.* 1991). By 33 months all permanent teeth have erupted (Ludbrook & Ludbrook 1981).

Geographic Variation

D. p. pygargus (Bontebok): occurs naturally within the south-western portion of the Western Cape, which is a winter rainfall region. Bonteboks, especially adult ♂♂ in good condition, show a beautiful purple bloom on their back and flanks; white face blaze usually continuous, not divided by a transverse brown band between the eyes; rump patch clearly white and extends around base of the tail; basal end of tail white; limbs white from the knee downwards; horns tend to be dark on upper surface of the rings.

D. p. phillipsi (Blesbok): occurs naturally within the true grasslands of the summer rainfall portions of South Africa. Blesboks do not have the purple gloss of the Bontebok and are generally duller in

Lateral view of skull of Bontebok *Damaliscus pygargus pygargus*.

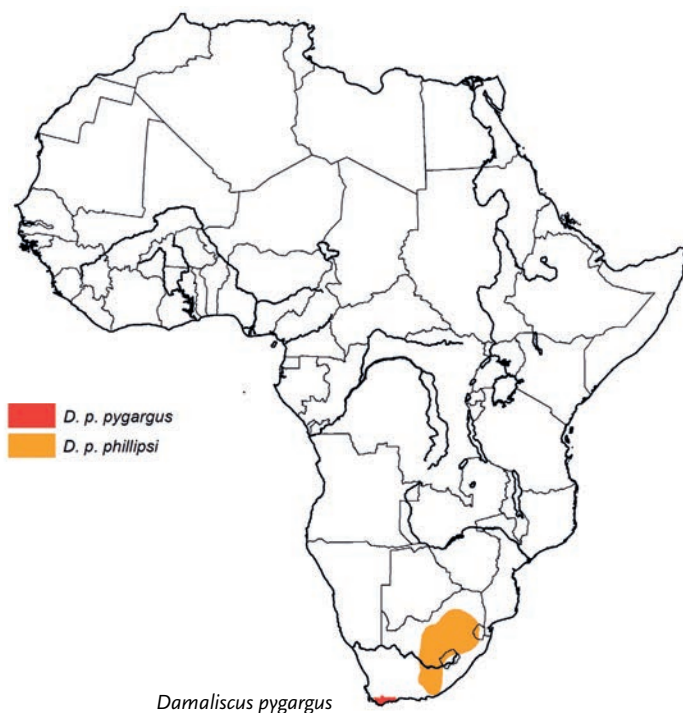

colour; white face blaze divided by a narrow brown band between the eyes; rump patch paler in colour (never white) and basal end of tail is white or pale brown; limbs brown in colour; horns usually straw-coloured.

Similar Species

Damaliscus lunatus. Only the Tsessebe is now sympatric, and then only with the Blesbok, which has been introduced to areas outside its historical (allopatric) range. Similar in shape, having the characteristic high withers and long face, but considerably larger, with no visible white colouration.

Distribution The Bontebok is endemic to the Western Cape of South Africa. Historically, the Bontebok appears to have been restricted to the coastal 'Renosterveld' plain bounded in the west by the Bot R. and probably by the Gouritz R. in the east, although it might have gone a bit further east, until approaching the coastal scrub and forest, which are unsuitable habitats for these grazing antelopes. The northern boundary would have been formed by the mountainous Riviersonderendberg range, the Langeberg range and possibly the Outeniqua Mts; the southern boundary is formed by the sea. This distribution within the Cape Floristic Region ('fynbos') covers practically the same area as the so-called Coastal Renosterveld and Coastal Macchia veld types of Acocks (1953). These represent the areas with the deeper and richer soils and the greatest abundance of grass to be found in the generally grass-impooverished and nutrient-poor 'fynbos' (see Bigalke 1955, Skead 1958, 1980, David 1973, East 1999, Skinner & Chimimba 2005).

The Blesbok, in contrast, occurred naturally in the eastern grasslands of the Northern Cape, the southern grasslands (including the highveld) of the North West and Gauteng Provinces, most of the grasslands of the Free State, marginally in the western and north-western grasslands of KwaZulu-Natal, and the true grasslands of the Eastern Cape (Skead 1980, East 1999, Skinner & Chimimba 2005). Blesboks became extinct in KwaZulu-Natal, probably during the first decade of the twentieth century, but were reintroduced (Rowe-Rowe 1994). Blesboks also formerly occurred in W Lesotho, but were exterminated before 1900 (Lynch 1994). There is no reliable historical evidence of the presence of Blesboks in Swaziland, but they probably occurred marginally in the extreme west and south-west of the country. They have since been introduced to Malolotja N. R. and Milwane Wildlife Sanctuary (Monadjem 1998). Blesbok have been widely reintroduced to private farmland, and also introduced widely outside their natural range; introduced populations occur throughout

much of Namibia, E Botswana and the midlands of Zimbabwe (East 1999).

The natural separation of the two subspecies by some 300 km is speculated to be related to the rise in sea level $\pm 15,000$ years BP after the end of the last ice age, prior to which extensive grasslands are thought to have been available on what is now the eastern Continental shelf. The rise in sea level thereafter resulted in the isolation of one population in the only area rich in grasses within what is today the Cape Floristic Region and another in the current grassland areas somewhat to the north-east, with mountain ranges separating them.

The present-day artificial distribution of both subspecies, largely as the result of pressure from the game industry, is considerably wider than the natural ranges of the two subspecies combined. Despite measures taken to try to minimize the threat of hybridization of the two subspecies, this threat persists in some of the provinces. This has resulted in a procedure for registration of Bontebok populations that have passed a photographically based test (Fabricius *et al.* 1989, Norton & Lloyd 1994). A register of these 'pure' populations is still maintained by the Western Cape and Eastern Cape provinces. Unfortunately, pure Blesbok populations and hybrids are not being monitored as comprehensively.

Habitat Bontebok and Blesbok are exclusively grazers, with a preference for short grass (Skead 1964, Du Plessis 1968, David 1973, Nolte 1973, Skinner & Chimimba 2005), and typically occupy flat or gently undulating grassland areas. Bonteboks are inhabitants of the coastal plain described above (60–200 m), whereas Blesboks are more typically associated with inland grasslands from lower (subcoastal) altitudes to areas up to 2000 m. Water is also an essential habitat requirement.

Abundance Registered Bontebok numbers in South Africa are currently estimated to be in excess of 3500 animals (P. Lloyd pers. obs.), more than 1000 of which are in formal conservation areas;

however, only about 1500 animals actually occur within the native historical range of the subspecies (P. Lloyd pers. obs.). Blesbok numbers are considered to be close to 250,000 (East 1999), with the overwhelming majority (97%) of this population occurring on private land. Many animals are on properties outside the natural range.

Ecologically meaningful densities are difficult to arrive at, since most populations of both Blesboks and Bonteboks are kept at managed densities. In Bontebok N. P., which is home to 250 Bonteboks in about 3000 ha, the density is one animal per 12 ha. In De Hoop (Provincial) N. R., there are 700 Bonteboks in about 5500 ha, yielding a density of roughly one animal per 8 ha.

Adaptations There is speculation that the rich body colour and purple sheen of the Bontebok is related to trace-element metabolism. Much of the natural range of the Bontebok is copper-deficient, and animals are known to suffer from 'sway-back' in the same way that large and small stock are affected, especially in terms of the loss of pigment. Particularly during and after long dry spells, several pale, almost whitish individuals have been observed on De Hoop (Provincial) N. R. The condition is largely reversible and either after treatment or after periods of rainfall, individuals can be seen to have regained their deep colouration. More serious is the poor development or weakening of the bones in copper-deficient areas, as is evidenced by the relatively large number of leg fractures during Bontebok capture operations on nature reserves in the Western Cape (Zumt & Heine 1978). Uncorroborated speculation has also suggested that Bonteboks can store metabolic copper at levels that are toxic to other artiodactyls. Since the Bontebok is effectively endemic to a copper-deficient region, this speculation may warrant further investigation. It is interesting that the Blesbok, endemic to areas with considerably higher copper levels, is the paler of the two subspecies.

Blesboks have a large rumen capacity and intestine length relative to body size, enabling a longer transit time in the gut (necessary due to the lower digestibility of forage consumed) (Klein & Fairall 1986).

The exocrine secretions of the interdigital glands and preorbital glands have been investigated in some detail (Burger *et al.* 1976, 1977, 1999b, c). The interdigital secretions comprise a total of 85 different compounds, including alkanes, alcohols, aldehydes, ketones, fatty acids, phenols, steroids and other compounds. No qualitative differences were found between the secretions of ♂♂ or ♀♀, or from animals from different habitats (Burger *et al.* 1999b). In contrast, the pale yellow preorbital secretions constitute some 42 compounds (19 in common with the interdigital secretions) and qualitative differences between the secretions of ♂♂ and ♀♀ were evident (Burger *et al.* 1999c).

Foraging and Food As stated above, Bonteboks and Blesboks are almost exclusively grazing antelopes, but in freshly burnt areas other grass-like plants, other monocotyledons and even dicotyledons are occasionally utilized (Skead 1964, Langley & Giliomee 1974). Gagnon & Chew (2000), in their review of the dietary classification of African bovids, classed the species as 'variable grazers', taking 60–90% monocots. Studies involving stable carbon isotope analysis confirm that grass dominates the diet (Sponheimer *et al.* 2003b). Species utilized by Bonteboks include *Cynodon dactylon*, *Themeda triandra* (David 1973), *Bromus rigidus*, *Bromus decedrus* (both introduced annual grasses), *Pseudopentameris macrantha*, *Tribolium*

uniolae, *Eragrostis capensis*, *Koeleria cristata*, *Merxmüllera stricta* (Nolte 1973), *Ficinia anceps*, *F. argyropa*, *Restio quinquefarius*, *Helichrysum orbiculare*, *Gnaphalium polycaulon* and *Pentaschistis* sp. (Langley & Giliomee 1974). Skead (1964) observed animals feeding on *Oxalis hirta*. Species utilized by Blesboks include *Themeda triandra*, *Eragrostis curvula*, *E. pseudosclerantha*, *Setaria nigrirostris* and *Chloromelas* sp. (Du Plessis 1968).

A detailed study of Bonteboks' daily activity in Bontebok N. P., during which activity was scored every four minutes for 12 hours per day, showed that on a year-round basis ♀♀ grazed significantly longer than territorial ♂♂ (64.9% : 54.7%) and had significantly less 'other' activity, which related to courtship behaviour and territory defence (4.7% : 12.7%). However, the time spent ruminating and resting was very similar for both sexes (David 1973). A comparison of seasonal differences showed that both sexes grazed for significantly longer in winter compared with summer, although according to Grobler & Marais (1967) the annual rainfall in the park is divided fairly evenly throughout the year, and is not necessarily highest in winter.

The Blesbok shows striking seasonal differences in its foraging behaviour in the summer rainfall regions where it occurs. This is due to the poor nutritional quality of the sourveld grasses on which it feeds during the dry winter months. This in turn leads to the populations in these areas adopting an 'energy-saving' mode of existence during winter, such that the herds reduce all activities to an absolute minimum and go into a state of semi-torpor, while awaiting the advent of the spring rains and the sprouting of fresh green grass (Du Plessis 1968, Lynch 1974).

Social and Reproductive Behaviour Bonteboks and Blesboks are gregarious and territorial animals but, whereas Bonteboks defend their territories throughout the year, Blesboks are territorial only during the rut, from Mar to May. The social organization comprises territorial ♂♂, female herds and bachelor herds. Territorial ♂♂ of both subspecies establish territories that, for Bonteboks in Bontebok N. P., vary in size from about 1 to 4 ha, with a mean size of about 2.5 ha (David 1973), whereas for Blesboks they range from 9 to 41 ha, with a mean size of 25 ha (Novellie 1979). Small herds of adult ♀♀ with their young, averaging only three ♀♀ with a maximum of nine in Bonteboks, and up to 25 with an average of ten in Blesboks, are associated with each territorial ♂ (David 1973, Lynch 1974, Novellie 1975, 1979). These female herds wander at will through the network of territories (female home-ranges typically include 2–3 territories), but in Bonteboks the year-round defence of territories results in a remarkable stability of the social order, since the same group of adult ♀♀ and young will often remain with the same ♂ throughout the year (David 1973, Estes 1991a). As such, territorial Bontebok ♂♂ spend most of their time with ♀♀; for example, four out of 18 ♂♂ studied in Bontebok N. P. were never seen alone in 235 observations and the remaining 14 were seen alone in only about 20% of observations (David 1973). The Blesbok social order is not so stable, since during the winter (Jun–Aug) territories are undefended and large aggregations of both sexes and all age groups (up to 650 animals) may be formed (Lynch 1974, Novellie 1975). Nevertheless, female herds still have well-defined home-ranges. By Sep these aggregations slowly disintegrate, and territoriality among ♂♂ becomes increasingly noticeable from Nov (Lynch 1974).

Bachelor groups form larger aggregations, consisting mostly of younger ♂♂, but also old ♂♂ and recently deposed territorial ♂♂. The young ♂♂ may become territorial at a later stage, but are unlikely to establish a territory, or depose a territorial ♂ from an existing territory, until they are sexually mature at about five years of age. Bachelor groups may also include small numbers of young ♀♀, which usually remain in the herd until they are about two years old. There is no hierarchy within bachelor groups and no aggression between members (David 1973, Novellie 1975).

Territorial ♂♂ advertise their ownership of a territory by assuming a 'proud' posture with head held high, ears extended sideways and by standing on raised ground where they are clearly visible. Males demarcate territories by deposition of secretions from the preorbital glands onto grass and other stems, though David (1973) questioned what role these secretions played in territorial marking. Apparently unique to Bonteboks and Blesboks is the subsequent transfer of these secretions from marked stalks to their horns by means of stroking their horns across the grass with a sideways movement of the head (David 1970, 1973, Lynch 1974). In some territorial ♂♂ this results in deposition of a black waxy substance a few millimetres thick between the horn annuli (Lynch 1974). This behaviour is not unique to territorial ♂♂, and adult ♀♀, bachelor ♂♂ and even young indulge in this 'glandular weaving'. In male Blesboks, secretions from the gland accumulate on the face and stain the white face blaze a yellowish-black (Lynch 1974); such face-staining was not observed in Bontebok (David 1973).

Another method of territory demarcation by territorial Blesboks and Bonteboks is through the creation of dung middens throughout their territories (4.3/ha in the latter in Bontebok N. P., David 1973), while bachelor ♂♂, ♀♀ and young defecate randomly. Territorial ♂♂ usually choose a dung patch to lie on and Blesbok ♂♂ wipe their preorbital glands on the dung patch and then on the neck and shoulder while lying down (Lynch 1974). Although David (1973) attributed no marking function to dung middens because bachelors and other territorial ♂♂ took no notice of them, they are clearly of significance to their owners and may serve as indirect territory markers (Lynch 1974). Novellie (1981) concluded that a territorial dung patch served to communicate its owner's identity to neighbouring territorial ♂♂, as male Bonteboks in captivity could distinguish between their own faecal pellets and those of a stranger. Both Bonteboks and Blesboks also have interdigital glands and so pawing, especially of the dung heaps, by territorial ♂♂ may be an additional factor in marking.

Males defend their territories against bachelor ♂♂ by aggression, and bachelors will always give way when chased or approached by a territory holder. However, against neighbouring territory holders, the territory is defended through a complex series of ritualized displays called a challenge ritual (David 1973, Lynch 1974). Serious fighting, involving ♂♂ dropping on to their knees with their foreheads close to the ground and locking horns in a violent pushing contest (Du Plessis 1968, Lynch 1974), is rare and was only witnessed in 3% of Bontebok challenge rituals (David 1973).

Challenge rituals are a significant daily occurrence in the lives of most territory holders and involve them either entering a neighbouring territory or receiving a neighbouring ♂ for the performance of the ritual. The average duration of Bontebok challenge rituals was 6.5 min, with a range from 1 to 23 min. The most frequent behaviours

seen during a ritual, which include both aggressive and submissive actions, include the following: approach and withdrawal while head-flagging, which involves turning the head and horns away from the opponent; standing flank to flank with the opponent, sometimes in parallel position, but usually in reverse parallel accompanied by mutual anus sniffing; aggressive head-shaking; lateral presentation, in which one ♂ stands sideways in front of the other; glandular weaving, in which the ♂ transfers secretions from the preorbital glands onto grass stalks and then waves his muzzle and horns across the same grass stalks; urination; defecation; soil horning while on the knees; cavorting, which involves a ♂ leaping into the air and kicking out with the hindlegs. Neutral activities such as grazing and grooming also form part of the ritual (David 1973).

Territorial ♂♂ of both subspecies court ♀♀ with a low-stretch display, holding the head low and outstretched with the tail curled over the back (David 1973, Lynch 1974, Estes 1991a, Skinner & Chimimba 2005). Males test the receptivity of ♀♀ by sniffing the vulva (the ♀ standing with tail out), although, unlike most antelopes, neither Bonteboks nor Blesboks exhibit flehmen (a trait shared with *Damaliscus lunatus* and *Alcelaphus*). If a ♂ sniffs the vulva of an unreceptive ♀, she turns to run round him in a tight circle, flank to flank, but always with head held low in a submissive posture.

Females do not isolate themselves from the rest of the female herd during parturition (David 1975, Estes 1991a). Young are capable of walking and following their mothers within half-an-hour (David 1975, Estes 1991a). There is no concealment behaviour, except when mothers are grazing (Langley & Giliomee 1974), and ♀♀ do not eat the afterbirth. Females only suckle their own offspring, driving others away. Young separated from their mother bleat loudly. Young are weaned at about four months. Young ♂♂ leave their mothers of their own accord at about 12 months of age, when the mothers produce their next offspring; they may remain solitary at first, but eventually join bachelor groups until sexually mature.

Associations with other ungulates specifically, and other species in general, are not clear, possibly since hunting during the past two centuries and enclosure within reserves has compromised 'natural' studies, but both subspecies have been associated with species such as the Plains Zebra *Equus quagga* and Mountain Zebra *Equus zebra*, Impala *Aepyceros melampus* and Ostrich *Struthio camelus*.

The only sounds made by Bonteboks during an 18-month study were the explosive alarm snort and a series of grunts emitted by a ♂ when mounting a ♀ prior to copulation (David 1970).

Reproduction and Population Structure Bonteboks and Blesboks are polygamous short-day seasonal breeders, with single young (weight 6–7 kg) being born after a gestation period of ± 240 days (Skinner *et al.* 1974, David 1975). The majority of Bontebok young are born between Sep and Nov (peaking in Oct) after the rut from Jan to mid-Mar (David 1973). Blesbok young, in contrast, are mostly born between Nov and Jan (peaking in Dec), after an autumn rut from Mar to May (Skinner *et al.* 1974). The differing strategies allow Bontebok young to be born in middle to late spring of the winter rainfall areas of the Cape Floristic Region, whereas Blesbok young are born somewhat later in the summer rainfall areas prior to the dry winter months, thereby optimizing the grazing available after the respective wet seasons. Novellie (1986) found that conception

rate was influenced by rainfall, which determines forage quantity and quality prior to the breeding season.

Blesbok ♀♀ mature sexually at about 2½ years of age (Du Plessis 1968), similar to records for Bonteboks that suggest they became sexually mature at about 2¼ years of age (David 1970, 1975). Male Bonteboks apparently reach sexual maturation at about three years of age (Estes 1991a), but only tend to become territorial at about five years. The same is probably true of Blesboks. Oestrous cycle length is 28–32 days (Marais 1988). In captivity, well-fed ♀♀ kept in proximity to a ♂ cycled throughout the year. The introduction of a ♂ to a group of isolated and non-cycling ♀♀ resulted in immediate synchrony of the oestrous cycle, which is likely to result in the bulk of the young being born within a short period of time (Marais & Skinner 1993).

In Bontebok N. P., David (1970) found the sex ratio of yearling and older Bonteboks to be 100 ♂♂ to 87 ♀♀ ($n = 215$) and a separate evaluation of roughly one-year-old young gave a similar ratio of 100 : 88 (26 : 23, $n = 49$).

Under captive conditions, Bonteboks have attained 15 years and seven months of age, compared with Blesboks, which have reached more than 20 years of age (Jones 1993). Historically, in the wild the life-span is likely to have been considerably shorter, but in current times the species is not exposed to predation by large carnivores and many individuals may attain such an age under relatively natural conditions.

Predators, Parasites and Diseases As animals adapted to grassland environments, both Bonteboks and Blesboks could be considered to be subject to predation by typical grassland carnivores. Historically, these would have included Lions *Panthera leo*, Leopards *Panthera pardus*, Spotted Hyaenas *Crocuta crocuta*, African Wild Dogs *Lycaon pictus* and, particularly for Blesboks, Cheetahs *Acinonyx jubatus*. Smaller carnivores include Black-backed Jackals *Canis mesomelas* and Caracals *Caracal caracal*, while other predators potentially implicated in juvenile mortality are Chacma Baboons *Papio ursinus*, the African Rock Python *Python sebae* and some of the larger raptors.

In Bonteboks, two important causes of death that have been recorded are verminosis and copper deficiency (Zumpt & Heine 1978).

Over the course of a ten-year study period in Bontebok N. P., Bonteboks were found to harbour eight species of ixodid ticks, of which *Rhipicephalus glabroscutatum* and *R. nitens* were most abundant (Horak *et al.* 1997); Horak *et al.* (1986) also recorded two louse species (*Damalinia* sp. and *Linognathus* sp.) and the larvae of two oestrid flies (*Gedoelestia* sp. and *Strobiloestrus* sp.). In the same park, Boomker & Horak (1992) amended the list of helminth parasites recovered to one trematode (*Paramphistomum microbothrium*), two cestodes (*Taenia hydatigena* and *Moniezia expansa*) and 19 nematode species, with *Longistrongylus curvispiculum* and *Nematodius spathiger* the most abundant and prevalent (see also Horak *et al.* 1982a).

The helminth and arthropod burdens of Blesboks from various reserves in South Africa were investigated by Horak *et al.* (1982a), who recovered 21 nematodes (*Haemonchus bedfordi* and *Trichostrongylus axei* were present in all regions sampled), two cestodes, six ixodid ticks, two lice and the larvae of five oestrid flies (see also Young *et al.* 1973b, Horak & Butt 1977, Horak 1978b, 1981b).

Conservation IUCN Category: Least Concern (*D. p. pygargus* – Near Threatened; *D. p. philippi* – Least Concern). CITES: Appendix II (*D. p. pygargus* only).

More than 95% of the estimated total population of 250,000 Blesboks occur on private land, with larger protected populations occurring in Suikerbosrand N. R. (Gauteng), and Willem Pretorius G. R., Sterkfontein Dam N. R., Tussen-die-Riviere G. R. and Golden Gate Highlands N. P. (Free State). The two most important conservation areas for the Bontebok are Bontebok N. P. and De Hoop (Provincial) N. R., the former with ± 250 animals and the latter (including the neighbouring privately owned Overberg Test Range, which has conservation as a secondary objective) with nearly 700 animals (making this the largest population of the subspecies). They also occur on Hottentot-Hollands (Provincial) N. R., which has limited suitable habitat, and has around 20 animals (P. Lloyd pers obs.).

Though historical records are lacking, it is likely that, due to its restricted distribution, the Bontebok was never very abundant. So it is perhaps not surprising that, as early as 1830, indiscriminate hunting and the enclosure of the best land for farms by the early settlers in the Western Cape had seriously reduced its numbers, so that the species was in real danger of extinction. Fortunately, enlightened landowners in the Bredasdorp district perceived the threat to the species and enclosed as many as they could on their land. Their timely actions undoubtedly saved the Bontebok for posterity, but numbers were still not very high by the time the first Bontebok N. P. was proclaimed near Bredasdorp in 1931 with a paltry total of 17–22 animals (Bigalke 1955, Barnard & Van der Walt 1961, Van der Merwe 1968).

This first park was not a success due to its small size and poor quality grazing and the decision was eventually taken to look for a wholly new park. After a long search a suitable site was found for the present park near the town of Swellendam and, in March 1960, 84 sedated animals were transferred by truck, of which 61 survived the critical first three days in the new park. The introduced Bonteboks thrived in their new environment and quickly improved both in condition and number (Barnard & Van der Walt 1961, Van der Merwe 1968). Today, the numbers in the park, which is about 3000 ha in size, have stabilized at around 250 animals. Surplus animals from this park have formed the nucleus of reintroduced populations in other protected areas, and have also been introduced outside their former range (for example, to West Coast N. P.).

The greatest threat to both Bontebok and Blesbok is deliberate or accidental hybridization at the intra-specific level (mixture of the subspecies). Despite some provinces taking measures to try to prevent such activities, such hybridization has unfortunately occurred and represents a threat to both the pure Bontebok and the pure Blesbok. Attempts are being made to ensure that such animals may not be translocated, may only be sold as venison, and should not be maintained in close proximity to pure animals of either subspecies.

Measurements

Damaliscus pygargus

D. p. pygargus

HB (♂): 1480 mm, n = 1

T (♂): 330 mm, n = 1

E (♂): 140 mm, n = 1

Sh. Ht. (♂): 988 mm, n = 1

South Africa (Roberts 1951)

Skinner *et al.* (1980) recorded adult Bontebok ♂♂ with a mean mass of 61.0 kg (range 59.6–63.6; n = 24)

Maximum recorded horn length for a Bontebok is 42.6 cm for a pair of horns from the former Cape Province, South Africa (Rowland Ward)

D. p. philippi

HB (♂): 1580 mm, n = 1

HB (♀): 1393 mm, n = 1

T (♂): 215 mm, n = 1

T (♀): 177 mm, n = 1

E (♂): 139 mm, n = 1

E (♀): 127 mm, n = 1

Sh. ht (♂): 912 mm, n = 1

Sh. ht (♀): 840 mm, n = 1

South Africa (Roberts 1951)

Maximum recorded horn length for a Blesbok is for a pair of horns from Vryburg, Northern Cape, South Africa, which measured 52.4 cm (Rowland Ward)

Damaliscus lunatus TOPI / TSESSEBE / TIANG / KORRIGUM

Fr. Damalisque; Ger. Leierantilope

Damaliscus lunatus (Burchell, 1824). Travels in Interior of Southern Africa 2: 334[1824]. South Africa, Northern Cape Prov., Kuruman Dist., 'Makkwarin' (Matlhwareng) River.

Tsessebe *Damaliscus lunatus lunatus*.Lateral and palatal views of skull of Tsessebe *Damaliscus lunatus lunatus*.

Taxonomy Polytypic, with as many as seven recognized subspecies (Haltenorth 1963, Ansell 1972). There are obvious differences between the southern *lunatus* and the other subspecies, for instance the horns of *lunatus* being crescent- rather than lyre-shaped (see also Geographic Variation). Consequently, while traditionally only a single species has been recognized (e.g. Grubb 1993c), a convincing case can be made for splitting the species into two, as has been done by some authors (Allen 1939, Grubb 2005).

More recently, Cotterill (2003c) examined specimens of *D. lunatus* from south-central and East Africa and distinguished between Tsessebés from C Zimbabwe, Botswana and southern Africa, and those in NE Zambia in the southern Bangweulu Flats, which he described as a new species *Damaliscus superstes* based on differences in cranial morphology and pelage (and see Ansell 1978). Cotterill (2003c) proposed considering animals from south-central Africa (south of, and including, Angola, Zambia and S DR Congo) as *D. lunatus* (with the exception of *D. superstes*), and all other populations from East Africa and the remainder of the range provisionally as *D. korrigum* (the approach subsequently followed by Grubb 2005). Analyses of mitochondrial DNA of Tsessebés from Botswana and East African Topis reveal some degree of genetic divergence between the two clades (Arctander *et al.* 1999). In this sense, the isolated population in Bangweulu represents something of an anomaly, the two clades otherwise being separated across the southern Tanganyika and Rungwe Rifts in SW Tanzania and neighbouring Zambia (Cotterill 2003d).

As with Hartbeest *Alcelaphus buselaphus*, further taxonomic investigation is needed, and pending the availability of more detailed studies using both molecular and morphological data – and in contrast to the classification presented by Grubb (2005), who regards *korrigum*, *lunatus* and *superstes* as distinct species – we adopt a conservative approach, treating the entire group under an interim scheme in which there are currently six subspecies (described below). This complex may well be eligible for treatment as a superspecies.

Synonyms: *korrigum*, *eurus*, *floweri*, *jimela*, *jonesi*, *korrigum*, *lyra*, *phalius*, *purpureus*, *reclinis*, *selousi*, *senegalensis*, *superstes*, *tiang*, *tiangriell*, *topi*, *ugandae*. Chromosome number: $2n = 36$ (FN = 60) in *D. l. lunatus* and *D. l. jimela* (Van der Veen & Penzhorn 1987, Kumamoto *et al.* 1996). Karyotypes of *D. l. jimela* have 12 metacentric/submetacentric and five acrocentric/telocentric pairs of autosomes. The X chromosome is the largest acrocentric element, and the Y is a small acrocentric (Kumamoto *et al.* 1996). This is in contrast to the karyotype of *D. l. lunatus* described by Van der Veen & Penzhorn (1987), where the X chromosome was submetacentric.

Description Medium-sized antelope with high shoulders and lower hindquarters. Muzzle is narrow and head long. Chestnut pelage is short, with a purplish bloom that shows a cline, being strongly marked in eastern and only slight in western populations. Dark, near black, patches on head, shoulders and hindquarters. Limbs are bright yellow and hooves black. Tail with a dark brown tassel of long hair at tip. Blaine (1914) described the visual impact of these animals as follows: 'A herd of korrigum presents a striking and beautiful colour-effect. They change from mauve to purple-red and black, against a background of brilliant emerald-green as the sunlight plays spectrally on their glossy painted skins.' Young are sandy coloured for first two months, and very similar to young Hartbeest. There are well-developed preorbital glands, and pedal glands between front hooves, particularly well developed on forefeet; there are no inguinal glands. Males slightly darker and larger (110–120% of the female body mass), but sexes are difficult to distinguish at a distance.

The horns, which occur in both sexes, are lyre- or crescent-shaped, deeply corrugated for nearly their entire length (only the tips being smooth), measuring up to 60 cm in the northern populations.

Topi *Damaliscus lunatus jimela*.

Males generally have thicker and longer horns than ♀♀, although horn length in ♂♂ decreases with age perhaps due to attrition from soil honing (Anthony & Lightfoot 1984). Horn size also increases from the southern *D. l. lunatus* (the Tsessebe) towards the northern subspecies (Estes 1991a).

Geographic Variation

- D. l. lunatus* (Tsessebe or Sassaby): central and southern Africa. Horns lunate (crescent-shaped) in profile, bending outwards in a uniform curve, then inwards and slightly forwards. Dark reddish-brown in colour, with lower parts of shoulders, upperparts of fore- and hindlegs, and thighs conspicuously darker than body colour; back of ears, hind-parts of rump, inside of hindlegs and abdomen, and base of tail all yellowish-white; lower parts of legs brownish-yellow, forelegs with a narrow band of dark brown on the front (Skinner & Chimimba 2005).
- D. l. superstes* (Bangweulu Tsessebe): Bangweulu Flats in NE Zambia; extinct in Katanga Pedicle of DR Congo. Larger than Tsessebe, horns thicker and wider spread, with a broader pedicle. In adults of both sexes, horns grow symmetrically outwards with tips curving inwards to form a sphere (distinct from the semi-lunate profile characteristic of Tsessebe *D. l. lunatus*). Larger body size, chocolate-brown pelage and spherical horn profile all appear as diagnostic in the field (Cotterill 2003c).
- D. l. korrigum* (including *purpurescens*) (Korrigum): West Africa, in the Sudanian and Sahelian zones, from Senegal, Gambia and Mauritania to Cameroon and W Chad. The border between Korrigum and Tiang is formed by a line from the Chari R. to the north, along the Logone R., in W Chad. Largest of the races with the longest horns. Pelage bright reddish-orange, paler below; lower legs from knees to hooves are fawn, banded with greyish-brown. Face greyish-black, speckled with white.

D. l. tiang (including *lyra*) (Tiang): SE Chad to SW Ethiopia and NW Kenya. Horns more slender than Korrigum. Redder in colouration than Korrigum, and the coat has a distinct reddish-purple tinge. There is often a faint dark stripe from the ear to below the eye.

D. l. topi (Coastal Topi): East Africa in Kenya and S Somalia. Medium length horns with pronounced lyrate curves.

D. l. jimela (Topi or Nyamera): East Africa in the Great Lakes region. Horns smaller than in other races, rounder in cross-section, and having the curve less pronounced (with only a slight inclination back at the tips). Darker in colour than Tiang, being a rich rufous cinnamon with a strong purplish iridescence. Dark facial markings are better defined than in Tiang.

Similar Species

Damaliscus pygargus. Historically, geographically separate (though now introduced outside its former range), with the Blesbok (*D. p. phillipsi*) living in C and S South Africa, and the Bontebok (*D. p. pygargus*) in the Western Cape.

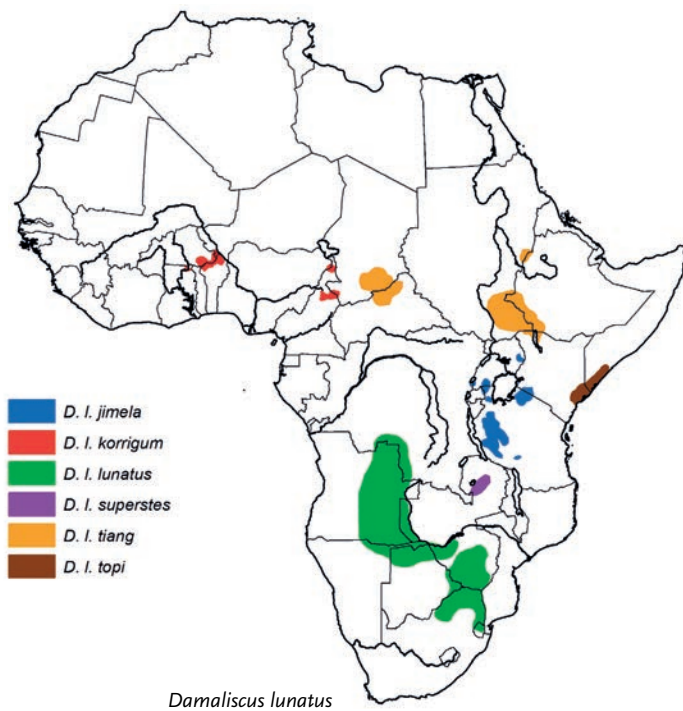

Alcelaphus buselaphus. Various subspecies of Hartbeest overlap in parts of their ranges with *D. lunatus*, but these subspecies are fawn-coloured, and readily distinguishable from *D. lunatus*. The only exceptions are the Red Hartbeest in N Botswana and Korkay in Ethiopia, which also have dark colouring and black patches on the flanks. Hartbeest further are distinguished by the presence of the pedicel supporting the horns (except for Lichtenstein's in south-east Africa) and by their complex, inverted horn shape.

Distribution Endemic to Africa, south of the Sahara, *D. lunatus* was, along with the Hartbeest, one of the most widely distributed African antelopes. The species formerly occurred from the Atlantic coast of West Africa from C and N Senegal and S Mauritania across the Sahel and Sudanian savanna to Ethiopia and Somalia, and south throughout the high-rainfall eutrophic and dystrophic savannas in all the countries of East and central Africa to South Africa, where it was replaced by the congeneric Blesbok in the Highveld and the Karroo (C and N South Africa), and the Bontebok in the Cape. The historical distribution of the species in southern and south-central Africa is discussed in detail by Cotterill (2003d). It has never been found, either as fossil remains or historically, in North Africa.

Historical Distribution The Korrigum formerly occurred in S Mauritania, C and N Senegal, Gambia, C Mali, Burkina Faso (excluding the south-west), N Ghana, N Togo, N Benin, S Niger, N Nigeria and widely on the Adamaoua Plateau in N Cameroon to W Chad (East 1999, Chardonnet 2004).

The Tiang occurred throughout S Chad (where it undertook extensive seasonal movements), in open seasonally inundated grasslands in N Central African Republic, and was formerly widespread in savanna and flood-plain grasslands in S and C Sudan. From there, its range extended into the south-western lowlands of Ethiopia and extreme NW Kenya (East 1999).

The Coastal Topi formerly occurred in S Somalia in riverine grasslands on the lower Shebelle and Juba Rivers and the area around Bush Bush N. P. In Kenya, it occurred in Lamu, Garissa and Tana River districts (East 1999). The Topi (locally distinguished as Nyamera) occurred in SW Kenya and NW and W Tanzania (on seasonally inundated grasslands within *Acacia* and *Combretum* savannas, and in

Brachystegia woodlands), E and SW Uganda, NE Rwanda and the eastern flood-plains and savanna grasslands of Burundi (East 1999).

The Bangweulu Tsessebe formerly occurred in the Bangweulu Flats in NE Zambia, bounded to the north by the Chambeshi and Luapula Rivers, and the Muchinga Escarpment to the south; it was formerly present in the Katanga Pedicle of DR Congo (Cotterill 2003c).

The Tsessebe formerly occurred across E Angola, and in Zambia was restricted to open plains and woodland edges west of the Zambezi R. In Namibia, it is naturally confined to the Caprivi Strip, while in Botswana it occurred widely in the north and east. In Zimbabwe, it occupied parts of the highveld plateau and the south, south-east and north-west, and occurred throughout parts of S Mozambique. In South Africa, it formerly occurred in the Limpopo, North West, Mpumalanga and Northern Cape Provinces (the original specimen on which the description of the species is based was collected just north-east of Kuruman). It also occurred in N KwaZulu–Natal where the last remaining herd was seen around 1925 (East 1999, Skinner & Chimimba 2005).

Current Distribution The species has undergone a drastic reduction in its range, largely due to hunting, competition from livestock and general encroachment. This range reduction has been most marked in the Korrigum in West Africa, where the species now no longer occurs in Mauritania, Mali (1970s), Senegal (pre-1930), or Gambia (early 1900s). An important population survives on the borders of Burkina Faso, Benin and Niger, in the large W–Arly–Pendjari complex of protected areas. Although believed exterminated in Ghana by the 1970s (East 1999), a relic population was reported recently still surviving in the Red Volta River valley in NE Ghana (J. Mason pers. comm.). The Korrigum probably no longer occurs in N Togo, where it was known until the late 1980s, except as vagrants (Grubb *et al.* 1998, East 1999). Further east, another relict population of the Korrigum survives in N Cameroon with a marginal occurrence in NE Nigeria (whereas they once occurred widely in the

northern savanna regions), mainly due to movements of populations from Waza N. P. in Cameroon (East 1999, Chardonnet 2004). Observations of animals in W Chad are likely due to vagrants from Bouba Ndjida N. P. in Cameroon (Chardonnet 2004).

The Tiang still occurs in S and SE Chad, in the basin of the rivers Bahr Aouk, Bahr Keita and Bahr Salamat, reaching Manda N. P. to the west and including Zakouma N. P. (Chardonnet 2004). The range in NW Central African Republic adjoins that in Chad, mainly the plains along the Aouk R., Bamingui R., Manovo R., Koumbala R., Gounda R. and St Floris plains (Chardonnet 2004). Most surviving animals are restricted to the Manovo–Gounda–St Floris N. P. In Sudan, East (1999) noted that it has been eliminated from most of the northern part of its former range (but that a small population survived in Dinder N. P.) and that Tiangs still occurred in large numbers in the south-east; recent surveys across a large part of S Sudan confirm they survive in good numbers particularly in the Jonglei area and in Boma N. P. (Fay *et al.* 2007). In Ethiopia, they still occur in good numbers in the south-west, while in Kenya they are confined to Sibiloi N. P. in NW Kenya (Marsabit district) (East 1999).

The current distribution of the Coastal Topi in S Somalia is not known, but it is now confined to isolated patches in its former range (East 1999); its range in Kenya is largely unchanged. The *jimela* subspecies (Topi) is abundant around L. Victoria, especially in the Serengeti–Mara where there were about 100,000 in 1989 (Sinclair 1995; though see East 1999), and is found southwards to L. Rukwa. In Uganda, it survives only in three areas in the east and south-west, with a very marginal extension into E DR Congo on the Rwindi–Rutshuru plain to the south of L. Edward, and in Rwanda only in the north-east (Akagera N. P.). It is extinct in Burundi.

The Bangweulu Tsessebe still occurs in the southern Bangweulu Flats in NE Zambia, but is extinct in the Katanga Pedicle in DR Congo (Cotterill 2003c). The Tsessebe occurs in a large number of fragmented populations in the countries to the south of Tanzania, and still occurs in small numbers throughout its former range in Zambia, west of the Zambezi. It also occurs in extreme SE Angola, NE Namibia, including the Caprivi Strip, but is now mainly found in the north in Botswana, particularly in the Okavango Delta, and in scattered localities in central parts of Zimbabwe and south of the central plateau. The Tsessebe became extinct in Mozambique around the late 1970s or early 1980s (having once occurred in the south) (East 1999); there are plans to reintroduce them to Gorongosa N. P. In South Africa, a small population lives in the northern part of Kruger N. P., mostly north of the Letaba R. (see Conservation), and, as elsewhere in southern Africa, they have been reintroduced to many parts of their former range from which they were eliminated, including in Swaziland, where the indigenous population is extinct (East 1999; and see Cotterill 2003d).

Habitat *Damaliscus lunatus* is a flood-plain species: two of its local names mean ‘mud’, and all the major populations are centred on wetlands. The importance of flood-plains to this species is exemplified by the decline in the population living around L. Rukwa (Tanzania) when a rise in the water level caused a reduction in the area of the flood-plain (Vesey Fitzgerald 1960, Rodgers 1982). The Jonglei District area of the Sudan is the supreme example of a flood-plain population of *D. lunatus*, where about half a million animals migrate between the wetlands of the Sudd in the dry season and the woodlands, bushlands and grasslands to the east (Boma N. P.) and the south. This

population interacts, in ways yet to be studied, with very much smaller resident herds that live year-round in favourable pockets. The species is not as specialized as the Southern Lechwe *Kobus lechwe*, and can be found in a wide range of grasslands, bushlands and woodlands, though it does better in open grasslands (Yoaci & Van Orsdol 1981); it does not occur in forests, arid or montane habitats (above 1500 m).

Damaliscus lunatus uses catena ridges in the wet seasons and sumps in the dry seasons, tracking medium-height (10–20 cm sward surface), semi-mature grasses whose flowering heads are just beginning to appear. It uses regenerating grasses in flood-plains after fire to a greater extent than other species (Wisley 1996). Densities in the habitats available to *D. lunatus* are predictable from the structure of the grasslands, so abundance is strongly affected by rainfall, grazing pressure and fire (Duncan 1975).

The spatial scale of movements by *D. lunatus* during the annual cycle of habitat use is closely linked to the geographical scale of the catenary sequence. When this is hundreds of kilometres, as in S Sudan, the Tiang migration covers some 400 km (Hillman & Fryxell 1988). The Serengeti ecosystem, like most savannas, is dissected by streams and rivers, so the scale of the catena is much smaller. In the central woodlands, the annual foraging cycle from the ridges to the sumps of the catenas occurs within a few kilometres, and the home-ranges of Topis are only a few square kilometres in size. Between these extremes, in the larger-scale landscapes of the western Serengeti ecosystem (in the flood-plains of the Grumeti and Mbalageti rivers), the animals move over tens of kilometres between sumps and ridges, and home-ranges cover tens of square kilometres (Duncan 1975).

Adaptations *Damaliscus lunatus* is a fast-moving antelope, and Selous claimed that the Tsessebe and the Hartebeest were the most difficult antelopes to run down on horseback (cited in Estes 1991a). The species shows no particular adaptations to wetlands, like the elongated hooves of the Sitatunga *Tragelaphus spekii*. Its most striking feature is its glossy bloom, apparently an adaptation for thermoregulation, and the species has behavioural and physiological adaptations for water conservation (e.g. timing of feeding, resting posture, orientation of the long axis to reduce solar radiation, and water retention from faeces; Jarman 1973). Though water-dependent, animals can go for months without drinking in the dry season if they are feeding on growing grass. These adaptations may be the basis of the species' wide historical distribution in the often treeless plains of the Sahel and the S Sudan, where wildebeest do not occur at all.

Abundance This was perhaps the most abundant African antelope before it suffered a drastic collapse in numbers and range, particularly in West Africa (see Conservation). East (1999) estimated total current population numbers for the species as a whole (correcting for undercounting bias in aerial surveys) at around 300,000, comprising 3000 Korrigums, 75,000 Tiangs, 100,000 Coastal Topis, 93,000 Topis and 30,000 Tsessebes. The total for the Tiang included an estimated 50,000 animals in S Sudan, which East (1999) acknowledged could be a gross underestimate; recent aerial surveys carried out during the dry season of S Sudan in 2007 indicate a population exceeding 155,000 (Fay *et al.* 2007), a large reduction from the more than 350,000 animals estimated by Mefit-Babtie (1983) in the northern part of the Jonglei. Chardonnet (2004) revised the estimate of the global population of Korrigums to 1850–2650, with perhaps 800 in W–Arly–Pendjari

complex and 800–1600 in Waza N. P. in N Cameroon, and estimated the number of Tiangs in central Africa at 3200. Based on East (1999; Appendix 4), numbers of Bangweulu Tsessebe are ~3500.

Population densities vary greatly. High densities (up to 45 ind/km²) are found in flood-plain systems (e.g. in the Ishasha Plain, Jewell 1972; and in the western Serengeti, Duncan 1975). Densities in woodland and bushland habitats are lower, ca. 5/km² in the central woodlands of Serengeti N. P. (Duncan 1975). In the dystrophic savannas of southern Africa, Tsessebes are widespread but rare, with for instance <0.1/km² in the northern third of Kruger N. P. (Dunham *et al.* 2005).

Foraging and Food *Damaliscus lunatus* is nearly exclusively a grazer (99% of the rumen contents in Serengeti N. P., 98% in the Lamu District, Kenya, Duncan 1975; and see Gagnon & Chew 2000b). These observations are confirmed by studies involving stable carbon isotope analysis (Cerling *et al.* 2003, Sponheimer *et al.* 2003). *Damaliscus lunatus* uses a wide variety of species, from species of the family Cyperaceae in wetlands to short grass species on the high ground. Their principal grass species in the Masai Mara include *Themeda triandra*, *Cynodon dactylon* and *Sporobolus* spp. (Hansen *et al.* 1985). In the woodlands of Serengeti N. P., *Digitaria macroblephara* is an important species, and in the western corridor *Setaria sphacelata* and *Echinochloa haploclada* and the wetland *Panicum* spp. are important in the dry seasons (P. Duncan pers. obs.); here, Topis switch their preferences between grass species according to the changes in the plants' structure, particularly the lengths of their leaves (see below). Animals do occasionally browse a few plants, such as *Dicrostachys*, *Combretum* and *Scleeryocarya*.

Damaliscus lunatus is a green leaf specialist, and its narrow muzzle and incisor arcade allow it to feed very selectively. These animals are capable of extracting diets with 75% green leaf from senescent swards that contain only 12% green leaf (Duncan 1975, Murray & Brown 1993) and are thus able to extract diets from such swards with higher metabolizable energy than are wildebeest (Murray & Illius 2000). However, on short leafy swards (<5 cm), where bite sizes are small, they are not as able to compensate by increasing bite rates as are wildebeest, so they are unable to maintain high levels of food intake. On senescent swards where green leaf is sparse, they are less selective than Hartebeest (Murray & Brown 1993).

As a result of its highly selective feeding habits, *D. lunatus* may be particularly susceptible to competition from other grazers such as Common Wildebeest *Connochaetes taurinus*, African Buffalo *Syncerus caffer* and cattle. Common Wildebeest should achieve higher rates of grass intake on short green lawns since they have higher bite rates and broader mouths, allowing them to obtain their maintenance requirements from 2 cm high swards, 1 cm shorter than the minimum height for *D. lunatus* (Bell 1971, Murray & Brown 1993, Murray & Illius 2000). Common Wildebeest may, therefore, be able to exclude *D. lunatus* competitively. In the central woodlands of Serengeti N. P., the density of resident Topis dropped from 4.4/km² to 0.8/km² in a week when a large concentration of Common Wildebeest ate 90% of the grass, and the sward surface dropped from >50 cm to <5 cm (P. Duncan pers. obs.). They returned within a month, so the competition may have been for space, rather than for resources (Duncan 1975). Competition, during a period of low rainfall, has been suggested to be the cause of a 70% decline in the Tsessebe population of a 436 km² ranch in Zimbabwe (Dunham *et al.* 2003). Inter-specific, as well as intra-specific competition may be a process determining the abundance

of *D. lunatus* in ungulate communities where resources are limiting. Topis are virtually absent from the short-grass plains in the south-east of Serengeti N. P., the wet season concentration area of the migratory wildebeest, zebras and gazelles.

The ability of *D. lunatus* to use a wide range of habitats in this flexible manner means that in ecosystems with flood-plains, their food is of high quality throughout the year, so they maintain good body condition throughout the year, grow quickly and breed fast (see below).

Social and Reproductive Behaviour It was in Topi that it was first noted that antelope mating systems can be very variable within and between populations (Monfort-Braham 1975). In most of its range, the ♂♂, as in many antelopes, defend resource territories where ♀♀ come for food, water or shade. These are up to 1 km in diameter, and ♀♀ move across the boundaries of a number of territories in small groups of up to a dozen ♀♀ with their young. Non-territorial ♂♂ from one year of age associate in bachelor herds, which also move through the mosaic of territories, but are vigorously separated from ♀♀, especially oestrous ones, by the territorial ♂♂. In Tsesebees, bachelors have been observed to live in herds of 2–22 individuals in Zimbabwe (Grobler 1973), and 2–31 in N Botswana (average = 8; Child *et al.* 1972).

Territorial Topi ♂♂ mark their territories by static optic displays on vantage points, and as in other antelopes, they also mark their territories with scent using urine, faeces and glandular secretions (Gosling 1986). Rubbing their heads on the ground spreads the secretions of the preorbital glands on the ground, and in the wet season can leave the ♂♂ with large amounts of mud on their heads and horns. Large dung heaps are another obvious visual indicator of this olfactory marking (Gosling 1987). Males and ♀♀ have interdigital glands between their front hooves, and both sexes mark grass stems with secretion from their well-developed preorbital glands. When the culms have flower heads, the animals bite off the flowers and carefully lower their heads on to the culms, which enter the gland and emerge with about half a centimetre of sticky secretion clearly visible. The secretions of these glands in the Bontebok/Blesbok, and presumably in *D. lunatus* too, are chemically complex and show qualitative and quantitative differences between ♂♂ and ♀♀ in the preorbital, but not the interdigital, glands (Burger *et al.* 1999c). The richness of olfactory communication in this species contrasts with their meagre acoustic communication. Apart from the alarm snort and distress squeaks of young, the only vocalizations used by *D. lunatus* are 'quacking and grunting calls', as in Hartbeest (Estes 1991a).

Territorial defence involves dominance and threat displays – lateral presentation in erect posture, nodding/head-casting, horn-sweeping, cavorting, ground-horning and head-shaking. Fighting involves dash-fighting, ramming, front-pressing and twist-fighting. Defensive and submissive displays involve the head-in posture, head-low posture and lying-out (Estes 1991a). The most striking display is by territorial ♂♂, which adopt the erect posture and lift their heads almost to the horizontal, with their ears down and tail held stiffly and horizontally, while walking stiffly with the front legs lifted high. When trying to stop ♀♀ leaving their territories this display can be carried out at the gallop – impressive though that is to the observer, it does not detain a determined ♀♀ for long.

When the spatial scale of the catena is fine and a single ♂ can defend both wet and dry season habitat in his territory, a group of ♀♀ may

stay year-round on the territory. At such times, the mating system comprises a single ♂ and a harem of 5–8 ♀♀, which may stay together for years (Duncan 1975). Such a mating system is probably exceptional in the Serengeti ecosystem, but common in low-density populations (e.g. Kruger N. P.; Joubert 1972). In the high-density flood-plain populations, a few groups of up to 100 ♂♂ defend tiny territories, usually on a knoll. These territories are small, 50–100 m across, and ♀♀ come to the leks principally for mating (and for resting), since there are no other resources (such as water, shade or food) on these leks or 'breeding arenas'. Even the ♂♂ have to leave their territories to obtain their food. Such leks have been found in Akagera N. P. (Monfort-Braham 1975), the western Serengeti N. P. (Duncan 1975) and the Masai Mara (Gosling & Petrie 1990). A similar mating system was described in Queen Elizabeth N. P. (Uganda, Jewell 1972): on the 80 km² Ishasha Plain, most of the 3700 Topis moved about in one or two large herds. A temporary territorial system, with ♂♂ spaced at about 50 m intervals, was set up wherever the large herds were. The ♂♂ were not known individually, so whether a particular individual defended one or multiple areas is uncertain.

Around Topi leks are resource territories through which herds of up to 1500 Topis of all ages and both sexes move. Males on the central territories of the leks obtain more matings than ♂♂ on resource territories or on peripheral lek territories; the tenure of the ♂♂ on the central territories is short, and is measured in days compared with the tenure of ♂♂ on resource territories of weeks, months or years. 'Of all the diverse mammalian mating systems, leks are the most bizarre' (Clutton-Brock *et al.* 1993). Leks are found in birds, bats and in a few mammals, but are commonest in ungulates, where they have been found in Fallow Deer *Dama dama*, Sika Deer *Cervus nippon*, Southern Lechwe and Kobs *Kobus kob* as well as Topis (Clutton-Brock *et al.* 1993). This mating system raises three questions: why do oestrous ♀♀ leave their usual groups, why do they aggregate on leks and why do they collect on particular territories? In such high-density populations it is clearly not possible for a ♂ with a resource territory to separate an oestrous ♀♀ from the non-territorial ♂♂, and it is likely that this system allows oestrous ♀♀ to reduce harassment by ♂♂, as in some other high-density ungulate populations (Clutton-Brock *et al.* 1993; but see Bro-Jørgensen 2003b). It has also been suggested that female Topis choose certain territories for the quality of the ♂ ('hotshots', see Gosling & Petrie 1990, Bro-Jørgensen 2003a, Bro-Jørgensen & Durant 2003) and perhaps also for their ecological characteristics (resources and risk of predation, Balmford *et al.* 1992).

The highly synchronized rut in Topi is a good model to study interactions between the sexes. The rut lasts c. 1.5 months, when individual ♀♀ come into oestrus for roughly one day, mate with four ♂♂ on average (range 1–13), with c. 11 intromissions from each partner (Bro-Jørgensen 2007). Most ♀♀ mating with central lek ♂♂ also mate with other ♂♂, resulting in intense sperm competition. Although data on actual fitness consequences of the different tactics are not yet available, detailed studies have used this model system to show that male Topis use a wide range of tactics to keep oestrous ♀♀ on their territories for as long as possible, thereby securing mating opportunities. These tactics include threatening young calves, which then bleat and attract their mothers (Gosling *et al.* 1986), and active signal falsification, of alarm snorts, to deceptively retain receptive ♀♀ in their territories (Bro-Jørgensen & Pangle 2010). It has also been suggested that ♀♀ which mate

Courting ♂♂ approach ♀♀ in the high-stepping walk, with ears dropped and tail raised. *Damaliscus* spp., along with

dry-season birth season. In more mobile populations the young generally follow their mothers, though they may hide at night and

some ♀♀ may leave the large herds for some weeks around the birth (Estes 1991a).

Damaliscus lunatus in low-density populations commonly associate with other species, such as the Impala *Aepyceros melampus* and Common Wildebeest. The function of such multi-species groups is, as in primates, probably anti-predator.

Reproduction and Population Structure *Damaliscus lunatus* is usually a strictly seasonal breeder, with the young being born after an eight-month gestation period within just a couple of months, in the dry season (e.g. Feb–Mar in the Sudan, Hillman & Fryxell 1988; Aug–Nov in the Serengeti ecosystem, Duncan 1975 and DR Congo, Mertens 1985; Jul–Aug in Zambia's Northern Plateau, Ansell 1960a; and Sep–Dec in Zimbabwe, Botswana and South Africa, Fairall 1960, Child *et al.* 1972). This timing corresponds with the season when flood-plain populations are on the highest quality food, but the savanna populations are on poor-quality, senescent grass at this time. The breeding season can vary within a population: the Tana R. population had two peaks at nine-month intervals in 1973–74, and in the Virunga population the birth period was Sep–Nov in the 1970s, but Mar–May in the 1960s (Mertens 1985). Offspring were apparently born to all adult ♀♀ (>2 years old) each year in the Serengeti and Lamu populations, and to a very high proportion of the two-year-olds (about 80%, Duncan 1975). In Tsessebes, about 97% of adult ♀♀ have offspring; two-year-olds occasionally breed (Huntley 1972), but usually do not (Child *et al.* 1972, Dunham *et al.* 2004). Female Topis (but not Tsessebes), therefore, mate at an earlier age than Hartbeest (but not before the third year; Stanley Price 1978a); in Common Wildebeest the proportion of second-year animals mating varies with the abundance of resources (about 40% do when resources are abundant, 6% when they are not; Mduma *et al.* 1999).

Mothers give birth to a single young, and birth-weight is 10–12 kg in Tsessebes (Child *et al.* 1972). In Topis, the young get their black patches by three months, when their shoulder height is about half that of the adults; at six months their horns have one or two rings and are about 12 cm long. Their coat develops the chestnut colour of the adults by about one year, when their horns have 6/7 rings and are about 24 cm long (Mertens 1984). Tsessebe horns are about 20 cm long at 12 months, and ca. 30 cm at 18 months (Child *et al.* 1972, Huntley 1973, Anthony & Lightfoot 1984). Their sharp seasonal breeding season allows the ages of young animals to be determined easily by reference to the development of their teeth (see Fig. 5, Child *et al.* 1972, which is based on a sample of 82 individuals collected over three years).

Growth rates in Topis are fast, and ♀♀ can reach 70% of their adult weight at nine months when resources are abundant (Duncan 1975). In Tsessebes, data from N Botswana suggest that the ♀♀ grow more slowly, reach adult weight at three years and breed only then; the weight of the testes suggests that ♂♂ mature in time for the rut in their third year (40–42 months; Child *et al.* 1972). Sex ratios are female-biased, with adults (>1 year old) in Topis and Tsessebes consisting of only 30–40% ♂♂ (Mertens 1985, Monfort-Braham 1975, Dunham *et al.* 2005).

Data on the vital rates of *D. lunatus* populations are sparse. The only life-table is based on the ages of skulls found in Virunga N. P. (DR Congo), Rwenzori Mountains N. P. (Uganda) and Akagera N. P. (Rwanda). Ages were determined by tooth replacement and wear (Mertens 1984), assuming two cementum rings per year in

the roots of the M1 teeth. It seemed that virtually all the animals died before the age of seven years, apparently from predation and poaching, and the life expectancy at birth was calculated as 2.4 years for ♂♂, 2.3 years for ♀♀ (Mertens 1985). The life expectancy of Tsessebes in N Botswana, using an approximation, was calculated to be a little longer (3.0 years; Child *et al.* 1972). Even this value seems very low for animals of their size, and in a species that feeds on flood-plain grasslands the assumption of two cementum rings per year is a weak one that needs to be checked with animals of known ages. In captivity, the life-span of animals that live to three years is 8–9 years with no significant difference between ♂♂ and ♀♀ (see Bro-Jørgensen & Durant 2003); some animals have lived to 23–24 years of age (Weigl 2005). In some populations, survival rates must be higher, since in favourable circumstances Topi populations can grow fast. In the western Serengeti N. P. they increased after the eradication of rinderpest from about 10,000 to about 50,000 in the ten years between 1966 and 1976 (Sinclair 1995).

Few data are available on the limitation of *D. lunatus* populations. The Kruger N. P. Tsessebe population (South Africa) has declined and is close to extinction: survival rates of adults and juveniles have declined in the last 20 years. Low rainfall, in interaction with a density dependent effect on adult survival, may be responsible for the decline (Dunham *et al.* 2005; see also Owen-Smith & Mason 2005); inter-specific competition and predation may also be involved (see below).

Predators, Parasites and Parasites Though vulnerable to many predators (newborn animals can be killed by jackals *Canis* spp.; Estes 1991a), *D. lunatus* appears to suffer low predation rates compared with other species. For example, in the Savuti ecosystem (Botswana), Spotted Hyaenas *Crocuta crocuta* preferred Plains Zebra *Equus quagga* foals to Tsessebes when the migratory zebras were present, and preferred Impalas *Aepyceros melampus* to Tsessebes when the zebras were not (Cooper 1990). In the Serengeti–Mara system, Topis are an important, if not a preferred, prey of Lions *Panthera leo* and Spotted Hyaenas (Kruuk 1972, Schaller 1972, Cooper *et al.* 1999). None the less, it is likely that the Topis in the woodlands of the central part of Serengeti N. P. have been predator-limited (Sinclair 1995).

Cleaveland *et al.* (2005) isolated bovine tuberculosis, caused by *Mycobacterium bovis*, from one out of a sample of nine Topis sampled systematically in 2000 during a meat cropping programme in Serengeti N. P. Steinberg (1988) reported on Johne's disease (*Mycobacterium paratuberculosis*, also known as paratuberculosis) in a captive Topi. Anthrax was reported from Tiangs in S Sudan (Ramachandran *et al.* 1988). Tsessebes appear not to be susceptible to, or to carry, *Cowdria ruminantium* (the tick-borne causative agent of heartwater in domestic ruminants) either by infection from ticks or by injection (Peter *et al.* 1999), although Kock *et al.* (1995) obtained positive samples from healthy, free-ranging Tsessebes in Zimbabwe taken during translocation from areas harbouring *Amblyomma* ticks. Jardine (1992) reported on a natural, fatal case of theileriosis (cytauxzoonosis) in Tsessebes.

In Zambia, three Tsessebes sampled on a game ranch in Central Province had six species of ixodid ticks, including *Amblyomma variegatum*, *Boophilus decoloratus*, *Rhipicephalus appendiculatus*, *R. evertsi*, *R. kochi* and *R. lunulatus* (Zieger *et al.* 1998a). In addition, two trematode and cestode species were recovered (*Calicophoron* sp., *Avitelinea centripunctata*) and four species of nematodes (*Agriostomum cursoni*, *Dictyocaulus* sp., *Gaigeria pachysclis* and *Impalaia* sp.). Two species of botfly were also

recovered: *Gedoelestia cristata* and *Oestrus variolosus* (Zieger *et al.* 1998b). A single Tsessebe in Kruger N. P. harboured helminths from the genera *Haemonchus*, *Trichostrongylus*, *Longistongylus*, *Cooperia*, *Impalaia*, *Parabronema* and *Skrjabinema* (Boomker *et al.* 1986). The most prevalent and abundant nematodes recovered from Tsessebés shot at Nylsvley N. R. in South Africa were *Cooperia hungi*, *Impalaia tuberculata* and *Trichostrongylus falculatus*. The nematodes *Trichostrongylus colubriformis sensu lato*, *T. thomasi* and *Haemonchus bedfordi* and trematodes of the genus *Paramphistomum* were also present (Reinecke *et al.* 1988).

Conservation IUCN Category: Least Concern (*D. l. korrigum* – Vulnerable C1+2a(i); *D. l. topi* – Near Threatened; *D. l. jimela*, *D. l. lunatus*, *D. l. tiang*, *D. l. superstes* – Least Concern); CITES: Appendix III (Ghana).

The history of the West African Korrigum exemplifies the fragility of this highly productive species, which has been severely reduced by overhunting/poaching across all of its range, as well as by other threats such as competition with livestock and loss of habitat. Once ranging over at least 1 million km² from Senegal to W Chad, by 1979 it had been reduced to one population in Mali, and another of a few thousand individuals around the W–Arly–Pendjari complex (SE Burkina Faso, SW Niger, N Benin; Sayer 1982, East 1999). Although the population in Mali has since died out, Korrigums still survive in and around the W–Arly–Pendjari complex (800 animals). The largest population occurs in Burkina Faso, with the range comprising Arly Total Reserve, Pama Faunal Reserve, Singou Game Ranch, Madjoari Faunal Reserve, Wamou and Arly Hunting Areas, Kourtiagou Faunal Reserve, W N. P. and Tapoa Djerma Hunting Area. Movements to the west are restricted by the man-made L. Kompienga, and movements to the north are only possible during the rains (Jun–Sep), though no such movements have been seen for several years (Chardonnet 2004). In Niger, the range is entirely restricted to W N. P., while in Benin the main stronghold is Pendjari N. P. and adjacent hunting areas of Pandjari, Atakora and Konkombri (Chardonnet 2004). Korrigums also survived in a small population in N Togo in Keran N. P. in the late 1980s, though this population has probably since been exterminated (East 1999), and the only animals likely to occur in N Togo are vagrants from the W–Arly–Pendjari complex (Chardonnet 2004). Another small population was observed in NE Ghana in 1999 (J. Mason pers. comm.), but no further information is available on the status of this population. Elsewhere, Korrigums also still occur in N Cameroon, with their stronghold in Waza N. P. (where the population is estimated at between 800 and 1600, down from 20,000 in 1962) and in smaller numbers (ca. 250) in Bénoué and adjoining hunting zones (East 1999, Chardonnet 2004). From here vagrants move into neighbouring NE Nigeria (into Chugurma–Dugurmi N. P.) and Chad (Chardonnet 2004).

Around one-quarter of the population of Tiangs occurs in protected areas (East 1999), including: Zakouma N. P. and Salamata Faunal Reserve and Aouk hunting areas (Chad), Manovo–Gounda–St Floris N. P. (Central African Republic), Boma N. P. (Sudan), Omo and Mago National Parks (Ethiopia) and Sibilo N. P. (Kenya); however, while Zakouma N. P. has the largest population in central Africa (1300), the population in Manovo–Gounda–St Floris continues to decline. There is no information on their status in Dinder N. P. in Sudan, where they may now number no more than a few dozen individuals (Chardonnet 2004). The large surviving population in the Jonglei remains unprotected.

Most Coastal Topis occur outside of protected areas, but Boni and Dodori National Reserves (Kenya) represent an important stronghold for this subspecies. Elsewhere, Virunga N. P. (DR Congo), Queen Elizabeth N. P. (Uganda), Akagera N. P. (Rwanda), Masai Mara National Reserve (Kenya) and Serengeti N. P. (Tanzania) for Topis (more than 90% of which occur in protected areas), and Liuwa Plain (Zambia), the Okavango and Chobe N. P. (Botswana) and Kruger N. P. (South Africa) for Tsessebés (40% in protected areas), represent important strongholds for this species (East 1999). However, many of these populations have been declining in recent years, such as those in Queen Elizabeth and Virunga National Parks (East 1999). Numbers of animals in Akagera N. P., the last effective stronghold for the Topi in Rwanda, declined from around 7500 in 1990 to an estimated 770 in the late 1990s following the reduction in size of the park from 2500 km² to 732 km² in 1997 (Williams & Ntayombya 1999), although the population has since recovered (Apio & Wronski 2011). Even the population in Kruger N. P., among the best-protected areas on the continent, doubled from about 500 to 1000 between 1975 and 1986, and then declined to 220 in 1996 (Dunham *et al.* 2005), while numbers in Masai Mara National Reserve declined ~70% between 1977 and 2007 (Ogutu *et al.* 2011).

Bangweulu Tsessebés survive in good numbers in Bangweulu, and have been translocated to a number of private game ranches in Zambia (Cotterill 2003c). The latter author called for the translocation of a population to Kasanka N. P. east of the Luombwa R.

The species is a generalist in terms of habitat and food requirements. Provided it is not excessively hunted and suitable habitat is available, its fast growth and reproductive rates mean that numbers build up quickly in eutrophic savannas. In dystrophic savannas, the densities of Tsessebés are so low that very large areas are required to maintain viable populations. The species has been successfully (re)introduced to many areas with a wide range of ecological conditions in South Africa, such as Marakele and Pilanesberg National Parks (East 1999) and Itala G. R. in N KwaZulu–Natal (Rowe–Rowe 1994), Swaziland (Mkhaya G. R.; Monadjem 1998) and Namibia (Etosha N. P.; Van der Walt 1989), and to private land both in South Africa and in the northern farming districts of Namibia.

Measurements

Damaliscus lunatus

D. l. jimela

TL (♂ ♂): 2230 (2075–2355) mm, n = 30

TL (♀ ♀): 2090 (1965–2210) mm, n = 17

T (♂ ♂): 528 (400–585) mm, n = 30

T (♀ ♀): 464 (380–520) mm, n = 17

HF c.u. (♂ ♂): 502 (475–515) mm, n = 30

HF c.u. (♀ ♀): 477 (462–505) mm, n = 17

E (♂ ♂): 194 (185–205) mm, n = 30

E (♀ ♀): 182 (165–200) mm, n = 17

Sh. ht (♂ ♂): 1150 (1040–1260) mm, n = 30

Sh. ht (♀ ♀): 1130 (1050–1180) mm, n = 17

WT (♂ ♂): 130.0 (112.0–147.0) kg, n = 30

WT (♀ ♀): 109.0 (91.0–130.0) kg, n = 17

Serengeti N. P., Tanzania (Sachs 1967)

Maximum recorded horn length for *D. l. jimela* is 61.9 cm for a pair of horns from Bugungu, Uganda (Rowland Ward)

D. l. lunatus

TL (♂♂): 2160 (2070–2290) mm, n = 21

TL (♀♀): 2130 (1900–2260) mm, n = 45

T (♂♂): 450 (400–520) mm, n = 20

T (♀♀): 420 (360–510) mm, n = 44

E (♂♂): 1960 (1840–2060) mm, n = 21

E (♀♀): 1920 (1770–2090) mm, n = 46

Sh. ht (♂♂): 1260 (1160–1340) mm, n = 21

Sh. ht (♀♀): 1250 (1080–1320) mm, n = 44

WT (♀♀): 127.0 kg

WT (♂♂): 140.0 kg

N Botswana (Child *et al.* 1972)

Maximum recorded horn length for *D. l. lunatus* is 46.9 cm for a pair of horns from Angola

A pair of horns of *D. l. korrigum* from the Central African Republic measured 84.1 cm – the longest on record for the species; maximum recorded horn length for *D. l. tiang* is 67.3 cm for a pair of horns from Nyala, Sudan (Rowland Ward)

GENUS *Alcelaphus*

Hartebeest

Alcelaphus de Blainville, 1816. Bull. Sci. Soc. Philom., Paris 1816: 75.

The genus *Alcelaphus*, the Hartebeest, appeared in the fossil record less than a million years ago, with the earliest fossil record dated at ca. 740,000 years BP (Gentry 1978, Vrba 1995), and is thus the most recently evolved of antelopes.

Hartebeest are specialist grazers and quickly radiated across the entire African savanna from the Cape to Morocco, apparently outcompeting and replacing previous forms (including relatives of the now rare *Hirola Beatragus hunteri*). According to the most recent molecular phylogeny (Flagstad *et al.* 2001), early populations became restricted to two refugia, one north and one south of the Equator, perhaps separated by the expansion of the central African rainforest belt in a period of global warming about 500,000 years BP. The subsequent radiations from these refugia now comprise the two most distantly separated groups of taxa within the genus. These clades meet in STanzania where Coke's Hartebeest *A. buselaphus cokii*, whose range is mainly in Kenya and Tanzania, adjoins that of Lichtenstein's Hartebeest *A. b. lichtensteinii*, a form characteristic of the extensive miombo woodland of south-eastern Africa including Mozambique, Zambia and Zimbabwe. About 400,000 years BP the northern clade divided into an eastern clade, giving rise to the modern forms *cokii*, *swaynei*, *tora* and *lelwel*, and a western clade, yielding *major* and the extinct *buselaphus*. The southern group consists only of *caama* and *lichtensteinii*, which, in contrast to accounts that place *lichtensteinii* into a separate species or genus (Vrba 1979), appear to be closely related having diverged only about 200,000 years BP (Flagstad *et al.* 2001). There is considerable morphological variation within taxa and a number of intergrade forms, perhaps hybrids, indicating that the genus is still in a state of rapid evolution (at least until recent times).

Here, as an interim measure, we take the view that these eight recent taxa are subspecies of *Alcelaphus buselaphus*, a scheme that is essentially consistent with that adopted by Sclater & Thomas (1894), even though these authors regarded the taxa as species of the synonym *Bubalis*. However, the scheme adopted is provisional and important problems remain: more detail is needed of genetic structure within the eight taxa to extend the findings of Arctander *et al.* (1999) and Flagstad *et al.* (2001); the taxonomic position of the Hartebeest (probably *A. b. buselaphus*) that extended across North Africa and into the Middle-East needs to be confirmed. Are the

descendants of the northern and southern clades separate species (as suggested by Flagstad *et al.* 2001)? Do any other taxonomic divisions merit specific status? Further taxonomic studies are thus urgently needed and they will almost certainly result in important changes to our interim scheme.

This genus exemplifies a rare pan-African distribution for a large mammal, a fact that may be linked to some critical feeding adaptations. The key to the Hartebeest's success may be the ability to extract high-quality food from tall senile grass swards and to survive on relatively low intakes: Hartebeest use their long thin muzzle to extract leaf blade from dry swards (Murray 1993, Murray & Brown 1993) and can even nibble off leaf sheath from grass stems (Stanley Price 1974). These traits allow Hartebeest to feed successfully during the dry season, the most challenging time for grazing antelopes, and may have been the key that allowed Hartebeest to occupy such vast areas of grassland across Africa, over a wide variety of climatic regimes, and to displace preceding forms.

The long thin legs and face take a trend found in the Alcelaphini to an extreme. The long thin legs are probably an anti-predator adaptation in an animal that lives on the open plains, in grassland clearings or across grassland/woodland ecotones. Hartebeest are vulnerable to both coursing-predators such as African Wild Dogs *Lycaon pictus* and, particularly when they come to drink, to ambush-predators, such as Lions *Panthera leo*. Hartebeest are notably alert animals with highly developed brains (Oboussier 1970b) and can run for very long distances at a fast canter. The long thin muzzle is an adaptation to feeding selectively (*Alcelaphus* retains the typical bovid dentition of 32 teeth), but the high placement of the eyes allows grazing animals to monitor their surroundings even with the nose thrust into a tall sward.

Hartebeest have one of the most varied and complex horn shapes of the bovids and these define the main taxa – and the hybrids that sometimes occur between them. The horns are fighting weapons and their different parts are co-adapted with their often violent combat. There are three basic parts to the horn: (i) a base that protects the top of the head from the horns of an opponent, either by catching the horn in a narrow 'v' or by enlargement into a spatulate boss in the case of Lichtenstein's Hartebeest; (ii) an intermediate part, sometimes

Fossil skulls illustrate evolution of *Alcelaphus* 'horn-twist'. From left, *Parmularius*, *Rabaticeros* proto-*Alcelaphus*, Lelwel Hartbeest *Alcelaphus buselaphus lelwel*.

incurred, which catches and in some cases locks the opponent's horns; and (iii) sharp horn tips that are used to stab the opponent when its head has been forced to one side and that may sometimes inflict fatal wounds (Gosling 1975). The remarkable shapes that combine these functions were determined by an extraordinary rotation of the horns during evolutionary history, and particularly in the transition from a damaliscine ancestor via a fossil genus *Rabaticeros* (Gentry 1978, Kingdon 1982); the horns of this antelope first show the rotation that produced the remarkable horn structure of modern Hartbeest. In most taxa the horns are placed on top of a tall pedicel, which provides further protection as ♂♂ engage in violent 'clashes'; the exception is Lichtenstein's Hartbeest in which the spatulate base of the horns may provide a functional equivalent. 'Folded' bone around the squat pedicels in Lichtenstein's Hartbeest has been interpreted as evidence for their phylogenetic 'collapse' from a previously taller condition (Kingdon 1982).

Like most ungulates, the mating system of Hartbeest is shaped by the movements of ♀♀ in relation to vegetation quality and abundance and by female sociality; these factors determine the potential for polygyny or the number of ♀♀ that ♂♂ can potentially monopolize (Gosling 1986). In most areas ♂♂ solve the problem of access to ♀♀ by defending against other ♂♂ a part of the food

resource that ♀♀ need; in other words, resource-defence polygyny (Emlen & Oring 1977). Breeding ♂♂ spend much of their time in such territories and try to mate with and retain ♀♀ when they visit. When female densities are very low, and when they range over large areas, ♂♂ are forced to adopt another strategy: that of 'following' ♀♀ throughout their home-range.

While behaviour has been studied to a variable extent on particular subspecies, there has been no systematic attempt to compare details across the entire radiation. The information in hand suggests some basic similarity. For example, one of the most conspicuous displays is the 'head-in' posture of subordinate ♂♂ in which the chin is drawn in and the tail recurved while the ♂ utters juvenile 'quack' vocalizations and moves in an exaggerated high-stepping gait (Gosling 1975). This striking display occurs when subordinate ♂♂ are threatened by territorial ♂♂, and probably has an appeasement function. Exactly the same display occurs in Coke's Hartbeest and Red Hartbeest (L. M. Gosling pers. obs.), representatives of the northern and southern clades, respectively, which suggests that this display originated at least half a million years ago when, according to Flagstad *et al.* (2001), these taxa diverged.

L. Morris Gosling

Alcelaphus buselaphus HARTEBEEST

Fr. Bubale; Ger. Kuhantilope

Alcelaphus buselaphus (Pallas, 1766). Misc. Zool. p. 7. Morocco. No locality cited but the name is based on 'Le bubale' of Buffon, 'en Barbarie & dans toutes les parties septentrionales de l'Afrique', and on other sources. Restricted to Barbary by designation of the 'Vache de Barbarie' of Perrault as the lectotype (Ruxton & Schwarz 1929: 575), and further restricted to Morocco by Lydekker (1914: 5).

Taxonomy Hartbeest are exceptionally variable morphologically, particularly in horn shape and coat colour, and up to the time when the destructive impact of man interfered (within the last 200 years) they were still in a state of dynamic evolutionary change. Hybrid or intergrade populations are common, particularly in the regions between relatively homogeneous types, and, as a result, the taxonomy of the group has been confused, with numerous races and subspecies described (see Ansell 1972).

Our understanding of Hartbeest taxonomy has improved in recent years through molecular phylogenies based on variation in mitochondrial DNA sequences (Arctander *et al.* 1999, Flagstad *et al.* 2001). These authors have suggested three principal Hartbeest clades arising from three geographic refugia: a southern clade (*caama*, *lichtensteinii*), a western clade (*major*, *buselaphus*) and an eastern clade (*lelwel*, *cokii*, *swaynei*, *tora*). The eastern and western clades may have originated from an earlier, single northern clade. On

this evidence, *caama* is most closely related to *lichtensteinii* and should not be more closely allied to the East African forms as in some recent classifications; further, while *lichtensteinii* is clearly morphologically distinct from *caama* in many respects, molecular evidence (Matthee & Robinson 1999a) suggests that it should not be given separate specific or generic status (*Sigmoceros*), as had been argued previously (Roberts 1951, Vrba 1979, Meester *et al.* 1986, Grubb 1993c).

Further taxonomic investigation is needed, based on these recent findings, but, until this is available – and in contrast to the classification presented by Grubb (2005), who regards *caama*, *lichtensteinii* and *buselaphus* as distinct species – it seems most sensible to retain an interim scheme that recognizes eight subspecies (described below). While nomenclature and taxonomic level have changed in most cases, the subdivision of Hartbeest into eight main forms is consistent with the scheme adopted many years ago by Sclater & Thomas (1894). This has the advantage of allowing a coherent approach to

the Hartebeest adaptive radiation, although the main disadvantage of treating Hartebeest as one entity is that if the numbers of all the local forms are summed it suggests that Hartebeest are still quite abundant and leads to misplaced complacency about their conservation status. In fact, Hartebeest are declining rapidly almost everywhere (except in parts of southern Africa) and valuable local forms and 'hybrid' populations have disappeared (*buselaphus*, *nakurae*, possibly *tora*; see below) or are severely threatened (*swaynei*, *jacksoni*, *keniae*). Thus, it is important to emphasize the importance of local taxa and populations and the importance of conserving this variation (see Conservation).

Synonyms: *ambiguus*, *bangae*, *basengae*, *boselaphus*, *bubalinus*, *bubalis*, *cama*, *caama*, *cokei*, *cokii*, *cookei*, *deckenii*, *dieseneri*, *digglei*, *dorcas*, *evalensis*, *frommi*, *gendagendae*, *godonga*, *godowiusi*, *gombensis*, *gorongozae*, *grotei*, *hennigi*, *heufferi*, *heuglini*, *inkulanondo*, *insignis*, *invadens*, *jacksoni*, *janenschii*, *kangosa*, *keniae*, *konzi*, *lachrymalis*, *lademanni*, *lelwel*, *leucopymnus*, *leupolti*, *lichtensteinii*, *lindicus*, *luzarchei*, *major*, *matschiei*, *mauretanicus*, *modestus*, *montanus*, *munzneri*, *nakurae*, *neumanni*, *niediecki*, *niedieckianus*, *niedieki*, *noacki*, *obscurus*, *oscar*, *petersi*, *prittwitzii*, *rahatensis*, *rendalli*, *roosevelti*, *rothschildi*, *rowumae*, *rukwa*, *saadanicus*, *sabakiensis*, *schillingsi*, *schmitti*, *schusteri*, *schulzi*, *selbornei*, *senegalensis*, *senganus*, *shirensis*, *stierlingi*, *swaynei*, *tanae*, *tendagurucus*, *tora*, *tschadensis*, *tunisianus*, *ufipae*, *ugala*, *ulanga*, *ungonicus*, *ungoniensis*, *uwendensis*, *wiesei*, *wembaerensis*, *wintgensii*. Synonyms based on names of hybrids or integrades include: *digglei*, *keniae*, *kongoni*, *nakurae*, *neumanni*, *rahatensis*, *ritchii*, *rothschildi*. Chromosome number: $2n = 40$ (Hsu & Benirschke 1975, Robinson *et al.* 1991). Hybrids between *A. buselaphus* and *Damaliscus pygargus* are known and characterized by $2n = 39$ and are sterile (Robinson *et al.* 1991).

Description Medium-sized antelope with long and slender legs. Conspicuous hump over the shoulders is due to the long dorsal processes of the vertebrae in this region; it is sometimes stated, incorrectly, that the forelegs are longer than the hindlegs or that the vertebral column slopes. Hair of face, neck, back, sides and upperparts of limbs ranges from sandy-brown to deep red-brown in the Red Hartebeest *A. b. caama* to deep purplish tinge in Swayne's Hartebeest *A. b. swaynei*. Dark 'blaze' down front of face from horn-base to nose in more deeply coloured Red and Swayne's subspecies. There is typically a horizontal 'eyebrow' stripe of lighter, contrasting colour to that of face; for example, Coke's Hartebeest *A. b. cokii* has pale dun-coloured eyebrow on darker brown face and the Red Hartebeest has chestnut-brown eyebrow contrasting with its black 'blaze'. Inside of ear has black hairless pattern consisting of four radiating branches, surrounded by long white hair. All forms have whitish underparts, extending down back of legs, with pale rump below a line level with base of tail. Dark grey or black patches occur on shoulders and flanks of the Red Hartebeest and Swayne's Hartebeest, taxa that have been separated for a very long time. Occurrence of these striking patches together with deeply coloured pelage suggests action of more intense sexual selection in these two subspecies than in others. Patches are reminiscent of those in related alcelaphines, *Damaliscus lunatus* and Blesbok/Bontebok *Damaliscus pygargus*, and could thus reflect ancestral patterns. Tails generally covered with short pale hair with long tuft of black hair at end; the Red Hartebeest has thick black hair along entire length of tail. Both sexes have preorbital glands (larger in ♂♂); glands are very active in Lichtenstein's Hartebeest *A. b. lichtensteinii*,

Frontal view of Lichtenstein's Hartebeest *Alcelaphus buselaphus lichtensteinii* face.

which sometimes have a patch of secretion on their side that is left when they rub the side of the face on their own body (Dowsett 1966). Both sexes have large, active pedal glands with an anterior opening in the forefeet; Reiter *et al.* (2003) investigated the constituents of the interdigital secretion of the Red Hartebeest and identified 53 compounds. No inguinal glands. Males about 15% heavier than ♀♀ and neck and forequarters are more heavily muscled as an adaptation to fighting.

With the exception of Lichtenstein's Hartebeest, horns are supported on a sometimes heavy, bony pedicle that varies in height between subspecies and may vary individually in putative 'hybrid' zones. In Lichtenstein's Hartebeest, cross-sections of skulls suggest that the heavily 'bossed' horns of this form may represent the phylogenetic 'collapse' of a previously tall pedicel, such as is found in the closely related Red Hartebeest (Kingdon 1982). Like all alcelaphines, ♀♀ also have horns, although they are more slender and less angular than those of ♂♂. Horns are grey/black and their length ranges from 30–39 cm in *buselaphus* to 50–70 cm in *major* and *lelwel*; they have a thick basal portion, a sloped, deeply ridged (though less so in *lichtensteinii*), intermediate portion, and sharply pointed, smooth horn tips (see also Adaptations).

Geographic Variation

A. b. buselaphus (Bubal Hartebeest): North Africa, from Morocco to Israel. Extinct. The Bubal was the smallest subspecies. Pelage was uniform pale brown with pale underparts, but lacked the pale rump below the tail-base that occurs in all other subspecies. Horns had a 'U'-shaped appearance from the front, being similar to those of the Western Hartebeest.

A. b. major (Western Hartebeest or Kanki): West Africa, from Senegal, Gambia and Guinea to about Cameroon. A very large subspecies with golden or mid-brown pelage, lighter underparts and lighter rump; colour gradations are gradual and gives the impression of uniform brown colouration; pale eyebrow stripe and pale shape under the eye. Horns diverge from the base before curving upwards then backwards into long sharp horn tips; 'U'-shaped from the front (only the extinct Bubal shares this characteristic). Horns are unusual in leaving an area of unprotected skull between the base of the horns, suggesting that fighting in this subspecies may emphasize horn-locking and 'wrestling' rather than 'clashes' (see Adaptations below). This may also be the case in Lichtenstein's Hartebeest, and both subspecies also have a raised bump on the forehead, perhaps as an adaptation to this form of combat.

Western Hartebeest
Alcelaphus buselaphus major.

A. b. lelwel (including *jacksoni*) (Lelwel Hartebeest): SE Chad and N Central African Republic east to SE Ethiopia and south to N Kenya and NW Tanzania. A large subspecies with rich mid-brown pelage. No distinctive coat patterns. Has the usual pale underparts and rump (below the level of the tail-base). Horns have high 'V'-shaped appearance from front; set on a very tall pedicel, with sharp horn tips projecting backwards.

Lelwel Hartebeest
Alcelaphus buselaphus lelwel.

A. b. swaynei (Swaine's Hartebeest or Korkay): Rift Valley of Ethiopia; extinct in Somalia. Reddish-brown pelage, which becomes deep purplish-black in some adult ♂♂, particularly on the face, neck and sides. In the darkest ♂♂ the eyebrow stripe is lost except for a spot above each eye. Dark patches on flanks and shoulders. Horns resemble those of Coke's Hartebeest in having a bracket shape in front view, but the bends between the three sections of each horn are more rounded giving a lyrate shape and the horns are more widely spread.

Swaine's Hartebeest
Alcelaphus buselaphus swaynei.

Tora Hartbeest
Alcephalus buselaphus tora.

A. b. tora (Tora Hartbeest): NW Ethiopia and SW Eritrea, and adjacent parts of Sudan. Pelage reddish-ochre to fawn with pale rump. Horns rather like Swayne's Hartbeest, a lyrate and widely spread version of the basic bracket shape; base and mid-section form a flattened 'V' from the front.

Coke's Hartbeest
Alcephalus buselaphus cokii.

A. b. cokii (Coke's Hartbeest or Kongoni): S Kenya and N Tanzania. Pelage mid-brown, light underparts and pale rump; pale eyebrow stripe. Distinguished by bracket-shaped horns with almost right-angle bends in front view; divided into short vertical basal section, horizontal mid-section and backward-pointing sharp horn tips.

Lichtenstein's Hartbeest
Alcephalus buselaphus lichtensteinii.

A. b. lichtensteinii (Lichtenstein's Hartbeest or Nkonzi): miombo woodland regions of south-central Africa. A large subspecies with mid-brown pelage, light underparts and pale rump, sometimes almost white under the tail-base; darker brown 'saddle' along back to tail-base. Sometimes a narrow pale eyebrow stripe, but this is often absent; sometimes pale marks over and under each eye. The side of the body behind the shoulder often has a dark mark caused by rubbing of the preorbital gland. The lack of a pedicel is diagnostic amongst Hartbeest as is the distinct bump on the forehead (Western Hartbeest have a less prominent version of this structure). Horns are short and distinctive in having a spatulate basal section that protects the top of the skull with a hook-shaped mid-section.

A. b. caama (Red Hartebeest or Khama): southern Africa. Distinctive striking chestnut-brown pelage, black facial 'blaze' and dark patches on shoulders and flanks; some animals have 'saddle' of dark hair along the back as occurs in Lichtenstein's Hartebeest. Only Swayne's Hartebeest in Ethiopia has such striking colouration. Horns resemble those of the Lelwel Hartebeest with a high 'V' shape on a tall pedicel, but also have a slight double-bending reminiscent of Lichtenstein's Hartebeest.

Intergrade populations occur between *lelwel* and *cokii* (Kenya Hartebeest: *keniae*; extinct Nakuru Hartebeest: *nakurae*), and have been reported between *lelwel* and *swaynei* and between *lelwel* and *tora* (*neumanni*, *rothschildi*, *digglei*, *rahatensis*) (Ruxton & Schwarz 1929), but these may be less extensive than previously supposed and in some cases may represent clinal variation in the main forms (Bolton 1973); Yalden *et al.* (1984) believe that the Blue Nile may have been an effective barrier between *lelwel* and *tora*.

Similar Species

Damaliscus lunatus. Similar distribution to the Hartebeest, but never occurred in North Africa and is absent from south-west Africa. Characterized by simple, scimitar-shaped horns about the same length as the head that sweep backwards or, in the case of Tsessebe *D. l. lunatus*, slender bracket-shaped horns with rounded curves that lack the angular appearance of Hartebeest horns; they lack the presence of a pedicel supporting the horns. Pelage is generally deeper in colour than that of Hartebeest, being typically deep chestnut-brown with various patterns, including black shoulder patches in the Topi *D. l. jimela*; however, Swayne's Hartebeest and Red Hartebeest also have deep chestnut pelage and dark patches.

Beatragus hunteri. Restricted to NE Kenya, where the Hartebeest does not occur, and probably has been exterminated in S Somalia where it was once abundant. The Hirola is distinguished from the Hartebeest by its long, Impala-like, lyrate horns and the lack of a pedicel.

While adult species of the genus *Beatragus* and *Damaliscus* can be readily distinguished from adult Hartebeest, this is not necessarily the case for the young. For the first few months of life, before adult features such as the pedicel of Hartebeest start to appear, the young of these three genera are virtually indistinguishable, reflecting their close phylogenetic links. In contrast, the brown young of wildebeest *Connochaetes* spp., with their characteristic low head position, are quite distinct.

Distribution Hartebeest formerly ranged from North Africa and the Middle East throughout the savannas and grasslands of sub-Saharan Africa and the miombo woodlands of south-central Africa down to the tip of southern Africa, being absent from desert and forest, notably the Sahara and the western rainforest.

Historical Distribution In North Africa, the Bubal Hartebeest occurred in Morocco (Loggers *et al.* 1992, Aulagnier *et al.* 2001), the steppes of the Hauts Plateaux and nearby mountains in Algeria (Kowalski & Rzebik-Kowalska 1991, De Smet & Smith 2001), the mountains of S Tunisia (Smith *et al.* 2001), Libya (where knowledge of their former range is unclear; Hufnagl 1972, Khatibi & Mallon 2001), and parts of the Western Desert in Egypt (Osborn & Helmy 1980, Saleh 2001). Numerous hartebeest remains have been found in excavations

Red Hartebeest
Alcelaphus buselaphus caama.

of fossils in Egypt and the Middle East, especially Israel and Jordan, and these, together with illustrations of hartebeest in the tombs of ancient Egyptians, are assumed to be *A. b. buselaphus*. The precise former southern limits of distribution of the Bubal Hartebeest are not known (Ansell 1972).

The Western Hartebeest occurred in the savanna woodlands of West Africa, from S Senegal, E Gambia, Guinea-Bissau and N Guinea eastwards through SW Mali and N Côte d'Ivoire to N Cameroon and W Central African Republic and SW Chad (Grubb *et al.* 1998, East 1999).

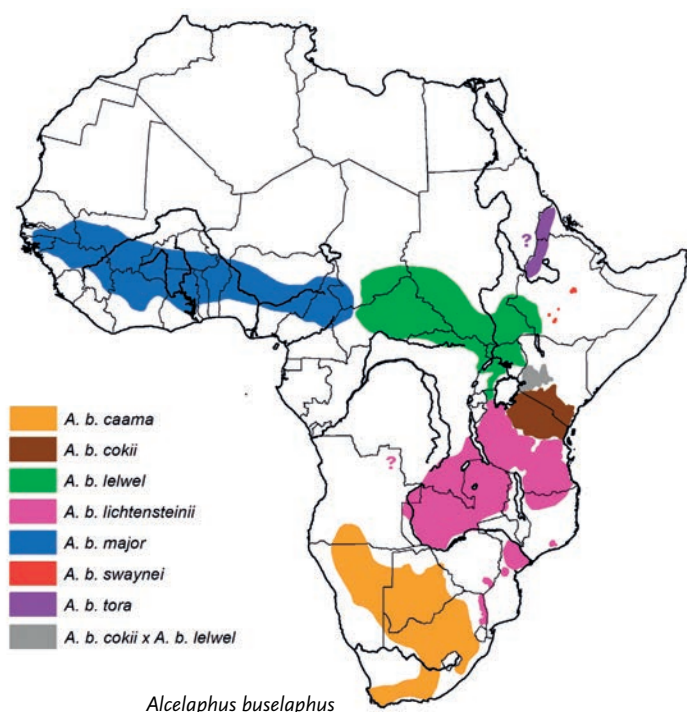

Tora Hartebeest formerly occurred in the western and south-western savannas of Eritrea, the north-western lowlands of Ethiopia and in the adjacent border regions of Sudan, while Swayne's Hartebeest occurred throughout the Rift Valley in Ethiopia into NW Somalia (Yalden *et al.* 1984, East 1999). Lelwel Hartebeest ranged from SC and SE Chad through N and E Central African Republic, SW and SE Sudan, the northern and north-eastern savannas of DR Congo, the south-western lowlands of Ethiopia, NW Kenya, much of N Uganda and extreme NW Tanzania. Coke's Hartebeest occurred widely throughout S Kenya and N and NE Tanzania (Stewart & Stewart 1963, East 1999).

Lichtenstein's Hartebeest formerly occurred widely in the miombo woodlands of south-central Africa, from W and S Tanzania, SE Burundi and SE DR Congo south to S Mozambique and NE South Africa (probably as far south as N KwaZulu-Natal; see discussion in Milstein 1989).

Except where they were replaced by Lichtenstein's Hartebeest (e.g. Mozambique, most of Zimbabwe, NE South Africa), Red Hartebeest occurred throughout much of southern Africa (with a marginal intrusion into S Angola near the Namibian border), except in the more arid regions of W Namibia and South Africa, and parts of N and E Botswana; they occurred only marginally in W Zimbabwe.

Current Distribution The range and numbers of Hartebeest have declined markedly and become increasingly fragmented, due to hunting, and the expansion of cultivation and livestock farming.

The Bubal Hartebeest is now extinct. The last report from SE Morocco was in 1945 (Panouse 1957), and the last animals were

shot between 1945 and 1954 in Algeria (De Smet 1989) and 1902 in Tunisia at the edge of the great Eastern Erg, south-west of Tataouine (Lavauden 1926b).

Western Hartebeest no longer occur in Gambia (though migrants may enter from Senegal), and have disappeared from much of their former range in this region, surviving mainly in and around protected areas; they are still reported to occur, albeit at low densities, in W N. P. in SW Niger (Hibert *et al.* 2004). Populations outside parks have generally declined, one well-documented example being the sharp decline outside Niokolo-Koba N. P. in Senegal (Galat-Luong & Galat 2001). They remain marginal or absent in extreme W Central African Republic and Chad.

There is limited recent information on the status of Tora Hartebeest, but they may survive in low numbers in the W and SW savannas of Eritrea and some inaccessible parts of Ethiopia (East 1999) although recent short surveys have failed to confirm their presence (Heckel *et al.* 2008, Heckel 2009); they are probably extinct in Sudan.

Swayne's Hartebeest survive in three isolated localities in the Southern Rift of Ethiopia, in Senkele Wildlife Sanctuary, Nechisar N. P., and the newly designated Mazie N. P. (East 1999, Flagstad *et al.* 2000, Refera 2005, Antonínová *et al.* 2008); they no longer occur in either Awash N. P. or Yavello Sanctuary (Antonínová *et al.* 2008). Swayne's Hartebeest is extinct outside Ethiopia.

Lelwel Hartebeest have undergone dramatic reductions in numbers, particularly in Uganda and Central African Republic, where they were once particularly abundant but are now reduced to a handful of protected areas; their status in NW Tanzania (around the Rumanyika Orugundu-Ibanda Arena Game Reserves) is not known.

Coke's Hartebeest have lost half of their former range in Tanzania, but populations still occur in Serengeti and Tarangire National Parks in Tanzania, and Tsavo N. P. and the Masai Mara National Reserve in Kenya (East 1999).

Lichtenstein's Hartebeest have been eliminated from many parts of their former range, and now occur mainly in wildlife areas in Tanzania, Mozambique and Zambia. In Zimbabwe, they remain confined to the south-east, while in Malawi they are largely or entirely restricted to Kasungu N. P. and Vwaza Marsh G. R.; the subspecies is extinct in Burundi, and probably in Angola (East 1999).

The range of Red Hartebeest was greatly reduced due to overhunting by European colonists, and they survived only in the Northern Cape Province of South Africa and in Namibia. They are now expanding again as they have been reintroduced into many protected areas and private game farms, and they have also been introduced outside their former range (e.g. to Swaziland in Malolotja N. R. and to private game farms in Zimbabwe). The Red Hartebeest remains extinct in Lesotho, while its current status in Angola is not known (East 1999).

Habitat Hartebeest are associated with grassland, but are rarely found in the centre of extensive grassland plains. In open areas, such as the grassland of Serengeti N. P. in Tanzania, they are typically found around the edge of woodland. When in woodland areas, such as the wooded savanna of West Africa or the miombo woodland of south-eastern Africa, they are typically associated with grassland clearings. They thus appear to be an edge or ecotone species (Booth 1985), generally avoiding more closed woodland. The remarkable variety of savanna habitats occupied, from woodland to the dry savannas of Ethiopia, vary substantially in primary production, climatic seasonality, habitat structure and openness (Bourlière 1983). Hartebeest body size varies in relation to differences in habitat primary production, such that subspecies in more productive habitats are significantly larger than those in less productive ones (Capellini & Gosling 2007). Throughout their range, Hartebeest are dependent on the availability of surface drinking water. They have been recorded at 3700–4000 m on Mt Kenya (Young & Evans 1993).

Hartebeest may be outcompeted in open grassland by specialized short-grass feeders such as Common Wildebeest *Connochaetes taurinus*. This relationship was illustrated by a 'natural experiment' in Nairobi N. P. in the 1960s. Before the 1962/63 drought, Common Wildebeest dominated the plains ungulate community and kept grassland in a short cropped form that was optimum for themselves and too short for Hartebeest. The severe 1960/61 drought reduced the Common Wildebeest population to low levels and the subsequent heavy rains in 1962 allowed grassland to increase to a height that Hartebeest could utilize more efficiently. Hartebeest thus increased in numbers and replaced Common Wildebeest as the dominant savanna ungulate (Gosling 1975). However, predation was also involved in this transition because Common Wildebeest were killed at a higher rate than expected from their relative numbers and this helped drive their numbers down. This situation persisted into the late 1960s when Hartebeest numbered around 1500 and wildebeest around 250 in the 144 km² area. In drier areas, with coarser grasses, Hartebeest may sometimes have dominated the central areas of grassland plains. Thus, in the Haut Plateau in N Somalia, Swayne observed that Hartebeest (of the subspecies that was subsequently named after him) literally covered the open plains; a dozen herds were in sight at one time with each herd consisting of 300–400 animals (shortly afterwards these herds were decimated by rinderpest [Hunt 1951], and Swayne's Hartebeest is now extinct

in Somalia). According to Lavauden (1926b), in North Africa the now extinct Bubal Hartebeest occurred in sub-desert steppe and semi-forested habitats, preferring rocky habitats to dunes (and see also Heim de Balsac 1936); however, by the start of the twentieth century, Bubal Hartebeest had been overhunted for centuries and may already have been forced away from their preferred habitat.

Abundance The most recent survey of Hartebeest abundance (East 1999) paints a picture of overall decline and fragmentation of the surviving populations, now mainly restricted to protected areas, many of which are poorly managed. An exception is the Red Hartebeest in southern Africa, which is currently increasing in numbers (see Conservation). The abundance of Hartebeest is best summarized with reference to the three main clades identified by Flagstad *et al.* (2001). The total number of the Western clade (*major*) is about 36,000 (correcting for undercounting bias in aerial surveys), but they are declining nearly everywhere because of illegal hunting. The more diverse Eastern clade (*lelwel*, *cokii*, *swaynei*, *tora* and intergrades) totals about 115,750 and is generally declining. Nearly all of this total consists of *Lelwel* (70,000) and *Coke's* (42,000) Hartebeest; *Tora* Hartebeest may already be extinct and both *Swayne's* (less than 800, with most in the Senkelle Sanctuary and Mazie N. P. in Ethiopia; Antonínová *et al.* 2008) and the Kenya (*cokii* × *lelwel*; 3500) Hartebeest are at dangerously low levels (East 1999). The *Lelwel* Hartebeest may have undergone a major decline since the 1980s, when total numbers were estimated to be >285,000, mainly in Central African Republic and S Sudan. Little information is available on its current status in Sudan, although recent survey work conducted in the dry season estimated totals of 1070 and 115 animals for Southern N. P. and Boma N. P., respectively (Fay *et al.* 2007); the latter is a significant decline from the >50,000 animals estimated in the dry season in 1980 by Fryxell (1980).

Lateral, palatal and dorsal views of skull of Lelwel Hartebeest *Alcelaphus buselaphus lelwel*.

Lichtenstein's Hartebeest in the southern clade totals about 82,000, with sizeable populations surviving only in Tanzania, particularly in the Selous ecosystem, and Zambia, in Kafue N. P. and the Luangwa Valley. The other member of the southern clade, the Red Hartebeest, totals about 130,000 and is increasing mainly due to reintroduction for consumptive use such as sport hunting.

The overall total for the species at the time of East's summary was about 360,000 animals. However, this total is strongly influenced by the contribution of the managed populations of Red Hartebeest in southern Africa. It is also a tiny proportion of historical numbers, and conceals the fact that Hartebeest are declining almost everywhere and that this rate of decline is accelerating with the increase in illegal hunting for the bushmeat trade. For example, Sournia & Dupuy (1990) gave the population of Western Hartebeest for the important Niokolo-Koba N. P. in Senegal as over 5000. When surveyed in 1990–93, the population was ca. 2325, and by 1994–98 it was ca. 1175 (A. Galat-Luong, G. Galat & M. Mbaye pers. comm.). Likewise, in Comoé N. P. in Côte d'Ivoire numbers declined by 60% from 18,300 in 1984 to an estimated 5200 in 1998 (Fischer & Linsenmair 2001a).

Densities of Hartebeest, like those of other African ungulates, must be considered with some reservations. Few populations are monitored sufficiently closely to know whether they are at carrying capacity. Many contemporary populations, including those in protected areas, are under severe hunting pressure or affected by fencing. While early explorer accounts were often exaggerated, few areas now seem even remotely close to the picture they gave of ungulate abundance. In addition, Hartebeest have specific habitat preferences and are never found at uniform densities across censused areas. With these caveats, Hartebeest density has been measured in a number of places: *Coke's* Hartebeest averaged 2.6/km² in the Athi/Kapiti plains in Kenya before the severe 1961 drought and 0.8/km² after it (Stewart & Zaphiro 1963); Western Hartebeest were recorded at 0.3/km² in 1990–93 and 0.01/km² in 1994–98 in Niokolo-Koba N. P. (Galat *et al.* 1998), 1.01/km² in Ali N. P., Upper Volta (Green 1979), 0.45/km² in Comoé N. P. (Fischer & Linsenmair 2001a), and 1.66/km² in Bénoué N. P., Cameroon; densities of Lichtenstein's range from 0.2 to 3.5/km² (Booth 1985).

Adaptations The skull of the Hartebeest is long and thin and the incisor row narrow (ca. 5 cm), probably as an adaptation to selective feeding. Hartebeest crop short green swards and green flushes that follow burning, when they are available, but they are most notably adapted to feeding selectively within medium and tall swards. The thin muzzle is pushed into the sward and is used to select grasses with a high proportion of leaf blade; Hartebeest can even nibble sheath from grasses that have had their leaves removed (Stanley Price 1978a, Murray & Brown 1993). This selectivity can be readily observed as Hartebeest lift their heads to look around while chewing (an anti-predator adaptation), often with the grass selected protruding from the mouth. Perhaps the most remarkable aspect of Hartebeest feeding is the ability to extract high-quality food from senescent swards (Murray & Brown 1993). Where Hartebeest and Roan Antelopes *Hippotragus equinus* overlap in West Africa, the two species graze on similar plants except in the driest time of year; at this point Roan Antelopes are forced to switch to browse while Hartebeest continue to feed on senescent grasses (Schuette *et al.* 1998). Hartebeest are thus particularly well adapted to survival in arid grasslands and in dry seasons and droughts.

Lateral, palatal and dorsal views of skull of Lichtenstein's Hartebeest
Alcelaphus buselaphus lichtensteinii.

The digestibility of dry matter and organic matter in the Hartebeest is higher, and the intake lower, than other alcelaphines (Arman & Hopcraft 1975, Stanley Price 1978a, Murray 1993). The combination of an ability to select high-quality components from senescent swards, coupled with low appetite and high digestive efficiency, could be the key suite of adaptations that allowed the Hartebeest to outcompete and replace more generalist alcelaphine precursors.

The horns and skulls of all male antelopes are adapted to fighting, but those of the Hartebeest show some unique features. They are also highly variable across Africa, probably reflecting different adaptations to fighting. In general, Hartebeest fight by pushing forward with the hindlegs into a horn 'clash', falling down onto their 'knees' as they do so. The horns meet with great violence and the 'bang' can be heard from hundreds of metres away. The horns then tend to interlock during 'wrestling' (see Social and Reproductive Behaviour), a phase of fighting in which animals push and twist their horns, trying to push the head of the opponent to one side. If they succeed, they disengage the horns and stab the face, neck and shoulder of the opponent with a backward hooking movement. Deep horn wounds are common in areas where competition is intense, and population densities high, and sometimes these wounds result in death (Gosling 1975).

Horns consist of three main sections: a finely ridged short but thick basal section, a deeply ridged middle section and a smooth, sharply pointed tip. Observation of fighting and wear facets on horns shows that the middle section is used to catch the blow of an opponent, and the sharp tip is for stabbing. The parts are angled so that the horns interlock during 'wrestling'. This angling has been achieved by rotational twisting and a complete reversal of the horns during a species-specific evolutionary development that is possibly reiterated during ontogenetic growth (Kingdon 1982); variations in this process are partly responsible for the characteristic variation in horn

shape across the different extant (and extinct) forms of Hartebeest. This angling reaches its most extreme in Lichtenstein's Hartebeest, where the middle-section and tip forms an incurved hook that catches the horns of the opponent and prevents it disengaging. In Coke's Hartebeest, the middle horn section is horizontal and catches the blow of an opponent above the head. In other Hartebeest, but at its most extreme in Lelwel's, the middle section is oblique and guides the horn of an opponent into the narrowing 'V' shape between the base of the horns, again stopping the blow above the head. In Lichtenstein's Hartebeest, the basal section is broad and spread over the top of the head to protect it. In all forms, except Lichtenstein's Hartebeest, the basal sections are set on a bony pedicel that again probably functions to extend the leverage and stop an opponent's horns well away from the brain. All of these structures are strong and heavy and designed to withstand heavy blows and violent 'wrestling'. Differences in fighting intensity between different Hartebeest taxa have not been quantified.

Hartebeest are renowned for their vigilance and for their speed and endurance. They can run at a fast canter for many kilometres and hunters report that they continue to run even when badly wounded. Presumably these traits were originally anti-predator adaptations in animals that live in open savanna environments (see Predators, Parasites and Diseases). However, their behaviour may also have been shaped by humans. The first Hartebeest appeared less than a million years BP in an area where stone tools made by successive *Homo* species have been abundant for 2.4 million years. The long dorsal processes probably function to support the powerful shoulder muscles and absorb the shocks of a fast prancing gait, but may also serve to increase the body surface in lateral displays to competitors and mates (see Social and Reproductive Behaviour).

Hartebeest thermoregulate by panting rather than sweating. In experiments to measure this response under natural solar radiation, Coke's Hartebeest started to pant at 32–34 °C; discounting the heat lost by re-radiation (80%) and convection, Hartebeest lose 61% of absorbed and metabolic heat by panting (Finch 1972). When individuals are hydrated, increased panting appeared to be a response to skin temperature but, when dehydrated (15% weight loss), the response was triggered at 39.5 °C by core (rectal) temperature (Finch & Robertshaw 1979). When dehydrated, Hartebeest thus accept an increase in body temperature in order to conserve water. Brain damage is presumably prevented, as in other antelopes, because blood that has been cooled by panting in the nasal mucosa removes heat from the blood entering the brain in the counter-current heat exchanger of the rete mirabile (Taylor 1969). These mechanisms allow a degree of water independence in the dry season. Under natural conditions, some Hartebeest seek shade to reduce exposure to solar radiation (Gosling 1975) and experiments (Finch 1972) confirm the physiological benefits. It is thus interesting that not all Hartebeest seek shade; some rest in the sun and some even stand on termitaria and other mounds in exposed positions. Perhaps this is because of the risks of predation from Lions *Panthera leo* and Cheetahs *Acinonyx jubatus* in areas where cover from trees and shrubs provides shade: Hartebeest might thus trade off the costs of thermoregulation against the risks of predation.

Foraging and Food Hartebeest feed mainly on grass (Stewart & Stewart 1970) and studies involving stable carbon isotope analysis

support field observation and faecal analysis in showing that they are almost exclusively grazers (Cerling *et al.* 2003, Sponheimer *et al.* 2003b). None the less, Hartbeest do browse, as evidenced by direct observations and the occurrence of browse in stomach contents (Van Zyl 1965, Wilson 1966c, Kok & Opperman 1975, Booth 1985; and see Gagnon & Chew 2000). Hartbeest feeding specializations may be the key to their explosive evolution that occurred at the expense of less-specialized grazing antelopes, notably the *Hirola Beatragus hunteri* and allies (Kingdon 1982). Hartbeest have long narrow noses and incisor rows that are adapted to feeding selectively within tall grass swards. They are particularly well adapted to taking bites with a high proportion of leaf blade from senescent swards and in feeding trials they rejected poor quality components of the diet at a higher frequency than wildebeest and Topis (Murray 1993). They can also scrape the leaf sheath off the stem in defoliated swards (Stanley Price 1974). Hartbeest cannot increase their bite size in taller swards and their intake rate is lower than that of Common Wildebeest and Topis (Murray 1993). Their low intake is probably because they have a lower metabolic rate than other extant alcelaphines and this, in combination with their ability to select a high quality diet and high digestibility (Arman & Hopcraft 1975, Murray 1993), gives them an important advantage in the dry season, a limiting time for many species. In the wet season they feed less selectively from short green flushes.

Seasonal changes in their feeding can follow a classic catenary sequence. In Nairobi N. P. they feed from short green grasses on the catena apex in the rains, then progressively shift to longer, coarser grasses in or near sumps as the dry season advances (Gosling 1975). This may be the basis of their ecotone habit (Lamprey 1973): they are ecologically poised to take advantage of a shift from one preferred food to another. Significantly, when the resource-defence territories of ♂♂ are subdivided between two competing ♂♂, the split generally occurs at right-angles to the grass zones within the original territory: each ♂ thus retains access to the full spectrum of seasonally optimum grass communities (Gosling 1975).

A number of ecologists have investigated the basis of possible niche separation between Hartbeest and other grazing ungulates. Bell and others (Gwynne & Bell 1968, Bell 1970) showed that grazing ungulates in Serengeti N. P., including Hartbeest, selected different plant parts from grass swards, and more recent feeding trials (Murray 1993, Murray & Brown 1993) suggest that specialization on particular growth stages of grass may be the fundamental reason why a diversity of grazers can co-exist. These specializations have a spatial dimension as well as a temporal one since tall dry swards can persist for longer in some areas than rapidly growing and more nutritious growth stages. Thus, Hartbeest can remain as residents when other alcelaphines such as wildebeest that are dependent on more ephemeral growth stages are forced to migrate to seek food elsewhere. This specialization also gives Hartbeest the ability to live in relatively arid grasslands and explains the fact that they extended further north, into Ethiopia, Eritrea, North Africa and the Middle East, in contrast to the more restricted distributions of the wildebeest and *D. lunatus*. However, they do not penetrate truly arid areas such as the Sahara. Their ability to extract a high-quality diet from senescent swards also gives them considerable commercial potential since they can exploit dry swards on a year-round basis more efficiently than any competitors, both alcelaphine or cattle.

The grass species eaten by Hartbeest have been documented in a number of studies using direct observation in the field and analysis of stomach contents and faeces. In Coke's Hartbeest in Tanzania, Lamprey (1973) found that grass occurred in the diet of Hartbeest at a frequency (96%) greater than in any other large herbivore in the area; 12 grass species were seen being eaten, the most common being *Cynodon dactylon*, *C. plechtostachyu* and *Cenchrus ciliaris*. In studies using faecal analysis in Kenya (Casebeer & Koss 1970, Stewart & Stewart 1971), the most common species detected were *Themeda triandra* and *Ischaemum afrum*. *Pennisetum mezianum* was avoided in the wet season although it was one of a number of grasses eaten at higher frequencies in the late dry season. Red Hartbeest also favour *T. triandra*, eating it throughout the year; other grasses eaten by this species in N South Africa include *Eragrostis* spp., *Panicum stapfianum*, *Cynodon dactylon*, *C. hirsutus* and *Sporobolus* spp. (Kok & Opperman 1975). Red Hartbeest are the only subspecies known to eat significant amounts of browse, but this only occurs in the dry season of particularly dry years (Skinner & Chimimba 2005). Swayne's Hartbeest appear to select grasses not only on the basis of nutrients, but also on water content and this may explain why they can survive in areas where no apparent free water is available (Matravers Messina 1993).

Daily activity patterns are similar to those of many other species of plains ungulates. At dawn in Kenya, a few Hartbeest are still lying at the end of a resting period. However, most are already grazing in medium or long grass areas and this activity predominates until the temperature rises in mid-morning and animals move to short grass areas where they rest. Early morning grazing may be particularly important for this water-dependent species, because grass is often wet with dew at this time. At the start of resting, often between 10:00 and 11:00h, many animals stand, sometimes in the shade of trees or shrubs and ruminate; as time goes on, progressively more lie down, so that by 13:00–16:00h most are resting in this way. As it cools at around 16:00h animals start to move towards long grass areas, grazing as they do so (Gosling 1975). This basic pattern of activity is similar in Red Hartbeest (Ben Shahar & Fairall 1987). In Coke's Hartbeest, grazing continues for one to two hours after sunset, when another resting period commences. There is at least one further grazing period before a resting phase just before dawn. However, activity at night needs further investigation. Movement to short grass areas during the day for resting seems likely to be an anti-predator adaptation, but the relationship between such movements at night and activity cycles is poorly known. Activity also varies seasonally with more grazing during the middle of the day in the rains (Gosling 1975).

Social and Reproductive Behaviour Like most of the plains antelopes, the primary determinant of the Hartbeest mating system appears to be the movements of ♀♀ in relation to food and water (Gosling 1986). Females invest most in offspring, particularly during pregnancy and lactation, and their ecology is thus shaped by selection to maximize nutrient intake for reproduction. There is no known post-natal care of their offspring by ♂♂. As noted already, ♀♀ have horns, and there is a moderate level of agonistic behaviour between adult ♀♀. This sometimes results in fights with violent horn contact and, as a result, a few ♀♀ are seen with broken horns. The context of agonistic behaviour between ♀♀ has not been studied

but it seems to occur when they come into close contact during drinking, earth-eating or feeding. One animal generally proves to be dominant in such encounters and the role of these dominance relations in mediating the access of ♀♀ to limiting resources is a priority for future study (for polygynous antelopes in general, as well as for Hartbeest). Sometimes ♀♀ seem to compete where no obvious resource is under dispute. For example, after rain, Red Hartbeest ♀♀ lie down and rub their face and neck in wet soil. Females engaged in this behaviour are sometimes approached and chased away by dominant animals (L. M. Gosling pers. obs.). Such behaviour seems linked to the establishment or reinforcement of dominance rather than to competition for a resource. The role of these dominance interactions in competition for access to mates is unknown (as is the existence of choice of mates, below).

Females aggregate into groups that are more or less well defined. These groups split and reform as ♀♀ move about the landscape and the only consistent associations are between a ♀ and her offspring. This association becomes looser as new calves are born. In Coke's Hartbeest, up to four successive offspring can sometimes be seen clustered with their mother and typically the distance from the mother to each offspring increases with its age.

The wide-scale movements of groups of ♀♀ are dictated by differences in the growth and persistence of different grass communities throughout the seasons and by movements during the day between resting and feeding locations. Hartbeest are water-dependent and, in the dry season, movements to permanent water sources become increasingly important. The savanna environment has a regular pattern of vegetation productivity in relation to rainfall and, in general, female movements are quite predictable. As a result, sedentary, 'sit-and-wait' mating strategies are a viable option for ♂♂ (Gosling 1986). Males compete to defend the areas that most ♀♀ visit and establish defended areas known as resource-defence territories; 38% of adult ♂♂ occupied territories in a three-year study of Coke's Hartbeest (Gosling 1975), indicating that an average of up to three ♂♂ may potentially compete for each territory. As a result of this competition, territories that attract most ♀♀ are smaller and tenure is shorter for their owners; lower-quality territories have fewer ♀♀, but they are held for longer periods (Gosling 1974). Territories provide a spatial reference for dominance, their owners being dominant over all other ♂♂ while in residence. This becomes particularly important during mating and, as far as is known, only territorial ♂♂ (or dominant ♂♂ that follow groups of ♀♀, see below) mate. When ♂♂ leave their territories, for example to drink, they are subordinate to ♂♂ resident in territories that they pass through. Males temporarily outside their territories are generally dominant over non-territorial ♂♂, although not always. The behavioural state of dominance in territorial ♂♂ thus appears to be under central nervous system control and can be turned on and off as they cross the boundary of their territory.

While Hartbeest do use the preorbital glands to some extent for marking objects in their territories, territories are scent-marked mainly by dung piles and these are particularly large at boundaries where resident ♂♂ interact with neighbouring territorial ♂♂; the interdigital secretion also probably plays a role in demarcation of territories (Reiter *et al.* 2003). Neighbours meet regularly in agonistic encounters, particularly where territories are relatively small. These encounters consist of much grooming (possibly to

avoid head-on orientations) and are marked by head-high postures with facing away. The focus of most encounters is ritualized scent-marking. Males sniff a dung pile, paw it, kneel, rub their head and horns, stand and defecate. The opponent then moves to the same position, noses the faecal pellets left by the preceding ♂ and repeats the actions. Repetitions of these sequences can go on for some time, sometimes with vigorous pawing that scatters the faeces and results in a depression at regularly used sites. In general, Hartbeest do not lie down in their dung piles during boundary encounters (in contrast to wildebeest) although they do lie on their own dung piles when resting (possibly a form of self-anointing with the odour used to mark their territory; Gosling 1982). Hartbeest break shrubs and dwarf trees such as *Acacia drepanolobium* with their horns then rub the surface of the preorbital gland on the end of broken branches; such marking sites are generally 1–3 cm in diameter (Gosling 1975). Males also 'self-anoint' by rubbing the secretion of the preorbital gland on their own sides leaving a distinct mark in the case of Lichtenstein's Hartbeest (Dowsett 1966). This area is sniffed and sometimes nibbled by opponents during agonistic encounters and these animals may be assessing their opponent (as a territory owner) by matching the smell on the pelage with that of scent marks in the territory (Gosling 1982). In the case of Lichtenstein's Hartbeest in Zimbabwe, self-marking increases in Sep just before the rut (Booth 1985); however, this behaviour occurs in all age and sex classes, which is curious and needs further investigation. Booth (1985) saw a territorial ♂ Lichtenstein's Hartbeest marking a ♀ on its rump just before mounting.

Horn contact behaviour usually starts with 'horn-tangling' (light butting and twisting against the opponent's horns). Serious fighting is generally absent during boundary encounters and also from most interactions with intruders. It occurs principally to determine ownership of a territory and at such times ♂♂ fight with great violence and are sometimes killed (see Adaptations); Dowsett (1966) reported one fight lasting more than an hour. Inter-individual body orientation is also very important in interactions between male Hartbeest. During encounters ♂♂ often orientate in the parallel or reverse parallel orientation. Encounters end with the ♂♂ gradually and reciprocally turning the head away after a period in the forward parallel orientation and eventually moving directly away from each other. They often graze at this point. Some interactions even consist almost entirely of two ♂♂ grazing next to each other ('grazing encounters') with subtle and reciprocated changes in body orientation.

Agonistic behaviour with intruding ♂♂ varies according to the dominance status of the intruder. Encounters with high status ♂♂ can contain many of the elements that occur between neighbouring territorial ♂♂, including escalation to horn contact. In rare cases, such interactions can escalate to full-blooded fights that become takeover attempts. However, the great majority of encounters with non-territorial ♂♂ end in the early flight of the intruder. Sometimes intruders simply turn and run as an owner approaches. Sometimes owners stand with the head erect and facing away. The intruder may then walk away with a lowered head. However, quite often the intruder approaches the owner and sniffs its cheek and neck, sometimes even nibbling down its neck. This behaviour ('neck-sliding') may function to smell the odour of the owner and test if it is the same animal that made the scent marks (dung piles) in the territory (the 'scent-

Hartebeest *Alcelaphus buselaphus*.

matching' hypothesis; Gosling 1982). Sometimes owners overtake the intruder as it walks or runs away and, turning in front of the retreating animal, perform a characteristic bucking lateral display: the intruder responds by a low head toss and accelerated withdrawal.

The bald fact that most breeding Hartebeest ♂♂ occupy resource-defence territories conceals a great deal of variation. In low and moderate population densities, territories are often large. For example, Dowsett (1966) recorded territories of 1.55–5.2 km² for Lichtenstein's Hartebeest in Zambia and Backhaus (1959) observed the behaviour of a Lelwel Hartebeest ♂ in a territory of at least 3 km². In both of these cases, small groups of ♀♀ remained for long periods within one territory; in Dowsett's study there were 1–9 ♀♀ in a sample of 11 such groups, while there were three ♀♀ in the group observed by Backhaus. In Uganda (Kidepo), several Lelwel ♀♀ were generally present in each male's territory (4–10 km²), but this female distribution pattern was very variable according to season and year due to massive emigration and immigration (J. Kingdon pers. comm.). At higher population densities, territories are much smaller. In a high-density population in Kenya, Coke's Hartebeest territories averaged 0.31 km² in a sample of 73 territories observed

over three years; territories in preferred ecotone habitats that attracted most ♀♀ were smaller than those in scrubland territories (Gosling 1974). In Nairobi N. P., at the time of these observations, ♀♀ had home-ranges of ca. 5 km² and these included 20–30 male territories. Female ranges may thus include from one (or a small number of territories) to over 30, a fact that must affect the potential for mate choice.

Some ♂♂ occur in quite dense clusters, particularly around short grass clearings (Gosling 1974: Coke's Hartebeest; Mattravers Messana 1993: Swayne's Hartebeest). In such cases ♂♂ rest on the short grass areas and also graze them intensively when green flushes occur after rainfall. However, Hartebeest are classic edge species and they graze into long grass areas in the evenings, and increasingly as the dry season progresses. These clusters of resource territories are sometimes so dense that it has been suspected that they might have similarities to a 'lek', an arena where clustered ♂♂ display and ♀♀ choose mates. However, the quality of the food supply is always critically important in attracting ♀♀ to such territories, and thus in the mating success of the male owners. Thus, while small, such territories should probably be regarded as resource territories; they

are not lek territories in the sense of the tiny territories on Topi leks. However, the clusters of territories found in Coke's and Swayne's Hartbeest would make it easier for ♀♀ to choose between territorial ♂♂; but variation in the degree of mating skew has not been measured.

Perhaps the best evidence for the role of sexual selection on male characteristics is sexual dimorphism in fighting structures (horns, pedicel and skull robustness). Not only do the sexes invest to a different extent in these traits, but the degree of difference between ♂♂ and ♀♀ varies across subspecies. This variation appears to be mainly a response to differences in the length of the breeding season. Species with shorter breeding seasons and thus a higher polygyny potential are relatively more dimorphic in horn dimensions, pedicel height and skull weight (Capellini & Gosling 2006). Sexual selection might also have favoured the occurrence of deep colouration together with other conspicuous patterns in the pelage of Red and Swayne's Hartbeest. There are indications that competition might be intense in these two subspecies with breeding restricted to a short annual breeding season in Red Hartbeest and restricted spatially in Swayne's Hartbeest in the territory clusters described by Mattravers Messana (1993). There may be enhanced male intra-sexual competition in both cases and, possibly, enhanced opportunities for female choice. However, more work is needed to fully explain variation in coat colouration, including the absence of conspicuous colouration in the two woodland subspecies, the Lichtenstein's Hartbeest and Western Hartbeest.

However, Hartbeest do show flexibility in male mating tactics: when they are at very low densities breeding ♂♂ follow groups of ♀♀ around their entire home-range. A well-authenticated case occurred in Amboseli N. P. where an individually known ♂ accompanied a group of ♀♀ throughout an 11 km² area (D. Western pers. comm.). Similar behaviour appeared to occur in Masai Mara National Reserve, where L. M. Gosling (pers. obs.) observed another low-density population in the late 1980s. 'Following' strategies may arise when resources are very unpredictable so that a ♂ is forced to follow ♀♀ in order to ensure that he is with them when they become receptive. However, neither Amboseli nor the Mara were particularly unpredictable habitats and it is more likely that a low density of ♀♀ and reduction in the level of competition between ♂♂ was critical in the appearance of following tactics. Males in resource-defence territories should generally win against following ♂♂ because of the benefits of owner advantage in a small scent-marked territory. Thus, 'following' can probably only succeed when there is a very low density of male competitors.

When ♀♀ enter a territory, ♂♂ stand at the boundary, circle behind them as they pass by and nose the vulva. Sometimes ♀♀ respond by urinating and ♂♂ sniff the urine as it falls and on the ground. However, remarkably (in view of its widespread occurrence amongst ungulates), Hartbeest do not show the oestrus testing display known as flehmen (a trait shared with *Damaliscus*). If ♀♀ are in oestrus, mating behaviour becomes prolonged. Again, body orientation is important: ♂♂ often stand in front of ♀♀ or even walk away from them to look intently at non-existent objects away from the ♀. These behaviours appear to be a subtle attempt to threaten the ♀ into stopping as she walks away but not to alarm her so that she starts to run. When near to the ♀ the ♂ employs the 'ear-down' posture with nose raised, ears down and the tail stiffly curved (Gosling

1974). In general, a ♀ can escape a male's attentions if she runs away quickly but if she is in oestrus, the ♂ will gallop hard to intercept her and bring her back, even if the ♀ has run into the neighbouring territory. When mating is in progress, neighbouring ♂♂ sometimes run into the territory and gallop at full speed through the group, trying to scatter it. This tactic presumably increases the chance that the oestrous ♀ will be displaced into its own territory. Copulation occurs repeatedly with the male's forelegs just in front of the female's haunches and the head dropped vertically over the female's shoulders. Most copulation in Coke's Hartbeest appears to be around mid-day, perhaps as an anti-predator adaptation since mating animals must be very vulnerable; Hartbeest are generally resting in short grass areas at mid-day and predators are usually inactive.

Parturient ♀♀ usually isolate themselves and retire to scrubland to give birth. Female Coke's Hartbeest eat the afterbirth and the calf stands about 30 min after birth (Gosling 1969a), considerably slower than wildebeest, which are more vulnerable in an open habitat. Young hide in long vegetation for about two weeks after birth (lying-out), emerging only to be suckled and for their mother to consume their urine and faeces; presumably this removes odours that might attract mammalian predators. Such hiding behaviour also occurs in Lichtenstein's Hartbeest (Mitchell 1965, Ansell 1970) and Red Hartbeest (Kok 1975). Variation in development of the young and lying out behaviour require more detailed study. It might be predicted that Hartbeest with a more synchronized calving period, such as Red Hartbeest, would stand more quickly after birth, if, as is believed, such calving distributions are shaped by predation pressure.

Males that fail to occupy resource territories live in groups. Males join male groups from about ten months of age up to two or three years of age. This timing depends partly on when they are separated from their mothers and thus, to some extent, on when the mother has further offspring. The mother keeps previous offspring further away from a new calf and, in the case of ♂♂, this makes the offspring more exposed to aggression from the territorial ♂. Further, when a young ♂ is chased away by a territorial ♂, the mother is more likely to intervene and to flee with it if the ♂ is her only offspring. Once young ♂♂ are separated from their mothers, territorial ♂♂ chase them with exceptional severity and try to horn them as they flee. As a result young ♂♂ are sometimes found isolated and are sometimes injured. When young ♂♂ join male groups they may also be chased by adult members of the group; as a result they sometimes cluster with other young ♂♂ in subgroups at the edge of groups of older ♂♂.

Such 'male groups' (sometimes called bachelor herds) comprise about 62% of the adult male population in Coke's Hartbeest (Gosling 1975). They occupy areas outside territories or, more usually, little-used parts of territories. It is not economically possible for territorial ♂♂ to keep all parts of their large territories free of non-territorial ♂♂. Rather, they tend to chase any intruder that comes too close to them, wherever they might be in their territory. Active defence is also more likely during cooler times of the day. References in the literature to male groups defending territories are certainly an error: single high-status non-territorial ♂♂ may sometimes establish a small temporary territory, but groups never do so. Groups of non-territorial ♂♂ vary in size from one to over a hundred individuals. Single non-territorial ♂♂ are common (particularly when high status ♂♂ isolate to try to find a vacant territory) and so it is impossible

to tell if a lone adult ♂ is territorial or not without observing its behaviour, preferably for a number of days.

By far the most common social behaviour in male groups is agonistic behaviour and ♂♂ form dominance relationships. When they reach high dominance status they leave the groups and wander about looking for vacant territories. If they have previously held a territory they return to the same area and sometimes succeed in taking it back, or in taking over an adjacent territory. Sometimes they occupy a territory when the owner is temporarily away, for example to drink, and an ownership contest occurs when the owner returns. Fights for territory ownership are by far the most severe type of contest. They consist of repeated violent clashes and often result in severe injury and sometimes in death. When a ♂ is defeated it may be pursued for several kilometres.

There are few vocalizations. The most distinctive is the 'quack'-like sound made by young calves. Significantly, the same call is produced by half-grown or young adult ♂♂ when they show the subordinate 'head-in' posture as they move away or flee from approaches or aggression by a territorial ♂ (Gosling 1974). The alarm snort is used in anti-predator contexts (below).

Reproduction and Population Structure The seasonal distribution of reproduction varies between different parts of Africa and appears to be adapted to seasonal patterns of rainfall/primary production. In Nairobi N. P., where there are two seasons of rains, there are two peaks of calving by Coke's Hartebeest. These peaks occur before the two seasons of rain so that the late phases of lactation, when ♀♀ need most food, coincide with the production of fresh green grass. This grass is also available as the young start to wean and it is not clear which of these two events is most important for this timing. Where there is only one season of rain there is only one breeding season. Thus, Lichtenstein's Hartebeest calve from Jul–Sep in Zambia, Mozambique and Zimbabwe (Ansell 1960a, Mitchell 1965, Wilson 1966c, Booth 1985), although Ansell (1960a) gives a season of Oct–Nov for the low-lying Luangwa Valley. In Namibia, there is a corresponding unimodal pattern of calving for Red Hartebeest with a peak in Nov and Dec, a month or two before the start of the rains (L. M. Gosling pers. obs.).

In Coke's Hartebeest, the seasons of calving are quite widely spread, reflecting the distribution of rainfall (Gosling 1969a). Thus, it seems likely that selection for the timing of mating reflects the timing of water-dependent primary production. However, in the case of Red Hartebeest in Namibia the calving peak is considerably sharper than that of rainfall. The general reason for sharp calving peaks is probably that young born outside the peak are more likely to be killed by predators so that natural selection favours calving within the peak (Estes 1966, Gosling 1969a). Coke's Hartebeest may be free of this constraint because young hide alone in long grass for the first two weeks of life (Gosling 1969a) and thus rely on crypsis rather than on saturating predation pressure. Under such circumstances, there could even be advantages in producing young when there are few others about to avoid the formation of 'prey images' by predators such as baboons and hyaenas. It is not entirely clear why Red and Lichtenstein's Hartebeest have such sharp calving peaks, but perhaps young rely to a lesser extent on crypsis; like Coke's Hartebeest, Lichtenstein's Hartebeest calves hide after birth (Ansell 1970), but duration and variation have not been quantified.

TOP: Coke's Hartebeest *Alcelaphus buselaphus cokii* horn development (from Gosling 1975)

ABOVE: Lelwel Hartebeest *A. b. lelwel* horn development (courtesy of J. Bindernagel pers. comm.).

Gestation is about eight months (Skinner *et al.* 1973). A single calf is born weighing about 15 kg (Wilson 1966c). Calves are weaned at about 7–8 months of age (Kok 1975). Most Hartebeest ♀♀ probably conceive for the first time between 15 months and two years old, although this may depend on condition due to variation in grassland production. Lichtenstein's Hartebeest ♀♀ are sexually mature at 16–18 months (Mitchell 1965, Wilson 1966c) and Red Hartebeest at 28 months (Skinner *et al.* 1973). Physiological maturity in ♂♂ may also be reached at about 18 months; ♂♂ of around this age have been seen crouching and ejaculating after sniffing or attempting to mount ♀♀ (Gosling 1975). However, ♂♂ do not mate until they have acquired a territory, probably not before three years of age, at least in moderate- to high-density populations. It is possible that territories are acquired earlier in low-density populations where male intra-sexual competition is lower, but there are no data.

Like most of the plains antelopes, Hartebeest generally have an adult sex ratio biased towards ♀♀. In Coke's Hartebeest, while the ratio at birth does not differ from unity ♂♂ comprise only 42% of adults (over 20 months old). The main cause of this difference is mortality indirectly caused by male competition. In particular, young ♂♂ chased away from their mothers by territorial ♂♂, and old ♂♂, excluded from high-quality territories, are often injured and isolated in scrubland. Such animals are vulnerable to predation, particularly by Lions (Gosling 1974).

A life-table, based on a sample of aged skulls from natural mortality in a population of Coke's Hartebeest, shows a typical mammalian pattern with high mortality over the first two years of life, relatively low annual mortality up to six years, and then accelerating mortality up to 12 years; ♀♀ outnumber ♂♂ in the oldest year classes and some probably live up to about 15 years (Gosling 1974, 1975). Weigl (2005) gives longevity record as 22–23 years in captivity, and Flower (1931) reports 19 years for a Bubal Hartebeest.

Predators, Parasites and Diseases Lions are the main predators of adult Hartebeest (Mitchell *et al.* 1965, Schaller 1972, Gosling

1975). Adults are occasionally killed by Cheetahs, although the only case confirmed in a long-term study of Coke's Hartebeest was an instance of four Cheetah ♂♂ hunting together (L. M. Gosling pers. obs.); Cheetahs do, however, kill large numbers of calves. Leopards *Panthera pardus* are known to kill calves in Serengeti N. P. (Bertram 1979) and probably kill small numbers throughout the species' range. The alert response of adult Hartebeest ♀♀ to jackals *Canis* spp. and baboons *Papio* spp. suggest that they kill very young calves. Adult and juvenile Hartebeest are also hunted and killed by Spotted Hyenas *Crocuta crocuta* (Kruuk 1972, Mills 1990, Di Silvestre *et al.* 2000) and African Wild Dogs *Lycaon pictus* (Creel & Creel 1995).

Predation on Hartebeest may be affected by the abundance of alternative prey. In Serengeti N. P., when migratory ungulates, such as Common Wildebeest and Plains Zebras *Equus quagga*, move into an area, Lions feed mainly on the migrants and pressure on resident species, including Hartebeest, is temporarily reduced (Bertram 1979). Hartebeest are extremely vigilant and respond to predators, particularly Lions, at great distances. When alarmed, Hartebeest face the predator directly with the head at maximum elevation, the nose drawn in and the ears directed forwards. They seek any rise in the ground to obtain a better view. At intervals related to the apparent level of danger, they make characteristic loud snorts by rapidly forcing air through the nostrils. They may approach and even follow a moving predator such as a Lion or Cheetah to keep it in sight and thus under sensory control. Hartebeest respond sensitively to the alarm behaviour of other nearby animals. Gosling (1975) observed an isolated territorial ♂ in scrubland respond to its neighbour's alarm snorting by snorting itself and adopting the same body orientation, even though it could not see the predator (a Lion) that the first animal had detected. The main function of belonging to groups is probably due to the benefits of selfish-herd membership (detection and dilution effects). When disturbed by predators, lone territorial ♂♂ in scrubland move closer to each other. Members of other species, for example wildebeest, sometimes take advantage of the extreme vigilance of Hartebeest by seeking refuge within Hartebeest groups when predators are detected. Flight distances appear to be related to vulnerability. In a group watching a predator, ♀♀ with young calves keep to the rear of the group and are usually the first to flee, running straight away from the back of the group. Active defence against predators is rare although young Hartebeest ♂♂ have been seen attacking Black-backed Jackals *Canis mesomales* after the jackals had killed a young gazelle (L. M. Gosling pers. obs.).

Hartebeest carry a large number of disease organisms, but there are few records of them showing any clinical symptoms of disease. Large-scale mortality may instead be generally due to starvation when food resources are exhausted within range of permanent water; examples include the die-off of Coke's Hartebeest in 1973 in Nairobi N. P. in Kenya (Hillman & Hillman 1977) and of Red Hartebeest in the Kalahari in 1985 (Knight 1995a).

Hartebeest generally have low susceptibility to rinderpest virus infection (Plowright 1982). For example, in the great pandemic of 1889–97, while *Damaliscus* spp. amongst other antelopes died in large numbers, Red Hartebeest were relatively unaffected (Scott 1970). However, sometimes Hartebeest were severely affected by rinderpest, as in the case of Swayne's Hartebeest in Somalia in 1897 (Simon 1962) and the Western Hartebeest in 1913–17 (Pecaud 1924, in Plowright 1982). Hartebeest typically live at lower

density than the most susceptible species (African Buffalo *Syncerus caffer* and wildebeest) and it would be interesting to know how far density explains this variation: Swayne's Hartebeest were known to reach high densities on open grassland before their numbers were reduced by overhunting. Antibodies have also been detected against bluetongue virus in Western Hartebeest (Formenty *et al.* 1994) and Red Hartebeest (Simpson 1978), against bovine ephemeral fever in Coke's Hartebeest (Devies *et al.* 1975) and bovine virus diarrhoea in Lichtenstein's Hartebeest (Anderson & Rowe 1998). Alcelaphine herpes virus-2 has been identified in a number of subspecies; it is closely related to alcelaphine herpes virus-1, which is carried by wildebeest and causes malignant catarrhal fever (Reid *et al.* 1975, Seal *et al.* 1989) but has not been linked to clinical MCF in Hartebeest.

Hartebeest have relatively low susceptibility to the anthrax bacillus, but they do die in moderate numbers when infected; examples are the 1999 and 2000 outbreaks in Mago N. P., Ethiopia, involving Lelwel Hartebeest (Shiferaw *et al.* 2002). The haemoprotezoan *Theileria* sp. has been isolated from the serum and from ticks carried by Red Hartebeest (Spitalska *et al.* 2005), but there were no clinical signs of theileriosis. *Trypanosoma brucei*, the protozoan parasite that causes African sleeping sickness, has been detected in Western (Jamonneau *et al.* 2003) and Coke's (Geigy & Kaufmann 1973) Hartebeest. However, Hartebeest are not favoured by tsetse flies (*Glossina* spp.) and were not detected as hosts in a sample of 13,145 blood meals collected throughout Africa (Clausen *et al.* 1998).

Most, perhaps all, adult Hartebeest carry a moderate number of ticks, including *Amblyomma* spp., *Boophilus* spp., *Haemaphysalis aciculifer*, *Hyalomma truncatum* and *Rhipicephalus* spp. (Hoogstraal 1956, Matthyse & Colbo 1987, Walker *et al.* 2000, Ntiamoa-Baidu *et al.* 2005). These are vectors of a number of viral diseases (see below and an overview in Walker *et al.* 2003). Ticks sometimes occur in clusters, notably around the edges of the ears. Records of the infestation of various wild bovid hosts suggest that Hartebeest are remarkably free of ticks compared with such species as Impala *Aepyceros melampus*, wildebeest and African Buffalo (Walker *et al.* 2000). This finding is supported by studies of the numbers of ticks per individual in relation to body size, which show that Hartebeest carry less ticks and have a smaller proportion of engorged ticks than would be expected (Olubayo *et al.* 1993). This may be linked to effective grooming with the incisors and hindfeet and also to their relatively open habitat. Oxpeckers *Buphagus* spp. rarely feed on Hartebeest. In a study of Coke's Hartebeest, oxpeckers sometimes attempted to land, but were nearly always immediately driven away (L. M. Gosling pers. obs.); in another study that included Coke's Hartebeest, none was seen feeding (Koenig 1997). The low incidence of ticks means that Hartebeest are probably little affected by tick parasitosis (direct damage due to wounds and blood loss). Hartebeest are sometimes infected by *Sarcoptes scabiei*, the mite causing sarcoptic mange (Pence & Uekermann 2002).

Gastrointestinal parasites of Hartebeest include helminths and nematodes (e.g. Bindernagel 1972, Boomker *et al.* 2000). Nematode faecal egg counts of Hartebeest in N Kenya were higher in drought years than non-drought years (Ezenwa 2004b), possibly due to nutritional stress.

Most adult Hartebeest appear to be infested with nasal botfly larvae, including those of *Oestrus ovis* (Howard 1977, Wetzel 1984, Mbassa 1986). These flies lay eggs in the nose and the larvae migrate upwards into the nasal cavity. L. M. Gosling (pers. obs.) once saw

a Coke's Hartbeest ♂ in Nairobi N. P. sneeze out a larvae and on inspection it proved to be *O. ovis*. Some individuals contain large numbers of these larvae and in necropsy of a Red Hartbeest ♂ in Namibia, L. M. Gosling (pers. obs.) was able to confirm that these penetrate even into the cavity of the pedicel. It is sometimes said that the larvae penetrate the brain, but evidence is lacking. Hartbeest sometimes sneeze unexpectedly and this could be a response to botfly larvae; the alarm snort is similar but is accompanied by alert behaviour, focused on a predator.

Conservation IUCN Category: Least Concern (*A. b. buselaphus* – Extinct; *A. b. cokii* – Least Concern; *A. b. lelwel* – Endangered A2acd; *A. b. swaynei* – Endangered C2a(i); *A. b. tora* – Critically Endangered C2a(i); *A. b. major* – Near Threatened; *A. b. lichtensteinii* – Least Concern; *A. b. caama* – Least Concern). CITES: Not listed.

The feeding habits of Hartbeest bring them into direct conflict with grass-eating livestock and, as numbers of livestock have increased, Hartbeest numbers have declined everywhere except in a few protected areas. Hartbeest also are valued for their high-quality meat and as the bushmeat trade escalates out of control, partly fuelled by the increase in modern guns, many Hartbeest populations are being hunted to extinction. Hartbeest are thus declining in most parts of their range and are now rare outside protected areas, many of which are too small to support viable populations.

Protected areas holding important populations of Hartbeest include: Niokolo-Koba N. P. (Senegal), although this population declined by half in the 1990s alone (Galat *et al.* 1998); Comoé N. P. (Côte d'Ivoire), Mole and Digya National Parks (Ghana) and Pendjari N. P. (Benin) for Western Hartbeest; Zakouma N. P. (Chad), Manovo-Gounda-St Floris N. P. (Central African Republic), Southern N. P. (Sudan), Mago N. P. and surrounds (Ethiopia) and Murchison Falls N. P. (Uganda) for Lelwel Hartbeest; Mazie N. P. and Senkelle Wildlife Sanctuary (Ethiopia) for Swayne's Hartbeest; Tsavo N. P. and Masai Mara National Reserve (Kenya) and Serengeti and Tarangire National Parks (Tanzania) for Coke's Hartbeest; the Selous ecosystem and Ruaha-Rungwa-Kisigo complex (Tanzania), Kafue N. P. and Luangwa Valley (Zambia), and Niassa G. R. (Mozambique) for Lichtenstein's Hartbeest; and, for Red Hartbeest, Kgalagadi Transfrontier Park (South Africa/Botswana), Etosha N. P. (Namibia) (East 1999) as well as various nature reserves and conservancies, such as the expanding population of Red Hartbeest of about 18,000 animals in the 400,000 ha Seeis Conservancy in E Namibia (H. Förster & B. Förster pers. comm.).

The failure to protect Hartbeest adequately is particularly tragic because there is poor recognition of local variation among Hartbeest populations and even less recognition of their evolutionary importance as the outstanding model of a mammalian adaptive radiation in the savanna environment. Many local variants have disappeared (*buselaphus*, *nakurae*). Hartbeest were kept in captivity by the ancient Egyptians, illustrated in the tombs of the pharaohs, and used for ceremonial purposes. However, the wild populations from which these animals were taken are now extinct, perhaps partly because of habitat destruction in the Mediterranean region, but mainly due to hunting. Bubal Hartbeest in North Africa were similarly reduced and probably died out around the 1950s (see Distribution); groups in zoos (including London and Paris) that could have ensured their survival were allowed to die out. The intergrade populations of the Kenya Rift

Valley were displaced by intensive farming and shot by settlers and troops; the last surviving Nakuru Hartbeest (a remnant of a once abundant intergrade population between *A. b. cokii* and *A. b. lelwel* in the Kenya Rift Valley), a ♂, was seen and photographed in 1967 (Gosling 1969b). Other subspecies and intergrades are severely threatened or may already have disappeared (*swaynei*, *jacksoni*, *keniae*, *tora*); there are now less than 800 Swayne's Hartbeest (Antonínová *et al.* 2008) and Tora Hartbeest have not been seen for some 10–15 years in any part of their range. The Hartbeest are the most important example of an antelope adaptive radiation in which most members still just survive; they illustrate better than any other group an adaptive radiation into varied savanna habitat and the evolutionary consequences of long-term climatic change. They thus represent an opportunity to conserve the spectacular manifestation of an evolutionary process rather than a museum collection of isolated taxa in protected areas. There is also a case for conservation at a local level. For example, the declining Kenya Hartbeest is a unique local race and should be a conservation priority in a country that values its wildlife and depends on it economically.

An important exception to the pattern of decline is the Red Hartbeest in southern Africa, which is important for various forms of sustained use such as trophy hunting. The latter case is a remarkable example of the success of the southern African approach to wildlife conservation, which involves the transfer of ownership of wildlife and thus any financial profit from its use to the landowner. So long as such practices continue on a rational basis, Red Hartbeest populations will remain secure; indeed its numbers are expanding. Lichtenstein's Hartbeest also seems to be relatively secure, partly because there are several very large reserves within their range (which is tsetse country) and perhaps because this species is exploited to a lesser extent. The lesson from population changes between Hartbeest taxa across Africa is that populations with consumptive use are stable or expanding while the others are plunging to short- or medium-term extinction. Future conservation measures should attempt to expand and improve the operation and sustainability of sustainable use schemes. However, they should also be combined with non-consumptive exploitation in properly guarded protected areas. A further obstacle to be overcome is that unless income from consumptive and non-consumptive use is shared by local communities, Hartbeest will not survive in the medium term. Their meat is highly regarded and they will be poached to extinction except where tangible economic benefits for entire communities outweigh the individual's short-term need or taste for food.

The expanding Hartbeest populations in southern Africa are descended from the small number of survivors of the slaughter of the seventeenth to nineteenth centuries by European colonists. Hartbeest were eradicated from most of their range (Skead 1980, 1987) and much genetic variation was undoubtedly lost at this time. For example, even though its taxonomic status is uncertain, the Hartbeest known as the Cape Red Hartbeest (and believed at the time to be a subspecies) was completely exterminated by hunting and only those known as Northern Red Hartbeest survived around the Kalahari and in what is now known as Namibia (Harper 1945). However, the survivors are numerous again and expanding as the considerable economic potential of the species is appreciated and exploited. The main conservation problem in southern Africa is that animals are sold and translocated to new areas without regard to natural spatial patterns of genetic variation. Local legislation needs to be revised, if only because populations are

most likely to thrive if introduced into areas to which they are locally adapted, that is, their natural range. There is an urgent need for an Africa-wide conservation strategy for the Hartebeest, one that transcends local custom and makes use of best-practice across the continent. Hopefully, before it is too late, conservationists at least will become aware of the impending loss of the finest existing example of a pan-African large mammal radiation.

GENUS *Connochaetes*

Wildebeest

Connochaetes Lichtenstein, 1812. Mag. Ges. Naturf. Fr. Berlin 6: 152.

Common Wildebeest *Connochaetes taurinus* myology.

Common Wildebeest *Connochaetes taurinus* skeleton.

There are two recognized species, the Common Wildebeest *Connochaetes taurinus* and the Black Wildebeest or White-tailed Gnu *C. gnou*. While the latter is monotypic, there are five distinctive subspecies of *C. taurinus*, at least one of which (*C. t. mearnsi*) may be different enough to be considered a separate species (Georgiadis 1995). Black Wildebeest ranged the temperate Highveld and Karoo of South Africa, from where *C. gnou antiquus* was described. *Connochaetes taurinus* is known from fossil remains in North and East Africa, and from lower, middle, and upper Pleistocene beds in South Africa. According to mtDNA analyses (Arctander *et al.* 1999), the Common Wildebeest shows a pattern of colonization going from southern Africa toward East Africa, probably following the expansion of savanna habitat during the past 2.5 million years. While the related *Alcelaphus* and *Damaliscus* species continued their pan-African distribution, western and northern *Connochaetes* populations disappeared and the species now only survives in the southern refugium, from mid-Kenya southwards.

The adaptations of the two wildebeest species to their respective savanna ecosystems made them the keystone species among guilds of grazing ungulates. Although their size and conformation are very different (the mass of an adult Common Wildebeest is 250 kg compared with a 157 kg Black Wildebeest), they share traits that help explain their success. The distributions of the two species overlapped periodically after the speciation of the Black Wildebeest ca. 1 mya (Corbet & Robinson 1991), but habitat preferences and behavioural differences have contributed to reproductive isolation (Brink 2005). However, the two species are also genetically close enough to produce viable hybrids (Fabricius *et al.* 1988), and indeed hybridization and introgression now pose significant risks to the Black Wildebeest due to injudicious translocations that have brought the species into contact with each other at numerous localities in South Africa (Grobler *et al.* 2011).

Wildebeest are adapted to exploit extensive grasslands that can support great concentrations of grazing antelopes, producing highly nutritious green pastures during growing seasons (Estes 1991a). Productivity is maintained by recycling of the manure distributed by the massed animals. Both species are equipped with broad incisor

arcades to take large bites of short grasses (in both species, the dental formula is $I^{0/3}, C^{0/1}, P^{3/2}, M^{3/3} = 30$, with the second lower premolar absent, as in *Beatragus*). They are bulk rather than selective feeders. The Common Wildebeest is virtually a pure grazer, whereas the Black Wildebeest also browses to some extent on karroid shrubs. Both species are territorial, which represents the original sedentary-dispersed social organization shared by all but a few antelopes in the subfamily Antilopinae. In the resident phase, the Black Wildebeest defends a far larger territory than its congener. In the migratory phase, the Common Wildebeest defends temporary, very small territories. How close migrating Black Wildebeest territorial ♂♂ would tolerate one another is unknown: there has been no migratory population since the species was nearly exterminated in the late 1800s. Though efforts to restore the species have been outstandingly successful, the thousands of Black Wildebeest now live in isolated herds on farms and ranches in the Highveld and also outside their natural range as far afield as Namibia.

What sets wildebeest apart from all other antelopes – and must contribute to their dominance of competing migrants – is their reproductive system. They have abandoned the ancestral system wherein newborn calves go through a hiding stage (for example, Hartbeest *Alcelaphus buselaphus*) that lasts days and even weeks, during which mothers must remain in attendance. In highly mobile aggregations, selection would favour reducing or even eliminating the hiding stage. Wildebeest abandoned it altogether and evolved an entirely new follower-calf system. The main features are extreme precocity of the newborn, which gain mobility within minutes of birth, aggregations of pregnant ♀♀ on calving grounds, a short peak during which some 80% of the calf crop is born, and associations of mothers and calves in maternal herds (Estes 1976, Estes & Estes 1979). In this way, not only are predation and predators limited, but herds with older calves provide essential cover for neonates (substituting for high grass) during the first day or two when they are most vulnerable.

Richard D. Estes

Connochaetes gnou **BLACK WILDEBEEST (WHITE-TAILED GNU)**

Fr. Gnou à queue blanche; Ger. Weisschwanzgnu

Connochaetes gnou (Zimmermann, 1780). Geogr. Gesch. Mensch. Vierf. Thiere 2: 102. South Africa, 'Die lander der Caffern, ziemlich tief ins land vom Cap gerechnet in grossen Waldern ohnheit der Uchtermanns Brenjes hogde und Camdebo'; since selected as Eastern Cape Prov., Somerset East Dist., Agterbruintjieshoogte (Grubb 1999).

ABOVE: Lateral and palatal views of skull of Black Wildebeest *Connochaetes gnou*.
LEFT: Black Wildebeest *Connochaetes gnou*.

The moniker Gnu derives from the Khoikhoi (aka Hottentot) descriptive term for the bellowing snort the animal gives when alarmed (Skinner & Chimimba 2005).

Taxonomy Monotypic, with no subspecies recognized. Synonyms: *capensis*, *connochaetes*, *gnou*, *gnu*, *operculatus*. Chromosome number: $2n = 58$ (Wurster & Benirschke 1968, Corbet & Robinson 1991). Hybridization with Common Wildebeest has been recorded, and hybrids are fertile (Fabricius *et al.* 1988).

Description Similar in appearance to its close relative the Common Wildebeest *Connochaetes taurinus*, but smaller in size, with strongly built forequarters sloping to more slender hindquarters. Rich, dark-brown colour; mature ♂♂ have a black face and a darker, almost black appearance; newborn calves are fawn-coloured. Head and face is less elongated than in Common Wildebeest, with a broad muzzle, erect facial tuft, preorbital glands and distinct tuft of hair under the chin. Further tuft of hair found on the chest, between the forelegs. Stiff, upright, trim mane, creamy-white with dark tips. Horse-like tail is creamy white but dark at base, almost reaching the ground. Pedal glands are present on front hooves and excrete a sticky substance; inguinal glands are absent. Males larger than ♀♀.

Horns, present in both sexes, are smooth with expanded bases, directed forward and downwards before curving up sharply. Adult ♂♂ have heavy horns with prominent bosses, while horns of ♀♀

are slighter. Calves have long spike-like horns that start to curve at approximately nine months; ♂♂ attain full horn shape at 4–5 years (von Richter 1971b). In addition to the differences in horn shape and horn base architecture, the skull of the Black Wildebeest can be distinguished from that of the Common Wildebeest in being generally smaller, shorter and dorsoventrally flattened. The angle of the braincase to the face is greater in the Black Wildebeest than the Common Wildebeest, the orbits are absolutely and proportionally enlarged, while the frontal suture is fused (Brink 2005). These features appeared progressively over the last million years, and can be observed in rudimentary form in the earliest fossil populations of ancestral Black Wildebeest (Brink 1993, 2005). All molar teeth are erupted by the third year of age, with the upper third and fourth premolars erupting at 28–30 months; patterns of tooth eruption are discussed in detail by von Richter (1971b).

Geographic Variation None recorded.

Similar Species

Connochaetes taurinus. Larger, greyish in colour with dark brindle stripes on the neck and shoulders; head and face elongated; chin with long beard and limp hair, and shaggy mane of long black hair under the throat; black tail almost reaching the ground; horns smooth, arising from swollen bosses and directed outwards and slightly downwards before curving up; horn tips pointed

inwards and often slightly backwards. Although the ranges of the two species formerly barely overlapped (with Black Wildebeest confined to the temperate, treeless Highveld and Karoo regions of South Africa, Swaziland and Lesotho), stocking of both species outside their natural range has led to fertile hybrids where the two species are kept on the same property (Fabricius *et al.* 1988).

Distribution Black Wildebeest are endemic to southern Africa. According to von Richter (1974) they formerly migrated in large numbers in both east–west and north–south directions, probably following the onset of rains and changing vegetation cycles.

Historical Distribution Formerly confined to the central inland plateau of South Africa, specifically the Highveld regions of Free State, Gauteng and North West Provinces, parts of the Eastern Cape and Northern Cape provinces, and marginally in the grassveld regions of western KwaZulu–Natal, in the foothills of the Drakensberg Range (von Richter 1974). It has been suggested that their occurrence in the western parts of KwaZulu–Natal may have been due to a local movement from the Free State during the winter months in search of better feeding grounds. Black Wildebeest were also recorded seasonally in grassland areas of W Swaziland and the western parts of Lesotho (where they were exterminated before 1900). A detailed discussion of the historical distribution of the species is given by von Richter (1971a).

Current Distribution Black Wildebeest have been widely reintroduced to areas within their former distribution range, as well as to farmland and reserves well outside their natural range. For example, although they do not occur naturally in Namibia, they have been introduced and now occur widely throughout Namibia's farming districts (East 1999). They have also been reintroduced in Lesotho (in Sehlabathebe N. P.) and in Swaziland in Malolotja N. R. (East 1999).

Habitat A species characteristic of the open plains Highveld grasslands (the Highveld BZ) and Karoo shrublands (the Karoo subzone) of southern Africa. The high central plateau grasslands are characterized by flat to rolling hills, and mountainous areas with altitudes ranging from 1350 to 2150 m. These areas are dominated by a single layer of grasses, with cover dependent on rainfall and the degree of grazing.

Abundance Several thousand are all that remain of the millions that once roamed South Africa's Highveld and Karoo regions. The total population is estimated at more than 18,000 animals (including the introduced population in Namibia), 80% of which occur on private land and 20% in protected areas. However, population size is increasing, especially on private land, with a large extralimital population now established in Namibia, where importations from South Africa led to a dramatic rise in the estimated total numbers, from 150 in 1982 to more than 7000 in 1992 (East 1999).

Adaptations Black Wildebeest actively condition their own preferred habitat by persistent grazing and trampling (von Richter 1974, Kok & Vrahimis 1995), especially applicable to sub-optimal areas, where territorial ♂♂ open up fairly dense vegetation. These ♂♂ are closely attached to their territories throughout the year; here, vegetation horning during demonstrative-threat displays plus sustained grazing in the immediate vicinity of the stamping ground keeps the grass in the favoured short state, thereby enhancing visibility (Kok & Vrahimis 1995).

Although scattered trees may be found in concentration areas, animals rarely use trees for shade and shelter. Generally these darkly coloured ungulates are exposed to direct solar radiation and other, often extreme, climatic conditions. During early morning and late afternoon, when temperatures are lower, animals present the long axis of their bodies to the sun to facilitate heat uptake (Vrahimis & Kok 1992). Conversely, during the heat of day, animals orientate themselves to expose the smallest surface to direct sunlight, thereby compensating for excessive heat load. In summer, when the hottest time of the day usually coincides with the highest windspeed, it is more likely that animals orientate with respect to wind direction, thus maximizing amount of airflow over the entire length of their bodies (Vrahimis & Kok 1992). Additionally, animals prefer lying down to standing during the heat of the day, thereby reducing the intake of reflected radiation from the ground.

Although they are subjected to high ambient temperatures during the day, the brain temperature in Black Wildebeest is usually within 0.2 °C of arterial blood temperature. Selective brain cooling is absent, even though brain temperature may rise to 42.0 °C (Jessen *et al.* 1994). Jessen *et al.* (1994) established that heat storage as a thermoregulatory tactic is relatively unimportant for Black Wildebeest. The Black Wildebeest may be considered to have extraordinary homeothermic capacity, the key being the insulation provided by its fur. Furthermore, due to enlarged evaporative surfaces in the long snout of the genus *Connochaetes*, heat is also dissipated by panting. Even in a thermal environment characterized by large contrasts between day and night, the circadian variation of body temperature in the Black Wildebeest appears to reflect an endogenous rhythm rather than a reaction to cyclic thermal loads. In addition, it was recorded that increased metabolic rate, as during

episodes of chasing, increases blood temperature (1.3 °C within 4 min). Without free access to water, heterothermy may be obligatory (Jessen *et al.* 1994).

However, regarding selective brain cooling, it has been established that the mammals with the greatest capacity for such brain cooling possess carotid retes, bilateral networks of arterioles in, or just outside the cranial cavity, in the main arterial blood supply to the brain (Gillilan 1974 and Simoens *et al.* 1987, in Mitchell *et al.* 2002). In the artiodactyls, the retes have a thermoregulatory function and are heat exchangers in which the arterial blood destined for the brain is cooled by venous blood returning from the evaporating surfaces of the nasal cavity (Baker 1982 and Mitchell *et al.* 1987, in Mitchell *et al.* 2002). Studies conducted in a free-living Black Wildebeest revealed that, as one would normally expect for artiodactyls, selective brain cooling could develop, but, unexpectedly, seldom actually did in their natural habitats (Jessen *et al.* 1994). Thus, Jessen *et al.* (1994) found that at a brain temperature that exceeded 42 °C, established under induced intense exertional hypothermia, selective brain cooling was abandoned and brain and blood temperatures were similar.

Foraging and Food The Black Wildebeest is predominantly a grazer and prefers short grassveld (von Richter 1974). A feeding study listed 41 plant species utilized, and showed that 63% of the Black Wildebeest's main diet consisted of grass and 37% of karroid shrubs (Van Zyl 1965). Grasses such as *Sporobolus* spp., *Themeda triandra* and *Cynodon dactylon* formed the bulk of their diet. Karroid shrubs were browsed during the colder months of the year, probably correlating with the decline in the nutritional value of the grass. Roberts (1963) found that, in the central Free State, 86.8% of the diet consisted of grasses, especially *Eragrostis lehmanniana* (31.3%), *Themeda triandra* (25.3%), *Panicum coloratum* (20.3%) and *Cynodon dactylon* (9.9%). Research conducted on feed utilization and digestion in Golden Gate Highlands N. P. in the Free State indicates that the diet of Black Wildebeest consisted of 80% grass and karroid shrubs and that the relatively high fermentation rate is due to suitable substrate for microbial activity found in that area (Van Hoven & Boomker 1981). These observations of grass predominating in the diet are borne out also by studies involving stable carbon isotopes (Sponheimer *et al.* 2003b).

The feeding preferences of a tame Black Wildebeest cow were investigated over a two-year period (S. Vrahimis pers. obs.). This animal was hand-reared, but subsequently integrated into a free-ranging herd. Results obtained during the free-ranging stage showed that this animal utilized grass (93.7%), karroid shrubs (3%) and herbs (3.3%). While mainly a non-selective grazer there was evidence of some preference for certain grass species. This was evident due to the fact that the animal would feed on a specific grass species for quite some time (approx. 20 min.), before moving on and feeding on another grass species, once again for a period of time. All social groups exhibit a typical bimodal feeding pattern with high-intensity grazing peaks during the early morning and late afternoon (Vrahimis & Kok 1993). Generally, ♂♂ spend more time grazing than ♀♀. For territorial ♂♂ this is perhaps explicable on the basis of their intensive involvement in territorial behaviour and, therefore, greater energy costs, while in the case of bachelor herds, which usually occupy marginal areas with poor grazing (often to avoid harassment by territorial ♂♂), the animals have to feed longer. In addition, the

two categories of grass plants found in grasslands described by Low & Rebelo (1996), namely, sweet grasses having a lower fibre content which maintain nutrients in winter (palatable), and sour grasses having a higher fibre content which tend to extract nutrients during winter (unpalatable), will also determine the time spent feeding during winter in different grassland areas. Black Wildebeest are dependent on water and drink regularly, mainly in the late afternoon.

Social and Reproductive Behaviour Black Wildebeest are gregarious, their social groups comprising female herds, bachelor herds and territorial ♂♂. Average size of a female herd is 28 animals (range 14–49; n = 144) and comprises adult and subadult ♀♀ and calves, and in most cases an attending territorial bull. A number of yearling ♂♂ are usually also found in these herds. Bachelor herds contain ♂♂ of various ages, including yearlings, with an average of 21 individuals (range 11–32; n = 52). Tolerance of the ♂♂ towards one another is notable in these groups (von Richter 1971b). Two types of territorial ♂♂ are recognized: isolated, solitary bulls, usually older animals, and those found in a territorial network. Definite dominance hierarchies are evident in such a territorial system where most matings take place. Home-range and size of territories is largely dependent on the density of animals and the size of the available area and available food source.

Von Richter (1971c) described territorial ♂♂ displaying vigorously, defending their territories and challenging neighbouring bulls or intruders throughout the year in the Free State. Territoriality is a prerequisite for reproduction, as non-territorial ♂♂ are excluded from the rut. Encounters between territorial ♂♂ are highly ritualized and resemble those of Common Wildebeest (von Richter 1974). Estes (1991a) records standing in erect posture, a rocking canter, calling, defecation preceded by pawing, kneeling, ground horning, rolling on stamping ground, herding and chasing as the means of advertising territories. The territories of neighbouring ♂♂ are separated by distances of 180–450 m (von Richter 1972). Agonistic behaviour between territorial ♂♂ is comprised of dominance-threat displays, defensive-submissive displays and fighting (ramming horns). In several instances, carcasses of ♂♂ with interlocked horns have been found.

Black Wildebeest are among the most vociferous of all antelope species. Territorial ♂♂ have a very specific call, best described as a loud 'woink', which carries over a long distance and is heard day and night. Calling is more intense at night, and the fact that this is the main signal available after dark is well demonstrated during full moon (when covering of the moon by a cloud leads to more intensive calling). When this call is made, the head jerks back and the mouth opens wide. Males respond to each other's calls.

Observations conducted during the mating season include the recording of interactions between territorial ♂♂ and ♀♀. Interactions consist of herding, chasing, inspecting for receptiveness and mating. On a daily basis, a build-up of interactions was evident from 13:00 to 18:00h; 39–66% of all interactions consisted of inspections of the receptiveness of ♀♀, while chasing comprised a third of all activities. Most matings observed were between 14:00 and 18:00h, but it is suspected that mating often occurs at night.

Female herds move from one territory holder to another and the time spent with each can vary from a few hours to several days. Herd movements occur mainly at night. When approaching a territorial

♂, the herd is usually met by the ♂ at the periphery of the territory, performing a typical, stiff-legged gait, which Estes (1991a) referred to as a 'rocking canter'. Once the herd has entered his territory, the ♂ moves about in the herd inspecting ♀♀ at random. When approached within a herd, ♀♀ lift and swish their tail. Heads are often held at an angle-horn position (agonistic behaviour – readiness for combat) and circling of the ♂ and ♀ then follows. Occasionally ♀♀ drop their heads and interlock horns with the ♂. Urination on demand and urine testing (flehmen) continuously take place (Estes 1991a). When about to mate, the ♂ approaches in the typical low-stretch posture (Estes 1991a), resting his chin on the female's rump, stands bipedally, and mates. Most matings take place on the periphery of the herd where the ♂ normally stands separately; a receptive ♀ usually approaches the ♂ here with her tail lifted and swishing.

Parturition takes place within the herd and all births witnessed were between 08:00h and 12:00h (S. Vrahimis pers. obs.). Females about to calve become very restless, lying down and standing up continuously. During the final stage the ♀ lies flat on the ground. Whether the ♀ eats the afterbirth, as sometimes occurs in Common Wildebeest, is unknown. Von Richter (1974) recorded an average of 9 min elapsing before a calf can stand on its feet.

Throughout the day, lying down dominates (85%) all categories of activities for calves 1–3 months of age. During subsequent months this activity stabilizes to a much lower level (55–56%) of the diurnal time budget. The most noteworthy development in diurnal activities involves a progressive increase in the time spent feeding (4–33%). From the second month, the formation of nursery or crèche groups is evident, showing synchronized activity distinct from the main body of the herd, such as playing and exploring. At approximately three months, aggregations of calves are more pronounced, with the young spending the largest part of the day together, indicating the start of the weakening of the mother–calf bond (Vrahimis & Kok 1994).

Regarding associations with other species, the distribution range of Black and Common Wildebeest (Aylward 1881, Sidney 1965, Skead 1987) was known to overlap slightly, especially in the Free State and regions of the Highveld. Associations of Black Wildebeest with the now extinct Quagga *Equus quagga quagga* were recorded (Bryden 1889, Sclater 1900/1901, Lydekker 1926). Ostriches *Struthio camelus* also co-existed with both wildebeest species. Early explorers and hunters passing through the central open plains of South Africa described huge aggregations of wildebeest, Quaggas, Plains Zebra *Equus quagga*, Blesbok *Damaliscus pygargus phillipsi*, Hartbeest *Alcelaphus buselaphus* and Springbok *Antidorcas marsupialis* (Cumming 1980 [1850], Bryden 1893).

Reproduction and Population Structure Black Wildebeest are seasonal breeders, and breeding appears to be triggered by shortening daylength (Skinner *et al.* 1973). The majority of calves are born within a three-week period (von Richter 1971c), from mid-Nov to end Dec. Generally, the peak mating season is from mid-Mar to end Apr. Most ♀♀ conceive at the age of 16 months and calve when they are two years old (S. Vrahimis pers. obs.), after a gestation period of approximately 8.5 months (Skinner *et al.* 1973). Males can mate successfully at the age of 16 months, but first have to secure a territory before being allowed to mate. In one area all adult ♂♂ were removed, leaving only young ♂♂ (16–18 months)

present during the mating season. These ♂♂ mated successfully, but the calving percentage was not as high as expected (68%). Average age of territorial ♂♂ is four years, but in areas where excessive hunting occurs, two-year-old ♂♂ were territorial.

A single calf is born (there being no records of twins; von Richter 1974, S. Vrahimis pers. obs.) and the average birth-weight recorded is 14 kg (range 12.5–15.5 kg; n = 4). Calves are weaned at 6–8 months; the composition of the mother's milk is discussed by Van Zyl & Wehmeyer (1970). Birth rates are generally high, ranging from 72 to 97% (S. Vrahimis pers. obs.). Von Richter (1971c) recorded lower reproductive rates (47–68%) in some areas of marginal habitat suitability, and stated that the reproductive performance, in a specific area, can be variable and is linked to seasonal climatic conditions, as 86% and 100% of cows were recorded birthing in the same area on different occasions. A lack of predators in the enclosed areas where Black Wildebeest are held today lowers mortality. The current primary cause of mortality is separation of calves from their mothers during game capture operations. Von Richter (1971c) recorded 5–11% mortality in two different areas, also ascribed to separation of cows and calves.

Wildebeest have a unique reproductive system, which includes a short, sharply defined calving season that generates a superabundance of newborn calves (Estes 1991a). Connected to the species' former migratory habits, there is a tendency to concentrate in large numbers, a preference for short grass and calves follow their mothers shortly after birth, all of which are incompatible with a concealment strategy. Although Black Wildebeest are no longer able to migrate and no longer permitted to occur in large concentrations, this could be a vestige of behaviour important for the survival of wild animals in the past.

Today, Black Wildebeest are extensively managed in protected areas that do not allow the formation of natural population structures. In most areas animals are captured and removed annually, depending on the animal numbers, climatic conditions and grazing. Attempts are made to maintain a balance, with sex ratios kept close to parity and equal representation of all age classes. Pre-natal sex ratio of 91 fetuses examined showed 1.17 ♂♂ : 1 ♀. Von Richter

Black Wildebeest *Connochaetes gnou*.

(1972) reported that game-capture operations changed sex ratios, whereas in one national park, from which no animals were removed, the sex ratio was near parity. Weigl (2005) gives a longevity record in captivity of 21.8 years, although in the wild longevity is estimated at approximately 14 years (based on the known age of a single animal; S. Vrahimis pers. obs.).

Predators, Parasites and Diseases Presently, in South Africa, these animals are confined to nature reserves and private farmland, where major predators no longer occur. In historical times, explorers and hunters described instances where large numbers of animals died as the result of the outbreak of diseases, apparently scabies or mange (Harris 1840, Cumming 1980 [1850], Bryden 1889). Von Richter (1974) suspected that rinderpest and foot and mouth disease, which seriously affected Common Wildebeest, could have had an influence on Black Wildebeest. Fatal, sporadic outbreaks of anthrax in Black Wildebeest were recorded up to 1943 (Neitz 1965). Black Wildebeest are also asymptomatic carriers of the virus that causes malignant catarrhal fever, a disease deadly to cattle. A survey conducted in 1988 to establish the extent of malignant catarrhal fever in the Free State showed that there were 13 confirmed cases recorded from 1977 to 1987. The survey involved 205 landowners that had either Black or Common Wildebeest, or both species on their properties (Vrahimis & Prinsloo 1988). As a result of malignant catarrhal fever outbreaks in South Africa restrictions were placed on the relocation of both Black and Common Wildebeest in 1982 and no new introductions were allowed. Malignant catarrhal fever was then also listed as a notifiable disease and all cases had to be reported. Due to the fact that it was later found that malignant catarrhal fever was not a significant problem, these restrictions were lifted in April 1993, once again allowing for free movement of both wildebeest species in South Africa.

The endo- and ectoparasite burdens of Black Wildebeest have been investigated at two localities in South Africa, which revealed a small number of species and relatively small number of helminths and ticks at both localities (Horak *et al.* 1983b). This was ascribed to fairly cold climates prevailing in the survey regions and the fact that Black Wildebeest appear to be fairly resistant to parasitic infestation. The nematode burden of Black Wildebeest examined in another survey was found to be extremely low when compared with that recorded by Horak *et al.* (1983b) and was also perceived to be a reflection of the adverse climatic conditions, namely hot summers and cold winters with low rainfall during either season (Boomker *et al.* 2000).

In Black Wildebeest, as in the Common Wildebeest, larvae of oestrid botflies inhabit the sinuses and nasal septa, apparently without causing obvious harm to the host. Horak *et al.* (1983b) observed an erratic, but progressive, increase in the numbers of first stage larvae of *Gedoeletia* spp. on the dura mater of Common Wildebeest calves until they reach the age of approximately 13 months; likewise, Horak (2005) noted that large numbers of first instar larvae of *G. hassleri* appeared to accumulate on the dura of Black Wildebeest in the Eastern Cape from June to August. Flies of the genus deposit first instar larvae on the cornea or conjunctiva of the eyes of their hosts from where they migrate either via the optic nerve tract or artery to the subdural cavity and dura mater, and then via anterior routes to the nasal passages where they moult to the second instar (see Horak & Butt 1977).

Conservation IUCN Category: Least Concern. CITES: Not listed.

By 1900 the Black Wildebeest was nearly exterminated by hunting and the reduction of available habitat due to human settlement (von Richter 1971a, 1974), as well as the periodic outbreak of diseases. Fisher *et al.* (1969) stated that Black Wildebeest were subjected to constant unregulated persecution for more than a century, culminating in slaughtering of immense numbers for their skins in the 1870s. Millais (1895) expressed concern, fearing the extinction of the species, as formerly, 'tens of thousands of these wildebeest had been scattered in troops of from twenty to fifty over the face of the Southern Transvaal and Free State Highveld, and after careful inquiries, there were hardly more than 550 in existence'. These animals were exterminated throughout the greater part of their former distribution range and recorded as being extinct in the wild (Stevenson-Hamilton 1917, Fitzsimons 1920, Shortridge 1934). Fortunately, the species was saved from extinction by conservation-minded farmers, especially in the Free State, by protecting herds on their farms.

Following the turn of the nineteenth century, Black Wildebeest numbers started to increase rapidly (Fitzsimons 1920). However, the drought in 1933 had a severe impact on this species, and von Richter (1971a) provides information from one population where only 15–20 animals, mainly ♂♂, survived out of a population of approximately 400 animals. According to Fisher *et al.* (1969), until 1936 the only Black Wildebeest surviving were all on private land, and later that same year animals were released into the then Free State G. R. (Somerville). When the Free State G. R. was abolished, the herd was transferred to Willem Pretorius G. R. in 1956, where numbers had increased to 370 animals by 1966. Gradually, over the years, reintroductions took place on a large scale. Translocations were mainly carried out from the small number of original herds in the Free State and to a lesser extent from a herd in the North West Province, as well as from the De Beers estate in the Northern Cape (von Richter 1971a).

Although it is now supposedly safe from extinction, Black Wildebeest numbers are still relatively low. Presently, the largest threat to the species is hybridization with the Common Wildebeest. Sidney (1965) mentions the occurrence of hybrids between Black and Common Wildebeest in KwaZulu–Natal, which is probably one of the first recorded instances. Fabricius *et al.* (1988) provide evidence that hybrids are fertile. As most recorded instances of hybridization have been Common Wildebeest ♂♂ cross-breeding with Black Wildebeest ♀♀, Corbet (1991) speculates that this could be due to the larger size of the former species being able to dominate the latter. The external appearance of hybrids can vary, with the most prominent and reliable feature being the shape of the horns. Although first generation hybrids are easily identified, hybrids interbred with pure stock Black Wildebeest are difficult to recognize on appearance alone and advanced backcrosses are hard to detect (Grobler *et al.* 2011); Ackermann *et al.* (2010) discuss several anomalous cranial morphological characteristics of hybrids. It has always been believed that hybridization only occurs under artificial conditions, but, recently, in a protected area (approx. 6000 ha) in KwaZulu–Natal where large herds of both Black and Common Wildebeest were housed together, all the wildebeest had to be destroyed because of hybridization.

For several years Tussen-die-Riviere N. R. in the Free State had large populations of both Black and Common Wildebeest together, with no apparent problem of hybridization. It was decided in the early 1990s that these animals should be separated and that preference should be given to Black Wildebeest (being endemic to central South Africa) and all Common Wildebeest were removed from the reserve. At one stage, this was one of the largest populations of Black Wildebeest in South Africa, but annual hunting on the reserve resulted in almost the entire Black Wildebeest population being concentrated in a narrow area south of the Orange R., causing serious habitat degradation. After all the Common Wildebeest on the reserve were culled, Black Wildebeest from other protected areas in the Free State were subsequently translocated back to Tussen-die-Riviere N. R.

Measurements

Connochaetes gnou

HB (♂ ♂): 1800 (1700–1880) mm, n = 92
 HB (♀ ♀): 1660 (1530–1750) mm, n = 53
 T (♂ ♂): 540 (460–610) mm, n = 92
 T (♀ ♀): 500 (420–560) mm, n = 53
 HF c.u. (♂ ♂): 470 (440–500) mm, n = 92
 HF c.u. (♀ ♀): 450 (430–480) mm, n = 53
 E (♂ ♂): 170 (150–190) mm, n = 92
 E (♀ ♀): 160 (140–180) mm, n = 53
 WT (♂ ♂): 160.0 (134.0–200.0) kg, n = 253
 WT (♀ ♀): 131.0 (117.0–149.0) kg, n = 64
 Free State, South Africa (S. Vrahimis pers. obs.)
 Maximum recorded horn length is 74.6 cm for a pair of horns from the Free State, South Africa (Rowland Ward)

Connochaetes taurinus COMMON WILDEBEEST

Fr. Gnou bleu; Ger. Streifengnu

Connochaetes taurinus (Burchell, 1824). Travels in Interior of Southern Africa 2: 278 (footnote) [1824]. Apparently 'Kosi Fountain', but lectotype came from South Africa, North West Prov., Vryburg Dist., 'Chue Spring, Maadji Mtn [Klein Heuningvlei]'; see Grubb (1999).

Common Wildebeest *Connochaetes taurinus albojubatus*.

According to Skinner & Chimimba (2005), the now uncommon name Gnu applies to the Black Wildebeest *C. gnou* and derives from the Khoikhoi (aka Hottentot) descriptive term for 'the bellowing snort they give when alarmed'. But as an onomatopoeic term, it sounds more like the territorial advertising call 'GA-nou!'. 'Wildebeest' is the misnomer bestowed on both species – first the Black – by the Dutch colonists because of a fancied resemblance to the 'wild ox' of Eurasia.

Taxonomy Five subspecies are usually recognized (Ansell 1972, Grubb 2005). Synonyms: *albojubatus*, *babaulti*, *borlei*, *cooksoni*,

corniculatus, *fasciatus*, *gorgon*, *hecki*, *henrici*, *johnstoni*, *lorenzi*, *mattosi*, *mearnsi*, *reichei*, *rufijianus*, *schulzi*. Chromosome number: 2n = 58 (Wallace 1978b, Corbet & Robinson 1991).

Description A large, long-faced antelope with cow-like horns, heavy-set body but thin legs, and forequarters higher than hindquarters. Head large, muzzle broad, with wide incisor row and flexible lips; nostrils covered with skin flap. Eyes obscured by long lashes, iris yellow, tapetum reflection greenish. Ears narrow, ca. 200 mm; frontal mask black (but subject to individual and subspecific variation). Neck short and thick, with mane upstanding or lax, and beard from chin to forelegs. Coat short, glossy with vertical 'stripes' of longer, dark hair on neck, shoulders and chest. Colouration of torso blue-grey, tan, or brown with vertical stripes of longer, dark hair on neck and thorax (subject to partial moult, most developed in breeding season, making individuals look darker). Tail, mane, backs of ears and facial blaze black; beard black, tan, or off-white. Lower legs lighter coloured. Calves fawn to tan, mask, beard, dorsum and tail black (but up to one in ten has blond crown). Change to adult colouration complete in third month. Hooves with little taper; false hooves well-developed. Tail hock-length with long hair reaching to heels (widely used as a fly whisk). Preorbital glands are developed in both sexes, but larger in ♂, and covered with hair, the central duct absent or vestigial, and the secretion appears as a clear oil. Pedal glands are present on the forefeet, but rudimentary on hindfeet (Pocock 1910, Ansell 1969). The secretion of the pedal glands is black, pungent and detectable to the human nose (resembling fresh tar); the constituents of the secretion have been examined by Wood (1998). Inguinal glands are absent.

Horns cowlike, present in both sexes, unridged and extend sideways with tips pointing inward; horns of ♂ are wider and thicker,

ABOVE: Lateral view of skull of Common Wildebeest *Connochaetes taurinus*.

LEFT: Common Wildebeest *Connochaetes taurinus taurinus*.

with well-developed bosses beginning in third year. Attwell (1980) considered the loss of the second lower premolar in adults (which retain only the third and fourth premolars) as representative of an advanced stage of evolution in ungulate dentition. Adult dentition is complete by just over three years; Attwell (1980) discussed age determination based on tooth eruption, attrition and cementum layers. Horn development to 24 months is illustrated in Kingdon (1982: 530) and herein.

Geographic Variation

- C. t. taurinus* (Blue Wildebeest or Brindled Gnu): Namibia and South Africa, north of the Orange R., to Mozambique and from Mozambique to Zambia south of the Zambezi R., and from SW Zambia, west of the Kafue R., to SE and S Angola. Bluish-grey coat, black beard and upstanding black mane. Also commonly called the Brindled Gnu because of the stripes of darker hair on the neck and shoulders extending back to about the middle of the body.
- C. t. cooksoni* (Cookson's Wildebeest): restricted to the Luangwa Valley, Zambia; believed to have ranged, but only as vagrants, onto the adjacent plateau into C Malawi (Ansell & Dowsett 1988). Browner than other races.
- C. t. johnstoni* (Nyassa, Johnston's or White-banded Wildebeest): north of Zambezi R. in Mozambique to east-central Tanzania, and formerly in S Malawi, but now extinct there (Ansell & Dowsett 1988). Sometimes referred to as the 'White-banded Wildebeest' for the pale chevron between its eyes (often absent in the Tanzania population). Distribution largely confined to *Acacia* savanna of

major river valleys within the miombo (*Brachystegia*) woodland zone. Former northern distribution limit Wami R., Tanzania.

- C. t. albojubatus* (Eastern White-bearded Wildebeest): N Tanzania to C Kenya just south of the Equator, west to the Gregorian Rift Valley; southernmost point in recent past (1950s) at least to the Handeni–Kondoa road (5° 30' S) (J. Kingdon pers. obs.). Lighter grey than *C. t. mearnsi*, larger and about 50 kg heavier, with wider horns but less-developed boss; beard white to tan.
- C. t. mearnsi* (Western White-bearded Wildebeest): N Tanzania and S Kenya west of the Gregorian Rift Valley, reaching L. Victoria at Speke Bay. This is the smallest, darkest and most numerous race – the Common Wildebeest of the Serengeti Plains. Horns shorter but boss most developed; beard white to tan. Male territorial advertising call distinctively different from other races: resonant croak with mouth closed repeated many times, compared with more metallic series of 6–12 calls with mouth open of other races. Female mimicry of male secondary characters includes a penile tuft of adipose tissue, rarely if ever present in other subspecies (Estes 1991b). Often unrecognized as a subspecies distinct from *C. t. albojubatus* (Heller 1913b, Allen 1939, Kingdon 1982), yet DNA studies support the phenotypical differences and indicate that *mearnsi* is the longest isolated, and genetically most unlike the other races (Arctander *et al.* 1999). A small resident population of *C. t. mearnsi* existed in the Gregorian Rift Valley near L. Naivasha, but was eliminated by fencing and shooting by the end of World War I (Roosevelt & Heller 1915). The only known place of potential contact now is via the Rift Wall opposite L. Natron, which is sometimes traversed by *albojubatus* (D. Peterson pers. comm.).

Similar Species

Connochaetes gnou. Fossil evidence indicates the two species separated ca. 3 mya (Gentry 1978, Vrba 1979, Flagstad *et al.* 2001); although the ranges of the two species formerly barely overlapped (with Black Wildebeest adapted to the temperate, treeless Highveld and Karoo), stocking far outside its natural range (Botswana, Namibia, Zimbabwe) has led to fertile hybrids where the two species are kept on the same property (Fabricius *et al.* 1988). These are much smaller, darker antelopes with more evenly developed limbs, dangerous horns that project forward like meathooks, and a white tail.

Distribution Endemic to Africa, historically ranging in short grasslands and open bushland and woodland from N and E Namibia, Botswana, N South Africa (generally, north of the Orange R., in the Northern Cape, North West, Limpopo, Mpumalanga, Gauteng, Free State and NE KwaZulu–Natal Provinces) and Mozambique to ca. 38° E (Chuyulu Hills) in S Kenya, west to L. Victoria at ca. 01° S. Palaeontological evidence indicates that *C. taurinus* lived in the Saharan region in the late Pleistocene (Gentry 1978), and more recently in West Africa, possibly in a ‘bovid’ western refugium (Arctander *et al.* 1999).

In pre-colonial times, Common Wildebeest dominated the teeming assemblages of plains game in most of the Acacia savanna ecosystems of eastern Africa. Migratory populations rivalling those of the Serengeti Plains existed in Kenya’s Athi-Kapiti Plains; in Tanzania, stretching from the Gregorian Rift Valley to Mt Meru, mainly comprising S Masailand; and in much of Botswana. Populations in the order of 25,000–50,000 inhabited the broad river valleys incised in the miombo (*Brachystegia*) woodlands of SE Tanzania and N Mozambique (*C. t. johnstoni*), the Liuwa Plains of Barotseland, SW Zambia, extending into SE Angola; the Limpopo Valley between Zimbabwe and Mozambique; South Africa from the lowveld of the Limpopo and Mpumalanga provinces west into the foothills of the Drakensberg; and in NE Namibia, Common Wildebeest migrated between Etosha G. R. into

adjacent Botswana and Angola, before a game-proof fence was erected along the Namibia–Botswana border, followed by fencing of the eastern border of Etosha N. P. Loss of range outside of protected areas has resulted in the replacement of migratory populations with smaller more sedentary populations within protected areas, as in the case of Etosha N. P. (Berry 1997, East 1999).

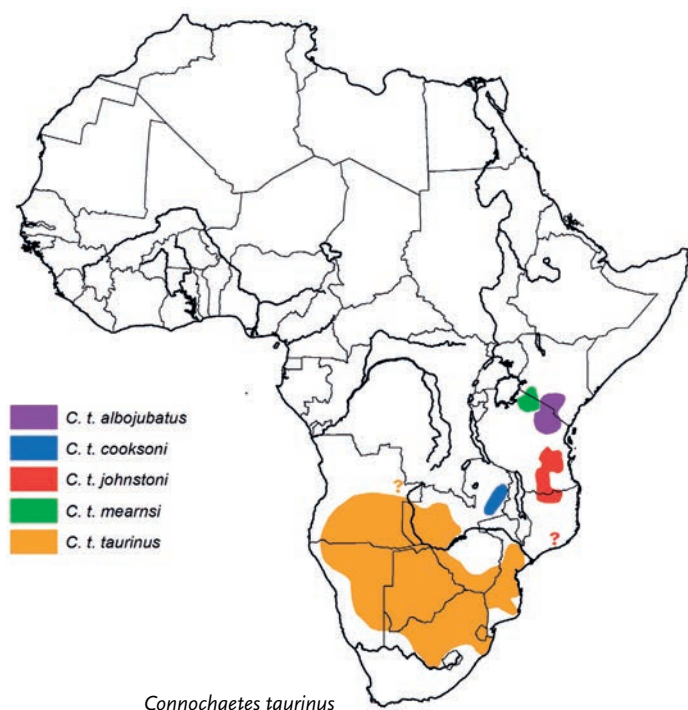

The only range state in which the Common Wildebeest has been exterminated is Malawi. According to Sidney (1965), the Nyassa Wildebeest’s range in Malawi used to be bounded by L. Malawi on the north, the Shire R. on the west and the Zambesi on the south. The alluvial plains of the river and Lakes Chilwa and Chuita must once have supported a sizeable population. But as one of the best agricultural regions of the country, it was capable of supporting a dense human population; the few animals that persisted at the south end of L. Chilwa were finally shot out in 1925 (Sweeney 1959; see also Ansell 1982, Ansell & Dowsett 1988).

Common Wildebeest have also been introduced to regions outside their former distribution range, including the Eastern Highlands of Zimbabwe, parts of KwaZulu–Natal and private farmland in Namibia.

Habitat A quintessential plains antelope preferring open short grassland, and closely associated with *Acacia* savanna. Rainfall averages between 400 and 800 mm across its range. Migratory populations disperse over the arid part of the range during the wet season, and concentrate in higher-rainfall areas with permanent water during the dry season. Prefers well-drained soils with firm footing, avoiding wetlands and waterlogged soil, although their dry season range typically includes extensive areas of black-cotton soil associated with *Acacia drepanolobium*, *A. seyal* and *Balanites aegyptica*. They are rarely found above 1800–2100 m (e.g. floor of Ngorongoro Crater in Tanzania), but may be transient in montane grassland and hilly terrain (e.g. movement between seasonal pastures; Estes & Small 1981, Estes 2002a, Musiega & Kazadi 2004).

Abundance During the late 1990s, the global population was estimated at around 1,298,000 (correcting for undercounting biases in aerial surveys; East 1999), with the migratory Serengeti–Mara population representing about 70% of global species numbers (942,000, having dropped below 1 million following the severe 1993 drought). Other population estimates were: Blue Wildebeest, 150,000 (with about half in protected areas, and one-quarter on private land and conservancies); Cookson’s Wildebeest, 16,000 (about 60% in protected areas); Nyassa Wildebeest, 96,000 (about two-thirds in protected areas, particularly Selous G. R.); and Eastern White-bearded Wildebeest, 94,000 (with about two-thirds in and around protected areas).

The most recent estimate of the total population size of Common Wildebeest is around 1,550,000 (Estes & East 2009), largely due to the rebounding of the Serengeti population of Western White-bearded Wildebeest to about 1,300,000 (Thirgood *et al.* 2004); other subspecies populations are estimated at 130,000 Blue Wildebeest, 5000–10,000 Cookson’s, and 50,000–75,000 Nyassa. However, the latest estimates of Eastern White-bearded Wildebeest indicate a steep decline in the subspecies’ populations to a current level of perhaps 6000–8000 animals. While the Common Wildebeest remains one of Africa’s most abundant game species at present, these figures highlight both the significance of the migratory Serengeti population and the vulnerability of the species to further adverse developments, such as those that

have affected the Eastern White-bearded subspecies during the last decade (Estes & East 2009).

Maximum densities of 35/km² have been recorded in the Serengeti and Ngorongoro Crater populations (Runyoro *et al.* 1995), although the Ngorongoro population density was closer to 55/km² up until 1980 (mean of 14,000/250 km²; Estes 2002a). Elsewhere, population densities estimated by aerial surveys are lower: less than 0.15/km² in areas such as Kafue N. P. (Zambia), Hwange N. P. (Zimbabwe) and Etosha N. P. (Namibia) and the southern Kalahari, to 0.6–1.3/km² in Kruger N. P. (South Africa) and North Luangwa N. P. (Zambia), Selous G. R. and Kajiado (see East 1999).

Adaptations The size, proportions and shape of the Common Wildebeest are all adapted to the species' migratory habits, including the ability to sustain a canter with minimal energetic cost, facilitated by high shoulders and slender legs (Alexander 1977, Pennycuik 1979, Christiansen 2002).

Common Wildebeest have a number of physiological adaptations including the ability to minimize water loss by allowing body temperature to rise in hot weather and by seeking shade (Taylor 1970a, Ben-Shahar & Fairall 1987). When body temperature rises above ca. 40°C, animals dissipate heat by nasal panting. However, the Black Wildebeest is more heat- and cold-tolerant than Common Wildebeest, and Hofmeyr (1981) found the latter to be at a disadvantage compared with Hartbeest *Alcelaphus buselaphus*, as its thin pelage and dark skin fail to provide significant protection against solar heat gain. In areas

devoid of shade, Common Wildebeest orientate their bodies to minimize insolation; they also face into the wind (Berry *et al.* 1984). Common Wildebeest are considered water-dependent, able to go without drinking for several days on green pasture, but no more than two days while subsisting on dry grass. Daily requirement has been estimated at 10 litres under arid conditions (Taylor 1968b). However, in Botswana's Kalahari Desert, Common Wildebeest go for months without drinking in sandveld areas where local rains have produced abundant plant growth such as tsama melons *Citrullus vulgaris* and tubers (Estes & East 2009). This suggests greater adaptability to environmental conditions than commonly supposed.

The rumino-reticulum of the Common Wildebeest is comparable with that of African Buffalo *Syncerus caffer* or cattle in proportion to size, with average capacity of 40 litres. Its wide muzzle, wide incisor arcade and flexible lips are adapted for non-selective bulk grazing, preferably on grasses in an early growth stage, between 3 and 10 cm, and green with more leaf than stem (Talbot & Talbot 1963, Bell 1970, Hofmann 1973, Gordon & Illius 1988).

Foraging and Food Classed as a variable grazer by Gagnon & Chew (2000) in their review of the dietary preferences of African bovids, and studies using stable carbon isotopes suggest that Common Wildebeest have such a high component of grass in their diet that they are best considered as hypergrazers (Cerling *et al.* 2003, Sponheimer *et al.* 2003b); Hofmann & Stewart (1972) classify them as a fresh-grass grazers dependent on water.

During the wet season in the Serengeti ecosystem, Common Wildebeest concentrate on the highly nutritious, productive short-grass plains, which sustain very high herbivore densities. In the dry season they pursue a rotational-passage grazing system as they move rapidly through medium and tall grassland in search of green pastures (McNaughton & Banyikwa 1995, Wilmshurt *et al.* 1999b). Grasses with the most leaf and least stem are selected. A comparative study of selectivity and feeding rate of Common Wildebeest, Hartbeest and Topis *Damaliscus lunatus jimela* in Serengeti N. P. showed that the Common Wildebeest has the fastest bite rate on swards with low biomass and high protein content of green leaf (Murray & Brown 1993).

Preferences for species and growth stages vary depending on season and availability and in different populations and ecosystems (Berry 1980, Ben-Shahar 1991, Ben-Shahar & Coe 1992, Murray 1993, Bodenstein *et al.* 2000, Ego *et al.* 2003). Shallow-rooted colonial species that carpet the ground are preferred (Bell 1970). Favourites include *Cynodon dactylon* (probably most important overall; Andere 1981), *Brachiaria brizantha*, *Sporobolus marginatus*, *Cenchrus ciliaris*, *Eragrostis superba*, *Digitaria milanjiana*, *D. macroblephara* and small sedges in short grassland (e.g. *Kyllinga*). Many other species are eaten in early growth stages or when preferred decreaser species are rare, such as *Themeda triandra*, *Chloris gayana*, *Pennisetum mesianum* and *Panicum maximum*.

Food availability is often limited in the late dry season following extensive wildfires. Forty years' worth of data collection prove conclusively that the Serengeti population is limited by food supply (Mduma *et al.* 1999). Nomadic/migratory movements are discussed further under Social and Reproductive Behaviour.

Social and Reproductive Behaviour The following account is based mainly on the author's observations of *C. t. mearnsi* in

Common Wildebeest *Connochaetes taurinus albojubatus* head and myology.

Ngorongoro Crater and Serengeti N. P. between 1963 and 2006, supplemented with information from other populations as indicated.

The Common Wildebeest is a highly social species, with a grouping and mating system based on male territoriality. Migratory populations move in vast herds and aggregate in dense concentrations on green pastures. Actively territorial ♂♂ segregate yearling and older non-territorial ♂♂ from ♀♀ and young, making three distinct social classes: female or nursery herds of ♀♀ and young; all-male (bachelor) herds; and territorial ♂♂ – the latter the only class normally ever found alone.

The Common Wildebeest has two related but different dispersion patterns: (a) sedentary/dispersed and (b) migratory/aggregated. The former is representative of most social, territorial antelopes; the latter, derived state is adapted to migratory habits. Depending on environmental variables, one form can change into the other, either way. In the sedentary/dispersed state, nursery herds of ♀♀, calves and attached (mainly female) yearlings occupy preferred grazing grounds, which competing bulls divide into a network of individual territories. The intolerance of breeding (= territorial) ♂♂ keeps bachelors in less favourable, lightly or undefended habitat. Female herds, comprised of 2 to ca. 25 cows and young (with a mean number of ten in Ngorongoro Crater), represent semi-exclusive associations derived from the tendency of ♀♀ with young calves to band together, and also due to durable mother–daughter bonds (which persisted two years in the case of a marked barren mother; Estes 1966). Strangers attempting to join resident herds in the Ngorongoro Crater were generally rejected, chased out by the attendant bull if treated with hostility by the cows. Each herd acted largely independently and remained within a restricted home-range, often less than 100 ha during the wetter half of the year (Nov–May), encompassing the territories of four or five resident territorial ♂♂. Captive migrating ♀♀ kept in a 25 ha enclosure behaved in the manner of resident herds, including establishment of a dominance hierarchy (A. Moss pers. comm.).

In Ngorongoro Crater, as pastures stopped growing after the rains ended, known female herds began to aggregate on the remaining green pastures. At the end of the day, each herd returned to its accustomed home-range (Estes 1966). However, as the dry season intensified, the small herds stayed in aggregations on the remaining greenbelts and within a few weeks apparently lost their separate identity. Nevertheless, when the short rains rejuvenated the Crater pastures, some of the known animals returned to the same home-ranges (Estes 1966, 1969, 1976).

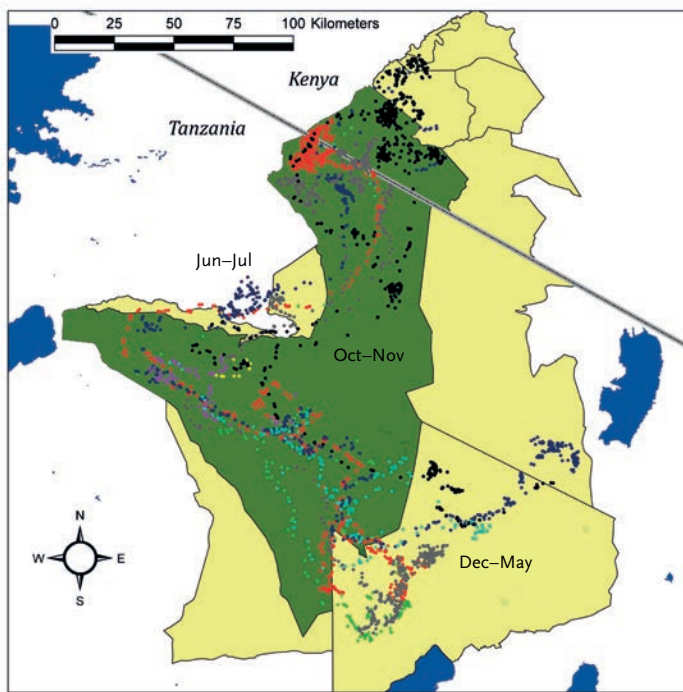

Bachelor herds include ♂♂ of all ages from yearlings to old bulls, with herd sizes ranging from two to thousands, depending on the size of the population and openness of the habitat: the more open the habitat, the larger the herds – as usual in social ungulates (Estes 1974, 1991a). Competition between bachelors is much less spirited than in male herds of Topis, Hartebeest and most other African antelopes (Estes 1969). This relatively unaggressive behaviour contrasts with the behaviour of territorial bulls. Males mature and become territorial at 5–6 years of age (Watson 1969). Rarely, a bull of three years can participate (briefly) in the rut (Estes 1966, 1969). In resident populations, bulls may hold the same territories for years, either continuously or discontinuously, depending on variable grazing conditions and proximity of ♀♀ (Talbot & Talbot 1963, Estes 1969). In Ngorongoro, average spacing between bulls is roughly 60 m in areas frequented by small herds, but even there bulls were alone 80% of the

time (Estes 1969). Except for the rut, territorial competition is most intense early in the rains (Nov/Dec) when rangeland abandoned in the dry season is reoccupied by ♀♀. The fact that mating opportunities are virtually non-existent so near the calving season suggests that the psychological advantage of established ownership promotes year-round occupancy where competition is strong.

Serious fights mostly involve attempts to establish a territory, which territorial neighbours fiercely resist. Rather than contest the territory of an established bull, a newcomer's best strategy is to win rights to a small plot between territories by wearing down the resistance of the neighbours, and then gradually enlarging it. Creating a 'stamping ground' is one of the first acts in laying claim to a space. It is created by pawing, kneeling and horning the ground, defecating, lying and rolling. These bare patches, centrally located and strewn with dung, are the olfactory foci of the territory; there may be several on a property, but usually one where the bull spends most of its inactive time. Female herds when present also frequently rest on the stamping ground. Fights between established bulls are uncommon, but neighbours engage in elaborate daily challenge rituals that serve to reaffirm the fitness of each bull to hold property. The ritual includes mutual urine testing with the vomeronasal organ. Male–male urine testing is highly unusual, as the primary function of this organ in ungulates is to detect female reproductive status through assaying hormone breakdown products in their urine (Estes 1969, 1972, Krieger *et al.* 1999). When a territorial bull leaves his property, he reverts to the status of a bachelor male as soon as he has passed beyond the territories of his immediate neighbours (Estes 1969).

The mobile/aggregated state is adapted to migratory and nomadic movements in extensive savanna ecosystems with a rainfall gradient from ca. 200 to 800 mm. Wilmshurst *et al.* (1999b) found that movements of Common Wildebeest are broadly similar to those of other large herbivores that migrate in response to resource gradients. In Serengeti N. P., the short, colonial grasses found in the lower-rainfall areas are kept growing by frequent rain and fertilized by herbivore concentrations, whose manure is buried overnight by hordes of dung beetles. Equally important, colonial grasses only 2–4 cm high virtually carpet the ground (Bell 1970, McNaughton 1984), unlike the medium and longer grasses in the higher-rainfall areas where wildebeest circulate in the dry season seeking swards of intermediate-height and greenness that offer the optimal combination of bulk and digestibility (Fryxell 1991, Morrison & Bolger 2012). Wolanski *et al.* (1999) suggest that excessive salinity triggers the migration of Common Wildebeest and Plains Zebras off the Serengeti short-grass plains.

Eight Common Wildebeest collared and monitored for 1086 wildebeest days in the Serengeti ecosystem moved an average 4.47 km/day (S.D. 5.26 km, maximum in one day 57.5 km). Daily movements increased from Mar–Jun with a peak in May (Thirgood *et al.* 2004, Hopcraft 2010). The structure and composition of aggregations vary according to habitat conditions, season, time of day, prevailing activity and level of territorial behaviour. The tendency of Common Wildebeest to associate in peer subgroups (see later) means that distribution is not random – which makes sampling to determine sex ratio and recruitment difficult, even though immature age classes are distinct (♂♂ to 3–4, ♀♀ to 2.5 years). Most samples of the Serengeti population suggest an equal adult sex ratio (Watson 1967, 1969, 1970, Sinclair 1979, Mduma 1996), whereas samples of resident populations generally indicate a female bias in the order of 1 : 1.5 or 1 : 2 (R. D.

The annual migratory route of eight female Common Wildebeest *Connochaetes taurinus* in the Serengeti-Mara ecosystem (each series of coloured dots represents the movement of one animal tracked using a GPS collar). Common Wildebeest retreat to the Mara River in the north-west during the dry season, often detouring via the (unprotected) Western Corridor on their way. Green corresponds to Serengeti National Park (Tanzania) and Masai Mara National Reserve (Kenya); yellow corresponds to surrounding buffer zones (map courtesy J. Grant, C. Hopcraft, Frankfurt Zoological Society and the University of St Andrews).

Estes pers. obs.). Common Wildebeest aggregations on the Serengeti short-grass plains are typically dispersed with wide individual spacing. But when feeding in tall swards, aggregations are compact with minimal individual spacing, possibly from fear of Lions *Panthera leo*.

Except during several months of the dry season when territorial activity is attenuated, mature bulls accompanying the migration space out and become active as soon as an aggregation stops moving. In short order they round up ♀♀ and weed out the bachelors, enforcing the same kind of segregation as in resident populations: nursery herds contained in a territorial network with bachelor ♂♂ on the periphery. Such groups have been called 'pseudo-herds', as the association of ♀♀ is merely temporary (Watson 1969). Only cows with young of the year keep together. They begin to separate after nine months, but female and some male yearlings are frequently associated with nursery herds, at least some of which continue to trail their mothers. When on the move in files or columns, both sexes and all ages join together. However, when the movement is halted by an obstacle (river crossing, tall vegetation, defile), bulls come to the forefront and are the first to risk going forward (R. D. Estes pers. obs.). When Common Wildebeest are in tree savanna they cluster in the shade during the hottest hours. At night, aggregations gather on the shortest available grassland and rest/ruminate in 'bedding formations', which may contain hundreds of animals but being linear, with enough separation to permit individuals to move in or out, can disperse immediately when alarmed, as when tested by hunting hyaenas (Estes & Estes 1979).

Territorial ♂♂ are capable of reproducing at any time and for a good six months of the year have continuing but declining mating

opportunities, as some 20% of ♀♀ fail to breed during the rutting peak; a few breed as much as five months later. The onset of the rut is marked by a peak of noise and activity. No other African wildlife event can match the spectacle of the Serengeti rut, which occurs during the migration from the short-grass plains into the woodland zone. An idea of the intensity of sexual competition can be gained from the number of territorial bulls in dense concentrations: up to 250/km² (R. D. Estes pers. obs.). This remarkably close packing of territorial bulls facilitates synchronous breeding of cows in migrating hordes: no ♀ in oestrus is likely to go undetected for long. The rutting uproar continues day and night, reaching a crescendo when aggregations are on the move.

As long as ♀♀ are present, territory holders neither rest nor feed but exert every effort to detain ♀♀, prevent raids by their nearest rivals, and seize opportunities to break up a neighbour's herd. Herding bulls do not engage in challenge rituals, but frequently butt heads. Tightly clustered herds within a network of single bulls is a hallmark of the rut clearly visible from an airplane or hilltop. Considering that up to half-a-million cows are mated during the rut, it is surprising how seldom copulations are witnessed. By far the most effort exerted by territorial bulls goes into herding, chasing and fighting. Their efforts may look, but are not, futile, as having a herd improves a bull's chances of gaining a cow in heat, because ♀♀ suffer less sexual harassment by going into a group rather than stopping with a lone ♂ (R. D. Estes pers. obs.). The more cows a bull encounters, the more mating opportunities. Bulls that establish territories in the main stream of a migrating horde obviously are fitter than bulls with peripheral territories where most passers-by are bachelor ♂♂. Good locations also vary with time of day or night. Bulls under a broad shade tree may have up to 100 ♀♀ and young during the hottest hours while unshaded neighbours have a few or none. Bulls that stay put on territories in a close-cropped, abandoned pasture may be rewarded come evening, when an aggregation returns to spend the night on short grassland.

In the hurly-burly of the rut, it is not unusual for a bull to overlook the presence of an oestrous ♀ in his herd, but having detected one, a bull copulates with her dozens of times, up to three or four mounts with ejaculation in a minute when not distracted by the need to repel invading neighbours. A preference to continue mating with the same bull is shown by ♀♀ in heat, which will follow and even solicit copulation. But if forced to leave, oestrous ♀♀ have been seen to copulate with a succession of bulls until no longer receptive (Estes 1991a). Oestrus lasts at most one day. While the energetic costs of rutting are rigorous for actively competing bulls, interludes when no ♀♀ are in the immediate vicinity enable them to rest and feed. Bulls that have been active over a sustained period may take a day or two off in a bachelor herd (R. D. Estes pers. obs.). Accordingly, the Common Wildebeest rut leaves breeding ♂♂ less spent than ungulates of the Northern Temperate Zone that persevere to exhaustion. However, serious injuries – to hooves, legs, horns, eyes – incapacitate possibly 0.05% of the competing bulls. Those with broken horns can hold their own as long as they have the bosses to absorb the impact of butting. But a bull that has lost a whole horn can no longer stand up to an intact rival. The end of the rut is marked by reduced intensity and volume of calling and by the presence in resting herds of adults of both sexes. The fat deposits bulls accumulate in the months prior to the rut are depleted by the end of it (Sinclair 1977b).

The fact that 80% of the annual calf crop is born within three weeks is linked to the evolution of 'follower young', a key adaptation to the mobile/aggregated state of migratory populations. Apart from the two wildebeest species and the Blesbok/Bontebok *Damaliscus pygargus*, the young of all other antelopes go through a hiding or lying-out stage of varying length. Selection for follower young born in a short time stems from the Common Wildebeest habit of massing on short, green grass. Tan calves are conspicuous among dark-coloured adults. As aggregations rapidly deplete pastures and move on, mothers guarding 'hider calves' adapted for concealment in tall, tan grass would be left behind. Changing to follower young led Common Wildebeest to lose all aspects of the ancestral hider strategy. Calves have lost the hiding instinct and accompany their mothers as soon as they can stand. This takes as little as 3 min (mean of 7 min), and the feeble stage when neonates cannot keep up with a herd is over within about two days (Estes 1976, Estes & Estes 1979). A drastic speed-up in the development of locomotory skills is key to this precocity. Common Wildebeest calves have almost adult muscle/bone length ratios at birth, whereas hider calves have only two-thirds the adult muscle/bone ratio at birth (Grand 1991). Common Wildebeest calves may be the most precocious of all ungulates.

Actual parturition is described in detail in Estes & Estes (1979). Mothers only lick their calves in the first hour postpartum; neonates neither receive nor need the stimulation of anogenital licking to void wastes. Mothers recognize their newborns by scent, and aggressively reject any but their own (Estes & Estes 1979). Calves may be seen to eat dung within a few days, presumably acquiring rumen bacteria. They start sampling grass within a week. Within a day or two mother and calf are mutually imprinted. Calves rest in crèches or lie alone while their mothers feed. Some mothers leave sleeping calves to join wildebeest filing to water. This practice came to light while following Ngorongoro cows returning from drinking, which were acting as though they had lost calves – running and bawling, sometimes joining forces and inspecting every herd with calves. After going some 3 km in this manner, several distraught mothers found their calves – just where they had left them. Up until then, a lone wildebeest calf was assumed to be orphaned and doomed (R. D. Estes pers. obs.) Associative behaviour is manifested within days of birth, in crèche formation and group play (chasing, cavorting, head-butting). Beginning as yearlings, peer subgroups of the same sex and age are discernible even in huge Serengeti aggregations. The annual calving season promotes further subdivisions into groupings of ♀♀ in the same reproductive state. In the months before and after calving the following subgroupings can be observed, in addition to the aforementioned divisions: pregnant ♀♀, maternity groups of cows with calves, non-pregnant ♀♀, and cows that have lost calves (both these often found grouped in male aggregations) (Estes & Estes 1979).

While resting, inter-individual spaces of approximately one metre keep herd members beyond horn reach. Only mother and calf lie in contact. Star-formations can be seen in small herds that enable members to monitor a full 360 degrees. Such circles form through settling back-to-back facing away rather than head-to-head. Bachelor herds can be discerned at a distance by their more regular individual spacing. Rubbing the muzzle or head on the rump or shoulder of another wildebeest, commonest between ♀♀, is also performed during the territorial challenge ritual. It appears sociable, although

these contacts apparently often include depositing secretions of the preorbital glands, which might be an assertion of dominance (Estes 1969, 1991a). Comfort behaviours such as lying down and rolling (rare or unknown in other ruminants) are most commonly seen in territorial bulls (though Common Wildebeest cannot roll over completely like zebras).

Common Wildebeest also have the habit of rubbing their preorbital glands on branches and trunks of trees, usually as the prelude to horning bouts. Olfactory communication is involved, as marking and horning are directed especially at sites that have already been marked and horned; and bouts begin with sniffing of the site. The behaviour is also infectious as Common Wildebeest will line up and take turns rubbing and thrashing the same tree. However, vegetation horning is primarily an activity of adult ♂♂; other animals horn much less often and vigorously. Bouts may last anywhere from 15 seconds or less to as long as five minutes. It is clearly aggressive in character and may either be directed, as in encounters between territorial bulls, or an undirected display of aggressive mood. What is extraordinary and generally overlooked is the environmental impact of Common Wildebeest horning in large populations. Data collected on the incidence and effects of horning beginning in 1979, in 1980–81, 1986, 1998 and 2003 show that on the Serengeti Plains and in tree savanna of the woodland zone two out of three young trees of suitable size and accessibility have been horned, many repeatedly over a period of years. In numerous cases the stems and branches of trees (especially *Acacia* spp. and *Balanites aegyptica*) have been destroyed every time they produced stems of thrashable size; the resulting growth in the case of *A. tortilis*, a dominant tree, is a supine hedge, within which a main stem of up to 10 cm diameter may be found. The evidence suggests that destruction of woody vegetation by Common Wildebeest was second only to fire and elephants in transforming Serengeti savanna woodlands into tree grassland during the 1970s and 1980s (Estes *et al.* 2008).

In undisturbed herds or aggregations of Common Wildebeest, the advertising calls of territorial bulls are the source of virtually all vocalizations. Calling by other classes is common in moving aggregations and consists mainly of exchanges between mothers and their offspring, which reach a crescendo when they become separated, as when massed at waterholes, crossing terrain that funnels many animals close together, or when stampeded by predators. Whereas differences in the advertising calls of *C. t. mearnsi* are discernible from other subspecies, the higher-pitched calls of other classes sound the same. Yet, mothers and dependent offspring recognize one another's calls. It enables nearly all separated pairs to reunite, facilitated by remaining at the separation site and running back and forth bawling (R. D. Estes pers. obs.).

With a dozen or more ungulate species in savanna herbivore communities, the Common Wildebeest inevitably is often found in the same place and time with some of them, especially with other grazers. The Plains Zebra *Equus quagga*, which eats many of the same grasses (Bell 1970, Casebeer & Koss 1970, Ben-Shahar & Coe 1992) is popularly believed to be closely associated, and indeed it is common to find aggregations that include both species. Research on the incidence and basis of association between Common Wildebeest and eight other grazing ungulates (Plains Zebra, Grant's Gazelle *Nanger (granti) granti* and Thomson's Gazelle *Eudorcas thomsonii*, Topi, Hartbeest, Waterbuck *Kobus ellipsiprymnus*, Impala *Aeypceros melampus* and Common Warthog *Phacochoerus africanus*) of the Serengeti

Common Wildebeest *Connochaetes taurinus albojubatus*.

ecosystem found a large overlap in distribution with the Common Wildebeest and that most species were eating the same plants in the same vegetation types (Sinclair 1985). Most species were found closer to Common Wildebeest than expected if distribution was random. In the wet season, 71% of the Plains Zebra population could be found near the main Common Wildebeest concentrations, but on the leading edge where they could graze before the sward was eaten down by the latter. But in the dry season, after migrating to the Masai Mara part of their range, the Plains Zebras avoided inter-specific competition by staying further away from the Common Wildebeest and grazing in taller grassland. The results of this study strongly suggest that the basis of the association is mutual protection against predators. As the Common Wildebeest is the preferred prey of all the large carnivores, the other species are safer in proximity to this most abundant herbivore. The conclusion: 'In general, predation appears to play as important a role as inter-specific competition in structuring this community' (Sinclair 1985: 916; and see Hopcraft 2010). Despite proximity, behavioural interaction and communication with associated ungulates are surprisingly limited. They get out of one another's way and respond to each others' alarm signals, but largely ignore their species-specific displays. Most ungulates react to the alarm signals of other species, including monkeys and baboons, jackals *Canis* spp., oxpeckers *Buphagus* spp. and other birds.

Reproduction and Population Structure The timing of calving and rutting is geared to the climate so that both occur under favourable conditions (Sinclair *et al.* 2000). Onset of the annual rut varies from year to year by as much as three weeks, under the influence of variable climatic conditions. For example, following the great East African drought of 1960, when most cows lost their calves, *C. t. mearnsi* and *C. t. albojubatus* calved two months earlier than normal; Estes 1966). In East Africa, the rut comes after the rains (Jun) when the animals are in top condition, thus ensuring an adult conception rate normally better than 90%. Some ♀♀ breed as yearlings (ca. 20% in the Serengeti ecosystem), but most conceive a year later (ca. 28 months). In the 1960s and 1970s, while the

Ngorongoro and Serengeti populations were increasing at the rate of 10% a year, the yearling conception rate was closer to 80% (Estes 1966, Watson 1969, 1970, Estes & Estes 1979, Sinclair *et al.* 2000).

Research conducted in the Grumeti Reserves bordering Serengeti N. P. in 2002–2004 on 17 captive ♀♀ (Monfort *et al.* 2001) yielded new information about the reproductive physiology of the species (Clay 2007, Clay *et al.* 2010). Regular assays of faecal hormones excreted by each ♀ revealed their reproductive-endocrine rhythms and determined that Common Wildebeest are seasonal, polyoestrous, spontaneous ovulators. The duration of oestrous cycles and luteal phases were quantified, and a gestation period of eight months was confirmed (Clay *et al.* 2010). The average duration of postpartum anoestrus was 100 days. No significant correlation was found between lunar phase and the timing of luteal phases as proposed by Sinclair (1977b). How the oestrous cycles of ♀♀ are synchronized has long been a subject of speculation (Rutberg 1987, Sinclair 1977b, Sinclair *et al.* 2000). A major objective of this study was to test the author's hypothesis that chorusing of bulls, which reaches a peak during the rut, serves this function (R. D. Estes pers. obs.). A month prior to the 2003 Serengeti rut, recordings of rutting calls were played to two groups of captive cows continuously for three weeks, one of which included a bull, while a third control group was kept isolated. Faecal progesterin assays showed that the oestrous cycles of the two exposed groups were synchronized more closely than in the control group. This research provides the first evidence of an auditory cue that modulates reproductive timing in the Bovidae (Clay 2007).

Calving occurs typically ca. two months before the period of most rain and maximum grass production (Talbot & Talbot 1963). Common Wildebeest calving is more tightly synchronized than that of any other African ungulate, comparable to the birth peak of Caribou *Rangifer tarandus* (Dauphiné & McClure 1974). The Serengeti migratory population usually calves in Feb, between short and long rains, but the resident population in the Western Corridor is subject to the wetter climate associated with L. Victoria and calves 1–2 months earlier. In southern Africa, the calving season is generally Nov/Dec (though sometimes later; Attwell 1977), but in

Liuwa Plains, SW Zambia, calving occurs in late Oct to early Nov just before the rains start (Howard & Conant 1983). Calves weigh between 14 and 25 kg at birth, with calves in southern Africa being larger (Talbot & Talbot 1963, Attwell 1977).

Maternal stress is considered to be most severe during early to mid-lactation (Eltringham 1979, Altmann 1980, Murray 1982b). During the abbreviated feeble stage, calf survival depends on the presence of harder-to-catch calves a few days older, which serve as cover for newborns. The more calves in a maternity herd, the higher the calf survival rate. Survival in the first month averages ca. 70% in migratory aggregations vs. 50% or less in resident small herds (Estes 1976). A calf's only defence is its own mother, which is quite effective against a single Spotted Hyaena *Crocuta crocuta* (Estes & Estes 1979). Young of the year begin to form separate groups at about nine months, following weaning at around eight months (Watson 1967). However, some continue to follow their mothers until the next calf crop is born. The potential payoff is that cows that lose calves allow their yearlings to nurse. Estimated calf survival to yearling stage in the Serengeti population in nine years between 1965 and 1994 averaged 22.9% (12.3–35.1) (Mduma 1996, Appendix 2).

Weigl (2005) gives a longevity record for the species in captivity of 24.3 years, which is about five years longer than maximum longevity recorded by Attwell (1977) in KwaZulu–Natal (1982). But the oldest animals recorded in Etosha N. P. were 13–14 years (Berry 1980) and individuals of over 12 years in Serengeti N. P. were considered very old (Mduma 1996).

For information on sex ratios see Social and Reproductive Behaviour.

Predators, Parasites and Diseases Common Wildebeest are typically the preferred prey of Lions and Spotted Hyaenas wherever they occur (Kruuk 1972, Schaller 1972, Elliott *et al.* 1977, Mills & Shenk 1992, Scheel 1993b). The fact that they tend to be the dominant large herbivore in savanna ecosystems may largely explain this preference. But there is also quantitative evidence that wildebeest are less vigilant than most associated prey species, including Plains Zebras, the second most-preferred prey (Scheel 1993b).

Aggregations are easier to approach than singles and small herds, probably because each individual feels and is safer in a large group. Observations of scanning rates showed that rates declined with increasing herd size, including herds containing individuals of different species (e.g. zebras) (Scheel 1993a). Scanning rates were also influenced by light and cover. Common Wildebeest scanned more at twilight and on moonlit nights than during the day. Scanning rate also correlated with nearby cover large enough to conceal hunting Lions. Greater vigilance, as indicated by increased scanning rates, would be expected in bushy habitat and tall grass, but oddly enough, wildebeest scanned less in such places than in more open habitat. Likewise animals in the interior of a group tend to scan less than those on the periphery. This is usually explained by the fact that animals on the outside are more vulnerable (Elgar 1989, FitzGibbon 1990a), but having their view blocked by other animals could explain reduced scanning rates of individuals inside a herd. Similarly, thick cover that renders the ability to detect approaching predators problematic could explain reduced scanning rates in such habitats (Scheel 1993a). Of eight species in the study, Common Wildebeest and Common Warthogs were the least vigilant, and both were preferred by Lions. Hence these species were at greatest predation risk (Scheel 1993b). However, Common Wildebeest and Plains

Common Wildebeest *Connochaetes taurinus* horn development.

Zebras were considered equally vulnerable to Lions in Kruger N. P., and no selection by season or sex was noted (Mills & Shenk 1992).

Although the hunting technique of the Spotted Hyaena is adapted to selecting the most vulnerable individuals, a single adult hyaena is capable of running down and killing a healthy full-grown Common Wildebeest (Wasson 1990). The hyaena's specialization on newborn calves during the calving season is a major factor in maintaining the short peak, as mortality of calves born before the peak is virtually total (Estes 1976). Cheetahs *Acinonyx jubatus* and African Wild Dogs *Lycaon pictus* as well as Lions partake of the birth bonanza. Jackals very rarely prey on wildebeest calves. The birth of thousands of calves during the short peak completely glut the predator market (Rutberg 1987, Ims 1990, Sinclair *et al.* 2000).

The infamous pan-African rinderpest epizootic of the 1890s, a virus transmitted from cattle brought into Somalia around 1887 during the Italian campaign, caused the mortality of up to 90% of the continent's cattle, African Buffalo, tragelaphines *Tragelaphus* spp. and wildebeest. No other livestock or wildlife disease has had such widespread mortality, and the survivors of the rinderpest pandemic, with at least partial immunity, mostly recuperated within one to two decades (Simon 1962). Called the 'yearling disease' because older Common Wildebeest calves were vulnerable to rinderpest in lean years (Talbot & Talbot 1963), rinderpest disappeared from the Serengeti population in 1963 (Dobson 1995). The population then increased five-fold from 250,000 to 1,250,000 by the mid-seventies (Sinclair 1979). Apart from such rare epidemics, studies of Common Wildebeest and African Buffalo suggest that disease rarely kills animals in good body condition. But disease, like predation, can cull animals in poor condition (Sinclair 1977a, Prins 1996). Common Wildebeest are carriers of malignant catarrhal fever (sometimes referred to as 'snotsiekte'), a viral disease fatal to cattle. The Masai have to keep their herds away from the short-grass plains during and after the Common Wildebeest calving season, to avoid pastures contaminated by afterbirths (Homewood *et al.* 1987). Anthrax, an endemic disease of African wildlife (Prins 1996), most prevalent in arid ecosystems, has been implicated as a major cause of the decline of the Common Wildebeest population in Etosha N. P. (Berry 1993). Protecting cattle from foot and mouth disease has been the justification for the veterinary cordon fences criss-crossing Botswana in total disregard of their effects on the wildlife, so that the ruling oligarchy of cattle barons can continue to profit from the European Union (EU) subsidized export of beef to Europe (Williamson & Williamson 1985a, Williamson 1994b; and see Conservation). Cleaveland *et al.* (2005) isolated bovine tuberculosis, caused by *Mycobacterium bovis*, from two of 18 migratory Common Wildebeest samples in the Serengeti system in 2000.

Similarly, healthy animals are hardly affected by external and internal parasites, but can be further weakened when in poor health. Ticks are the most serious external parasites, and botflies (oestrid flies) are common parasites of Common Wildebeest throughout their range (Howard & Conant 1983). Larvae of *Gedoelestia* spp. are typically deposited on the cornea of the eyes, and then make their way to the nasal/sinus cavities via the ocular-cranial route or ocular-vascular-pulmonary route. Larvae of *Oestrus* spp. are deposited in the nostrils. The larvae develop to mature larvae in the sinus cavities and then crawl out to pupate. Botflies do not seem to cause Common Wildebeest any harm, although *Gedoelestia* larvae have been found in the braincase and on the dura mater (Talbot & Talbot 1963, Horak *et al.* 1983b). Horak

et al. (1983b) recovered parasites from 55 Blue Wildebeest in Kruger N. P. and recorded 13 nematodes (particularly *Haemonchus bedfordi*), four cestodes, one trematode, the larvae of five oestrid flies, three lice, seven ixodid ticks, one mite and the nymphae of a pentastomid species (*Linguatula nuttalli*, indicative of the large number of Lions in Kruger N. P., the final hosts of the pentastomid). Remarkably, they recovered very few adult ticks of any species. Only one species, the lungworm *Dictyocaulus viviparus*, was attributed to any ill-effects observed in Common Wildebeest, causing fairly extensive pulmonary lesions, though seemingly not severe enough to cause death.

Conservation IUCN Category: Least Concern. CITES: Not listed.

Reductions in historical geographic range have been relatively minor, with only the elimination of *C. t. johnstoni* from Malawi being perhaps most notable. However, all the major Common Wildebeest populations except the Tanzania populations of *C. t. mearnsi* and *johnstoni* have undergone declines, some by as much as 90%. Fences that blocked migration between wet- and dry-season ranges have had the most obvious impact. Denying access to water and to higher-rainfall refuges during severe droughts have caused mass die-offs. But many other anthropogenic factors have taken their toll: ever-expanding settlement, mechanized agriculture, overstocking with cattle and habitat degradation, elimination of water sources through watershed deforestation and expropriation for irrigation, poaching, bushmeat trade, armed conflicts – and last but not least, game eradication programmes in failed efforts to eliminate the wild hosts of sleeping sickness (nagana) and other diseases of domestic livestock.

The decline in numbers and episodes of mass mortality of Common Wildebeest in Botswana caused by veterinary cordon fences that blocked drought-induced migrations received considerable notoriety, particularly after thousands died at L. Xau in the north-east of the Kalahari Desert in 1980 (Owens & Owens 1980), followed by other large die-offs in subsequent years (Williamson & Williamson 1985a, Parry 1987, Estes & East 2009, Gadd 2012). But Spinage (1992) documents historical evidence that the decline actually began much earlier. Archive records show that there was at one time a significant migration every winter east and south-east from the southern Kalahari to the Molopo R. into South Africa through the unfenced boundary between Tsabong and Khuis (with Common Wildebeest moving as much as 40 km per day). Wildebeest here were once so numerous that they were regarded as a menace by local farmers because they competed with local cattle for grazing and transmitted malignant catarrhal fever. Large-scale killing of Common Wildebeest followed, at least until 1961, when the species was classified as a game animal that could only be hunted with a licence.

Fencing of national park boundaries caused Common Wildebeest populations to crash in Kruger N. P. (Whyte & Joubert 1988) and Etosha N. P. (Berry 1997). Mechanized farming, cattle ranching and fencing of the Loita Plains wet-season range of the Masai-Mara population of *C. t. mearnsi* led to a decline of 75% between 1977 and 1997 (Homewood *et al.* 2001, Ottichilo *et al.* 2001, Serneels & Lambin 2001, Ogutu *et al.* 2011). Progressive fencing of the Athi-Kapiti Plains keeps reducing the range available for wildlife; the Kitengela corridor between the plains and Nairobi N. P. is now so tortuous that Common Wildebeest rarely come into the park, which was formerly an important dry-season concentration area. Completing the fencing of the park by closing the connection to the Athi-Kapiti Plains is now advocated by many (Cowie 2004).

The migratory population of the Western White-bearded Wildebeest defines, and is largely conserved in, the Serengeti ecosystem, including Ngorongoro Conservation Area and the Masai Mara National Reserve. Thirgood *et al.* (2004) radio-tracked eight Common Wildebeest during 1999–2000 in relation to protected area status in different parts of the ecosystem, and found that the collared animals spent 90% of their time within well-protected core areas. However, two sections of the migration route – the Ikoma Open Area and the Mara Group Ranches – currently receive limited protection and are threatened by poaching or agriculture. Comparing current Common Wildebeest migration routes with those recorded during 1971–73 indicates that the western buffer zones appear to be used more extensively than in the past. Thirgood *et al.* (2004) suggest that the current development of community-run Wildlife Management Areas as additional buffer zones around the Serengeti represents an important step in the conservation of this UNESCO World Heritage Site.

The Serengeti migration was seriously threatened in 2010 by the proposed construction of a paved highway from Musoma on L. Victoria to Tanga on the Indian Ocean coast across the northern part of Serengeti N. P. Intended to transport oil, minerals and produce to the coast from landlocked countries to the west and north, this road would have carried thousands of vehicles a day and permitted roadside development along the route, threatening sooner or later to truncate the migration. International outcries by scientists (e.g. Dobson *et al.* 2010; and see Holdo *et al.* [2011], who predicted a decline in the wildebeest population by one-third), conservationists, tour operators, UNESCO and IUCN finally persuaded President Jakaya Kikwete to accept an alternative route south of the Park and to construct only a gravel road across the northern Serengeti, as proposed in the original 2005 plans. However, in Sep 2011, the Minister of Transport announced plans for a railway across the Serengeti along the same route, pledging that, despite opposition, the project will be completed or reach advanced development within the next five years.

Priorities for research and conservation in the future include: (1) identifying, restoring and maintaining access to water and drought refuges for Common Wildebeest, zebras and other water-dependent herbivores; (2) maintaining corridors and dry season refuges, and promoting Transfrontier Conservation Areas (TFCA) that enlarge and protect viable ecosystems; (3) applying pressure from national and international conservation organizations to stop the EU from subsidizing beef exports from Botswana to Europe at above-market prices (Williamson 1994b); and (4) enforcing separation of Black and Blue Wildebeest introduced on ranches in South Africa, Botswana and Namibia to prevent hybridization.

Existing TFCAs of potentially great importance for restoring Common Wildebeest populations to something approaching their former abundance include: the Kavango–Zambezi TFCA, spanning an area of approximately 287,000 km² at the confluence of Namibia, Angola, Zambia, Zimbabwe and Botswana and including the Caprivi Strip, Chobe N. P., the Okavango Delta and the Victoria Falls; the Great Limpopo N. P. connecting Zimbabwe, Mozambique and South Africa, facilitating the doubling of the size of Kruger N. P. by adding an adjoining section of Mozambique and the Gonarezhou N. P. in Zimbabwe; and the Kgalagadi Transfrontier Park, which combines South Africa's Kalahari Gemsbok N. P. with Botswana's Gemsbok N. P. Serengeti wildlife would also benefit from the proposal to incorporate the Mara range in a TFCA. Efforts are also under way to

link Selous G. R. in STanzania with Niassa G. R. in N Mozambique via Selous–Niassa Wildlife Corridor. Another promising conservation initiative is establishment of private wildlife conservancies adjoining and extending protected areas, as exemplified by Sabi Sand G. R., and the Timbavati and Klaserie Private Nature Reserves on the western boundary of Kruger N. P.

Richard D. Estes

Tribe HIPPOTRAGINI

Horse-like Antelopes

Hippotragini Sundevall, 1845. Öfversigt. Kongl.-Vetensk. Akad. Förhand. for 1845, parts 2 and 3, p. 31.

Beisa Oryx *Oryx beisa* myology.

Beisa Oryx *Oryx beisa* skeleton.

Hippotragini are large, barrel-bodied antelopes with long, slender and well-annulated horns, long ears and broad, heavy hooves (with well-developed pedal glands on all four feet). The tribe is represented by six extant African species in three genera, *Hippotragus*, *Oryx* and *Addax*, and a seventh species (the Arabian Oryx *Oryx leucoryx*) in Arabia. Four of these are desert or near-desert species, and the morphology of both fossil and living forms confirms the common ancestry of all hippotragines and the likelihood of an early accommodation to heat, desiccation and a marked trend towards grass-eating (Gentry 1978). False hooves are particularly well developed in the oryxes and the Addax *Addax nasomaculatus*. The coat is sleek, in various shades of tan, white and black and the face is striped rather like a goat or gazelle. The thick, tapering necks and mane earned these antelopes their tribal name Hippotragini, which means 'horse-goat'. Sexes are similar, but males are heavier and have thicker horns. Preorbital glands are absent, although they are vestigial in some species (for example, in *Hippotragus* and Scimitar-horned Oryx *Oryx dammah*); inguinal glands are absent. Pedal glands are present on all four feet. Females of all species have two pairs of inguinal nipples.

The earliest hippotragine fossils are difficult to separate from the earliest caprines and the earliest alcelaphines (Gentry 1978), which is consistent with the three tribes emerging from a common stock during the early Miocene (Hassanin *et al.* 2012). Fossils from India and Europe indicate that hippotragines were once more widespread and might even have penetrated Africa from a Eurasian source (Simpson 1953, Gentry 1978, both authors who allied this tribe with the preeminently Eurasian Bovinae, whereas

Kingdon [1982] associated hippotragines with caprines). Molecular studies have confirmed a relationship with Caprini, but suggest an even closer affinity with the Alcelaphini (e.g. Gatesy *et al.* 1997, Matthee & Davis 2001, Hassanin & Douzery 2003, Hassanin *et al.* 2012). As for geographic and ecological origins, incipient deserts in mid-Miocene North Africa or even outside Africa are possible centres of endemism or evolutionary origin. In as much as caprines almost certainly originated in Asia, there could also be a continental dimension for Hippotragini, fossils of which were first found in Eurasia and might signify a non-African emergence, possibly as the larger-bodied, lowland branch of a proto-Caprine lineage (Kingdon 1982). An early accommodation by ancestral hippotragines to cooler, drier climates (and more grass in their diets) might have begun during a marked trend towards global cooling and increasing aridity in Africa at about 14 mya (Cerling *et al.* 1997a, Retallack 2001, Zachos *et al.* 2001).

Because deserts make considerable demands on the physiology of any animal it is certain that such adaptations were acquired incrementally by the ancestors of Hippotragini. Lineages that have a head-start in any set of favourable adaptive traits tend to retain their advantages in suitable habitats. In the case of other Antilopinae lineages, adaptations to drought were first made by small-bodied animals at around the Oligocene/Miocene boundary, but there is no certainty that the immediate ancestors of Hippotragini were as well suited. Indeed, Kingston & Harrison (2007) have shown that Pliocene Hippotragini were still less than wholly committed to a grass (C4) diet than the contemporary species. None the less, it seems likely

Tentative phylogenetic tree for Hippotragini (modified after Hassanin & Douzery 2003 and Hassanin *et al.* 2012).

that the hippotragine trend towards large-bodied grazers coping with desiccation might have begun in the mid-Miocene, either in North Africa or neighbouring areas of western Asia.

This period well preceded the divergence between *Hippotragus* and *Oryx*, which has long been known to have been early (Kingdon 1982), but molecular studies have now narrowed this divergence down to the mid-Miocene (approximately 10.5 mya) followed by a surprisingly early divergence (8.5 mya) between *Hippotragus niger* and *Hippotragus equinus* (Hernández Fernández & Vrba 2005). By 10.5 mya, hippotragines must have been well established in Africa and a predominantly northern African focus for proto-*Oryx*/*Addax* and a southern focus for proto-*Hippotragus* would seem likely. This was a particularly benign period (also marked by a major exchange of fauna with Eurasia), but a dry south-west African focus would have already existed. It is therefore very interesting that a recently extinct hippotragine, the Bluebuck *Hippotragus leucophaeus*, shared characteristics of both the Roan and Sable Antelopes, but was smaller than either of them. This relic species survived in the Cape of Good Hope, a dry but cool region, until 1779. Its affinities were closer to *H. equinus* than to *H. niger* but it seems to have retained more generalized features than either. It may also be significant that Sable Antelope populations have been found to have the greatest intra-specific genetic diversity known for any mammal (more than 18% of divergent maternal ancestry, Pitra *et al.* 2002), with almost imperceptible differences in general morphology. Perhaps this level of genetic divergence has been influenced by a lineage history of more than 8 million years since the *H. niger* lineage diverged from the morphologically very similar *equinus/leucophaeus* lineage.

It is significant for our broader understanding of hippotragine evolution that the 8+ mya split between *H. niger* and *H. equinus* (if the molecular clock calibration is correct) took place a mere 2 million years after the probable north/south split between proto-*Hippotragus*

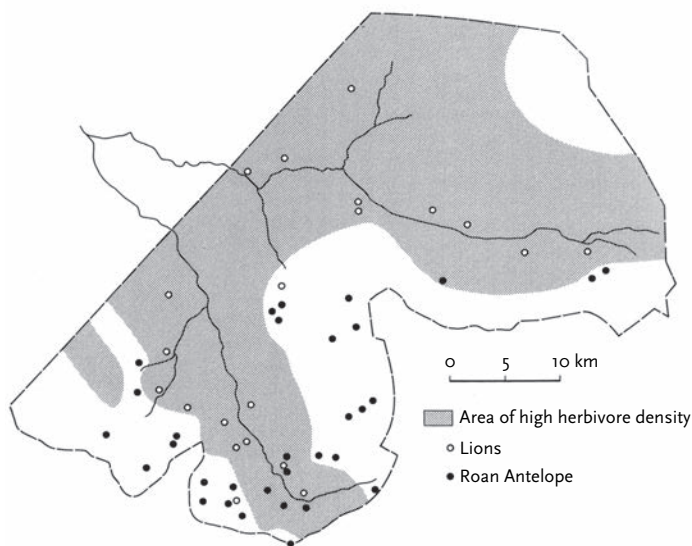

TOP: Facial myology of Sable Antelope *Hippotragus niger*.

and the proto-*Oryx*/*Addax* lineage. This is consistent with benign conditions having continued over much of tropical and southern Africa during the late Miocene, but this ended with the closing of the Straits of Gibraltar and the beginning of the Messinian (6.5–5.3 mya), when the Sahara Desert first spread over the whole of northern Africa. Before the Messinian was over, at least two hippotragine lineages of true desert antelopes had evolved, but the ancestors of *Addax* were clearly the earliest and best equipped large herbivore to have adapted to the very driest conditions of the Sahara. This left *Oryx* to find a slightly less extreme niche across a wider range of deserts and desert fringes. *Oryx* species differentiated during other periods of intense aridification in the late Pliocene and Pleistocene. Ancestral Gemsboks took advantage of one of these arid periods in the later Pleistocene to colonize south-west Africa by means of an arid corridor that connected Somalia with the Namib and Kalahari deserts.

Today, Hippotragini are broad-spectrum grazers with broad, heavily crenellated teeth, well adapted to cope with tough foods (see Figure above). Their selection of food plants also shows few signs of being particularly specialized. All hippotragines, but most subtly, *Hippotragus* species, have specialized in exploiting zones with an impoverished fauna and flora. Their narrowed choice, even within

Map of Kidepo Valley N. P. showing area of high herbivore density with records of Lions *Panthera leo* and Roan Antelopes *Hippotragus equinus* over 23 months (Kingdon 1982 from data collected by I. Ross).

the tropics, is marked by an attachment to particular localities in which they build up intimate knowledge of large home-ranges (which includes systematic avoidance of areas with numerous predators and competitors). Rigours of the environment are often sufficient to explain why *Oryx* occupy areas with few other herbivores, but this is insufficient to explain why Roan and Sable Antelopes also shun apparently suitable areas in spite of rainfall being relatively high and plant productivity also being good, even if seasonal. Powerful, long-horned hippotragines are certainly not excluded from pastures by aggression from competing species, so their apparently voluntary spatial restriction must be guided by environmental clues that are not readily apparent to a human observer. It has been demonstrated, in several localities, that Roan, Sable and Beisa *Oryx* *Oryx beisa* avoid areas with high densities of other herbivores (Kingdon 1982). Why should hippotragines be limited to small localities or discontinuous vegetation belts in which the density of other herbivores is markedly lower than in neighbouring areas? Early studies of predation revealed that Roan and Sable Antelopes were disproportionately susceptible to predation by Lions *Panthera leo*, even when their numbers were already low (Pienaar 1969a, Harrington *et al.* 1999, McLoughlin & Owen-Smith 2003). Likewise, Beisa *Oryx* time their visits to water

Dry season visits to artificial waterholes in Tsavo N. P. showing temporal separations between Beisa *Oryx* *Oryx beisa* and carnivores. Arrows indicate peaks of visits (from Ayeni 1975).

to coincide with least likelihood of predator activity (Ayeni 1975). In Kidepo Valley N. P., Uganda, Roan Antelopes very seldom intruded into areas with a high density of grazers and, concomitantly, such areas supported numerous Lions. Thus, over a two-year period, Roan consistently preferred drier, better-drained ground where both predators and potential competitors were fewer (see Kingdon 1982). This suggests that predation can be the decisive force in shaping habitat-choice for vulnerable species and that food resources, as well as direct competition for those resources, may be less influential in determining local dispersal over the landscape. The role of predation in selecting for detailed and species-specific patterns of habitat-choice may be operating at both the direct, ontogenetic level as well as at a genetic level. In the first instance, direct attrition as a result of sustained predation could bring about such patterns. In the second instance, survivors could have been selected for their ability to choose habitat in response to a wide variety of environmental clues that, over many generations, effectively reduced their chances, or their offspring's chances, of being taken by a predator.

Behaviour, modes of communication, social structures, ecological dispersal patterns and anatomy have probably all been influenced by an ancestral exposure to dry impoverished habitats. Young animals, once emerged from their 'hider' phase, are exceptionally social and active. They spend much of their time playing or rushing around with stylized gaits, horning objects or mock-fighting. Hippotragines are unusual in that the ♀♀ have horns that are as long as those of the ♂♂. Female social units tend to have closed membership and horns provide them with the means of excluding outsiders from scarce resources and resisting any attempts by ♂♂ to limit their movement or threaten their offspring.

Hippotragines pose special challenges for conservation, not least because of their extensive ranges. As agricultural and 'development' interests continue to excise, diminish, constrict or obliterate conservation areas, many local populations will be extirpated, as has already happened in many areas.

Sable Antelope *Hippotragus niger kirkii* adult male.

GENUS *Hippotragus*

Roan and Sable Antelopes

Hippotragus Sundevall, 1845. Öfversigt. Kongl.-Vetensk. Akad. Förhand. for 1845, parts 2 and 3, p. 31.

Polytypic genus with two extant species: the Roan Antelope *Hippotragus equinus*, in both savanna woodlands and grasslands of sub-Saharan Africa, and the Sable Antelope *Hippotragus niger*, confined to the southern savanna regions of Africa and, more particularly, to the miombo (*Brachystegia* dominated) woodlands.

Judging from their relatively abundant representation in Pliocene fossil beds, *Hippotragus*, or its close allies, were more common then than they are today and, supposedly, more ecologically diverse. For example, a very large type of Roan Antelope, *H. gigas*, is known from Sterkfontein and other late Pliocene deposits and a closely related genus, *Praedamalis daturi*, is known from upper Pliocene beds at Laetoli (Kingston & Harrison 2007). These authors have attributed the apparent decline of *Hippotragus* and hippotragines to competition from more recently evolved grazers, notably alcelaphines, but the susceptibility of *Hippotragus* to predation can only have accelerated the decline of this genus and could be the single most significant factor defining the ecological niche of *Hippotragus* within the African antelope spectrum (Kingdon 1982). Roan and Sable Antelopes are subject to less predation in the miombo woodlands they occupy, while also minimizing competition with the diverse array of other large grazers that live in surrounding savannas (see discussion in Sable profile under Adaptations). Likewise, other members of the tribe escape competition by occupying the most arid habitats.

When the carbon profiles of teeth from eight hippotragine specimens from Pliocene beds at Laetoli were compared with those of contemporary *Hippotragus* (and *Oryx*), the living species were confirmed to be unambiguously grass-eaters, with predominantly C₄ diets, whereas the Pliocene species were all much less exclusively C₄ dominated, indicating that they were mixed feeders, relying more on C₃ browse than contemporary species (Kingston & Harrison 2007). That carbon profiles may reflect the gross diet but fail to show up some subtleties of actual foraging patterns should, however, be borne in mind. For example, in his studies of Sable Antelopes in several localities, R. D. Estes (pers. obs.) has found that during the dry season animals eat quite a lot of foliage and forbs. Even so, the findings of Kingston & Harrison (2007) clearly reveal differences that could be interpreted in more than one way: (1) the fact that the fossil samples come from Pliocene populations could be indicative of a wider spectrum of dietary types within *Hippotragus*; (2) a preponderance of C₃ browsers in the Pliocene samples could be taken as evidence for less grass-dominated habitats; and (3) the fact that several tribes of the Antilopinae, notably Hippotragini, Alcelaphini and Reduncini, have all become progressively more and more specialized for grass-eating strongly suggests a phylogenetic dimension. It seems likely that the three explanations may all be correct and are probably not easily disentangled.

Although Roan and Sable Antelopes are the sole survivors of this genus, the now extinct Bluebuck *Hippotragus leucophaeus* was a relict species, which lived along the south-western coast of the Cape Province from about Caledon to Plettenberg Bay (Ansell 1972, Meester *et al.* 1986). Considered by Haltenorth (1963) to be a dwarfed subspecies of Roan Antelope, molecular studies have placed the divergence

Roan Antelope *Hippotragus equinus* skeleton.

between *H. leucophaeus* and *H. equinus* in the region of 3 mya (Hernández Fernández & Vrba 2005). This molecular clock dating suggests that gigantism in the *H. equinus* lineage arose after this divergence. The delicate build, smaller size and peculiar colouring of *H. leucophaeus* could represent morphological responses to the impoverished or chemically peculiar soils of the Cape or they could signify conservative retentions in a formerly more widespread precursor within the ancestral lineage of *H. equinus*. The last individual Bluebuck was shot around 1800, the first African antelope to be hunted to extinction by European settlers (Klein 1974). Detailed reviews of the species are provided by Mohr (1967) and Klein (1974), and see Smithers (1983) for a synopsis.

Of special interest are recent revelations of hybridizations between Roan and Sable Antelopes in Kruger N. P., South Africa (Estes & Whyte 2006) and the discovery that several members of the Giant Sable herd in Cangandala N. P., Angola, are clearly hybrids sired by a Roan Antelope bull (Vaz Pinto 2006). A major question, and one that is of crucial importance for the conservation of *Hippotragus* species, is whether Roan–Sable hybrids are viable. While Robinson & Harley (1995) have described such hybrids as viable it is the genetic details that matter. The lineages of *H. niger* and *H. equinus* are estimated to have remained separate in spite of having maintained partially sympatric ranges for at least a portion of their estimated 8.5 million year existence as separate lineages (as determined by molecular clock, Hernández Fernández & Vrba 2005). This reinforces the urgent need to study the genetics of currently known hybrids to determine whether any danger exists that they might contaminate the *H. niger variati* genotype, a potential catastrophe for this very distinctive population that is already on the brink of extinction.

Richard D. Estes & Jonathan Kingdon

Hippotragus equinus ROAN ANTELOPE

Fr. Hippotrague rouan; Ger. Pferdeantilope

Hippotragus equinus (É. Geoffroy Saint-Hilaire, 1803). Cat. Mamm. Mus. Nation. Hist. Nat. p. 259. 'Inconnue'; now thought to be South Africa, Western Cape Prov., Plettenberg Bay (Grubb 1999). For dating the name to É. Geoffroy Saint-Hilaire, 1803 see Grubb (2001b, 2004, 2005).

Roan Antelope *Hippotragus equinus*.

Lateral and palatal views of skull of Roan Antelope *Hippotragus equinus*.

Taxonomy Ansell (1972) distinguished six subspecies, based primarily on morphology. Matthee & Robinson (1999b) analysed the mitochondrial DNA population structure of 13 samples representing four of Ansell's subspecies (*H. e. equinus*, *H. e. cottoni*, *H. e. langheli* and *H. e. koba*) and confirmed the existence of at least four, well-delineated maternal clades (of course, mtDNA relates only to maternal lineages). Subsequently, Robinson & Alpers (2001) investigated both mtDNA and nuclear DNA patterns (via microsatellites), and greatly expanded the sample database from the earlier work. Their results distinguished several geographically defined genetic groupings. First, there is a clear genetic separation, both mitochondrial and nuclear, of the western African assemblage (based on samples from Benin, Ghana and Senegal). This group is referable to Ansell's *H. e. koba*. Second, three other assemblages are recognized: the north-eastern assemblage with N Tanzania, Kenya and Uganda; the south-eastern assemblage with Zimbabwe, Zambia, Malawi and S Tanzania; and the south-western assemblage with Namibia, Botswana and South Africa (the 'Kruger National Park lineages' are not included in this assemblage because of probable previous genetic mixing with animals from elsewhere). Third, the authors reported that Ansell's *H. e. charicus* (from Nigeria, Cameroon, Chad, Central African Republic) should not be considered part of an eastern and southern clade, nor of the western clade. It seems that there is still no definitive support for a central clade, which *H. e. charicus* and *H. e. bakeri* (from Sudan)

might belong to. With the exception of *H. e. koba* representing the western African assemblage, there is no exact correspondence between Ansell's subspecies and results based on DNA. Other Roan populations form a geographically diverse assemblage with no clear genetic correspondence between subspecies. Alpers *et al.* (2004) distinguish two evolutionarily significant units (per Ryder 1986) for the Roan: the western African group, and a 'rest-of-Africa' group (including *cottoni*, *equinus* and *langheli* subspecies), but noted that more work is needed to clarify the status of *charicus* and *bakeri* subspecies.

Synonyms: *aethiopica*, *aurita*, *bakeri*, *barbata*, *charicus*, *cottoni*, *docoli*, *dogetti*, *gambianus*, *jubata*, *koba*, *langheli*, *rufopallidus*, *scharicus*, *truteri*, *typicus*. Chromosome number: $2n = 60$ (Robinson & Harley 1995). Despite very different phenotypes, and subtle differences in chromosomes (Fordyce-Boyer *et al.* 1995), the Sable *Hippotragus niger* and Roan Antelope are genetically close enough to produce viable hybrids (Robinson & Harley 1995; see Estes & Whyte 2006, Vaz Pinto 2006, and *Hippotragus niger* species profile for further discussion).

Description Large-sized antelope, the second tallest after the Common Eland *Tragelaphus oryx*, and third heaviest after the Common Eland and the Bongo *Tragelaphus eurycerus*. Horse-like body-shape with short, stiffly erect, greyish-brown mane edged with black extending from neck to withers. Pelage uniform sandy-fawn, or light reddish-fawn to grey, or dark rufous. Conspicuous facial mask with striking colouration comprising white parts on cheeks, muzzle, chin and on two oblique and parallel stripes along each eye, contrasted against deep dark black background. Face pattern varies both individually and regionally, with black markings more extensive in

north, and light markings in south. Black patches of facial mask become greyish with age, even turning whitish in very old individuals. Ears long and narrow and terminate in tufts 3–5 cm long. Shoulders higher than hindquarters. Legs long and hooves large; false hooves prominent. Tail reaches heels, with black tassel on lower half. Preorbital glands are vestigial and there are pedal glands on all feet; inguinal glands are absent.

Both sexes have paired ringed horns that rise steeply and curve evenly backwards with diverging tips. Horns strongly ridged for most of the length, but tips are smooth. Sexual dimorphism is weak, ♂♂ being only slightly heavier than ♀♀, while horns, head and neck are slightly thicker in ♂♂ than ♀♀.

Geographic Variation As noted above, six subspecies have been identified by Ansell (1972); however, the validity of some of these subspecies is still in doubt, and recent genetic studies have shown that only the western African subspecies (*koba*) constitutes a genetically separate group from those inhabiting the rest of Africa (Robinson & Alpers 2001, Alpers *et al.* 2004).

Western populations:

H. e. koba: Senegal to Benin. General colour pale tawny, although specimens from West Africa tend to be reddish; forehead chestnut in both sexes.

Central populations:

H. e. charicus: E Nigeria, Cameroon, Chad and Central African Republic. No discernible differences with *H. e. koba*.

H. e. bakeri: Sudan. Browner than the other races; forehead blackish in ♂♂, reddish-brown in ♀♀; chest pale, as are ears and front of pasterns.

Eastern and southern populations:

H. e. langheldi: S Sudan, Ethiopia, N DR Congo, Uganda, Kenya, Tanzania, Rwanda, Burundi. General colour pale reddish; forehead reddish-brown in both sexes.

H. e. cottoni: S DR Congo, Angola, Zambia, C and N Malawi, N Botswana. No discernible differences with *H. e. equinus* (see below), except they are redder than other specimens.

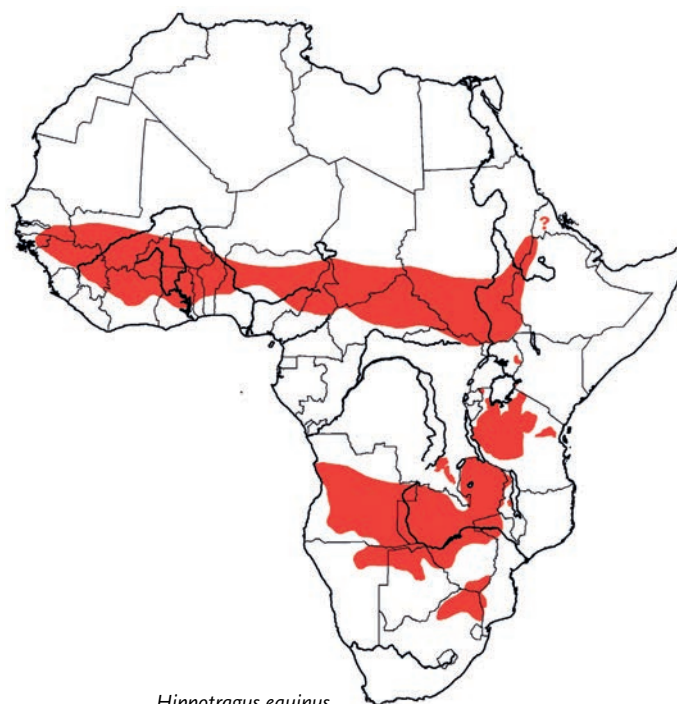

H. e. equinus: Zimbabwe, South Africa and Mozambique. General colour greyish, with forehead black in both sexes.

Similar Species

Hippotragus niger. Sympatric through most of the southern savannas.

These two grazing species tend to remain in different vegetation types, the Sable being a species less of grassland/tree-savanna and more of open miombo woodland. The Sable is smaller on average, characterized by sexually dimorphic colouration – deep black pelage in adult ♂♂ (sorrel to chestnut in ♀♀ and young); horns are longer, commonly exceeding 1 m.

Distribution Endemic to Africa. Formerly one of the most widely ranging of African antelopes, found throughout savanna woodlands and grasslands of sub-Saharan Africa, but now greatly reduced in range (East 1999), though remarkably still locally abundant in parts of West Africa (Poché 1974). Roan were probably present in Egypt until 2000 BC (Osborn & Osbornová 1998).

Historical Distribution In West Africa, Roan Antelopes ranged from C and S Senegal, Gambia, S and E Guinea-Bissau and S Mauritania east through SW Mali, N Guinea, N Côte d'Ivoire, Burkina Faso, Ghana, Togo, N and C Benin, SW Niger, and C and N Nigeria. From there, they ranged eastwards through N Cameroon (from L. Chad to the Adamaoua Plateau), S Chad, Central African Republic and N DR Congo and S Sudan to the western lowlands of Ethiopia in the Sudanian region between latitudes 15 and 19°N; they ranged as far north as the south-western savannas of Eritrea. Southwards they ranged through NE and SW Uganda, S Kenya, Tanzania, NE Rwanda and Burundi to Angola (except in Cabinda and the arid south-west), S DR Congo, NE Namibia, Botswana (where older records evidence that they formerly occurred much further south than they do today; Smithers 1971) and Mozambique (East 1999). In South Africa, an observation dating to 1778 suggests that a population of Roan Antelope formerly inhabited the Western Cape in the vicinity of Plettenberg Bay (consistent with the fossil record), but were likely extirpated from the region during the late 1700s (Faith 2012). In recent times, their range has extended only as far as the bushveld/lowveld regions of the North West, Limpopo and Mpumalanga Provinces, and the Northern Cape.

Current Distribution The range of the Roan Antelope has contracted greatly since the beginning of the twentieth century, and they have been eliminated from parts of their former range surviving mainly in and around protected areas as well as in non-protected areas with low densities of people and livestock (East 1999). A striking feature in the distribution of the Roan Antelope is a clear contrast between West and central Africa, where it remains one of the most common antelopes, and East and southern Africa where it is one of the rarest.

In West and central Africa, its range has contracted in the face of hunting and habitat degradation although the species remains locally common. On one hand, Roan Antelopes have disappeared

from areas lying on the fringe of the typical habitat such as Mauritania, Gambia (where they now occur only as vagrants in the east), N Sierra Leone, N Liberia, C Mali and C Niger; on the other hand, they remain locally abundant in the heart of typical habitat such as SE Senegal, SE Burkina Faso, N Benin, SW Niger, N Cameroon, SE Chad and N and E Central African Republic (East 1999). Dowsett & Dowsett-Lemaire (1989) give Roan Antelopes as occurring in the savanna of Congo, based on records from two localities – Les Grandas and Lefini; however, the species is certainly no longer recorded there.

In East and north-east Africa, the Roan Antelope is extinct in Eritrea and in Burundi, but still survives in W Ethiopia (e.g. in Gambella N. P.) and in SW and SE Sudan (J. O. Heckel pers. comm.). In Kenya, Roan Antelopes are present only in Ruma N. P., where they are entirely surrounded by cultivation (East 1999). In Uganda, East (1999) reported them surviving only in Pian-Upe G.R. They are still widely present, albeit patchily, in Tanzania (notably Biharamulo, Moyowosi, Kigosi, Katavi, Rukwa, Rungwa). In Rwanda, they are restricted to Akagera N. P., although they have been in perpetual decline since the park's boundaries contracted (Williams & Ntayombya 1999, Apio & Wronski 2011).

In southern and south-central Africa, Roan Antelopes are still widely distributed in Zambia, where they survive mainly within protected areas and game management areas, including the Luangwa Valley and Kafue N. P. In Angola, there is limited information, but they are reported to survive in some areas (P. Vaz Pinto pers. comm.). In Malawi, they are now confined mainly to four protected areas in the north and south, with the largest population in the small Nyika N. P. (East 1999). In Mozambique, there are two locations with very limited populations of Roan Antelopes: in the hunting areas of western Tete Province and in Great Limpopo Transfrontier Park (East 1999); there are also plans to reintroduce them to Gorongosa N. P. In Namibia, the present 'natural range' of the Roan Antelope includes the East and West Caprivi Strip, Khaudom G. R. and Nyae Nyae Communal Conservancy. They were introduced to Etosha N. P. in 1970 and to Waterberg Plateau Park in 1975. However, the Kaross area in the west of Etosha, where the main Roan population is located, falls below the 300 mm rainfall isohyet and the population has not thrived (Martin 1983). Roan Antelopes are today confined to the northern savannas of Botswana, while in Zimbabwe they have disappeared from the Highveld but are still present in limited numbers in the Hwange ecosystem, in the mid-Zambezi valley and in patches of the lowveld (East 1999).

The Roan Antelope is among the most threatened antelopes in South Africa. The species still survives in the north of Kruger N. P. (but see later), and has been reintroduced elsewhere, including Marakele N. P. in Limpopo Province. A breeding population of Roan is maintained in Percy Fyfe N.R. in Limpopo Province. Although there is no evidence that Roan Antelopes formerly occurred in KwaZulu-Natal, they have been introduced to reserves such as Weenen and Karloof Nature Reserves (Rowe-Rowe 1994). The indigenous population that formerly occurred in NE Swaziland is extinct, but Roan Antelopes have since been introduced to Mkhaya G. R. (Monadjem 1998).

Habitat The Roan Antelope is usually present in dystrophic (nutrient-poor) savannas, such as miombo woodland, and inhabits

gently undulating terrain of open woodlands and savannas with long grass, low tree density and canopy cover (Pienaar 1963, Joubert 1976, Wilson & Hirst 1977, Dörgeloh 1998a, b, Perrin & Taolo 1999b). Cover of high grasses and woody plants plays an important role for both grazing and calving (Taolo 1995, Dörgeloh 1998a). Calving ♀♀ select habitats with long grass and woody plants, which provide shelter for the newly born calves (Allsopp 1979, Dörgeloh 1998b). The highest densities of Roan Antelopes are found in areas with an average rainfall of around 1000 mm, where soils are mainly infertile and support grazing of low quality. They tend to avoid areas of short grass and woodland where the trees form a closed canopy or where the bush forms thick, closed stands (Heitkönig & Owen-Smith 1998). Permanent water is important. Shrub encroachment seems to have a negative effect on Roan Antelopes (Joubert 1976, Wilson & Hirst 1977), even though they tolerate low shrub growth (Ben-Shahar 1990).

In Comoré N. P., Côte d'Ivoire, Roan Antelopes are notably present in woodlands during the wet season. They do not cover great distances, but range over different types of altitude and vegetation depending on the season. At the beginning of the wet season they leave the plains bordering the rivers and migrate towards higher areas, where they are frequently observed in the open woodlands (Steinhauer-Burkart 1987). In Bouba Ndjida N. P., N Cameroon, situated in the savanna woodland belt and receiving an average annual precipitation of 1200 mm (falling mainly from May to Oct), Roan Antelopes occur in *Terminalia laxiflora* wooded savanna. The trees of this habitat do not exceed 3 m in height and grass cover consists mainly of tall perennial Andropogoneae. These grasses grow up to 3 m high during the wet season and constitutes the principal forage for the majority of large herbivores. Roan occur to a lesser extent in the *Isoberlinea doka* savanna woodland, but seem to avoid fringing forest (Van Lavieren & Esser 1979). In Bénoué N. P., Cameroon, Roan Antelopes prefer *Burkea-Detarium* open savanna rather than *Isoberlinea* woodland and *Anogeissus* riparian forest during the dry season. During the wet season, *Burkea-Detarium* open savanna is still the preferred habitat, but they also occur in *T. laxiflora* and *T. macroptera* open savannas (Stark 1986b). In Zakouma N. P., Chad, Roan often occur in the Combretaceae wooded savannas (52% of observations) or in the *Acacia seyal* savannas. They are less frequently observed in more open areas (Dejace *et al.* 2000). In Kenya's Lambwe valley, Allsopp (1979) observed that Roan selected open *Themeda/Setaria* grassland, and never observed them in *Hyparrhenia* grassland or in dense continuous thickets.

In the Waterberg region in Limpopo Province, South Africa, part of the moist savanna biome dominated by woody plant species such as *Terminalia sericea*, *Burkea africana* and *Combretum* spp. and characterized by abundant and perennial water-courses and rivers, Roan Antelopes occupy an area of flats with sandy acidic soils and low rock cover. They also venture onto rocky slopes further away from water resources (Ben-Shahar 1990). In Kruger N. P., favoured habitat is on slightly undulating land consisting of heavy clay soils derived from basalt; hillier areas on clay-loam soils derived from dolerite are also used to a lesser extent (Joubert 1976).

Abundance East (1999) estimated the total population of Roan Antelopes at about 40,000, although correcting for undercounting bias in aerial surveys gives a slightly higher estimate of 76,000 animals,

of which 60% occur in and around protected areas. According to East (1999), the largest populations survive in Burkina Faso (>7370), Cameroon (>6070), Zambia (>5080) and Tanzania (>4310). Winter (1997) noted that more than 50,000 Roan Antelopes survived in S Sudan in the 1970s, including 4100 in the Jonglei region and 2000 in the Boma region. Spinney (1996) commented that Roan Antelopes in Sudan survived locally in relatively stable numbers. During recent surveys conducted during the dry season of S Sudan, only 21 individuals were counted in Southern N. P., with a small group sighted in the Jonglei and two other sightings in Boma N. P. (Fay *et al.* 2007).

Historical accounts indicate that the Roan Antelope was extremely rare in certain localities but could reach considerable densities in areas where environmental factors were favourable, for example in parts of West Africa (Poché 1974). Densities vary greatly across their distribution, but the average density is quite low (Wilson & Hirst 1977). In natural conditions, the density does not exceed 4/km², even in areas where nutrients are not deficient (Wilson & Hirst 1977). But under intensive management, Roan Antelopes may be stocked at high densities of up to 20/km² (Dörgeleh *et al.* 1996). For example, in Nylsvley N. R. (South Africa) density could reach about 8/km² (Dörgeleh 1998b). Effective management could explain why, in the 18 years preceding 1992, the Roan population in South Africa grew at approximately 1% per year. The result of the national inventory in 2001 was 1237 animals.

Aerial surveys provide estimated population densities of 0.007/km² in Kruger N. P. (Kröger & Rogers 2005), 0.2–0.6/km² in Pendjari N. P. (Benin) (Chardonnet 1995, Rouamba & Hien 2002), and 0.8–1.5/km² in Pama–Arly–Singou (Burkina Faso) (Lungren *et al.* 2004). Aerial surveys of Arly N. P., where the species is common, have produced densities of 1.1/km² (Barry & Chardonnet 1998) and 0.34/km² (Bouché *et al.* 2004). Aerial surveys of Bouba Ndjida N. P. gave a density between 0.2 and 0.6 herds/km² with a mean herd size between 4.2 and 6.9, producing a total population size estimated at 4114 (Van Laveren & Esser 1979).

Ground surveys provide densities ranging from 0.03 to 0.10/km² in areas like Manda N. P. (Chad) (Chai 1996), Comoé N. P. (Fischer 1996, Fischer & Linsenmair 2001a) and Dinder N. P. (Sudan) (Hashim *et al.* 1998). In Waza N. P., where Roan densities have been monitored over several decades, they declined from 2.4/km² (1960s, following 20 years of above-average rainfall and effective protection) to 0.7/km² (mid-1990s, following droughts and transmission of disease by livestock) to 0.2/km² (early 2000s, following increased poaching) (Scholte *et al.* 2007). In Konkoumbouri Hunting Area (Burkina Faso), density was 3.9/km² (Bouché & Lungren 2004), which is considerably higher than the density of 0.27/km² recorded in the same area based on aerial surveys (Bouché *et al.* 2004).

Adaptations Roan and Sable Antelopes share common arid-adapted ancestors with other hippotragines. These ancestors came from North African or western Asian biomes (Kingdon 1982) and probably came to occupy both northern and southern savannas following a dry period in the mid-Miocene (Hernández Fernández & Vrba 2005). Since semi-arid savannas were already occupied by several ungulate species, it is possible that *Hippotragus* had to adapt themselves to broad-leaved deciduous woodlands and grasslands of the mesic savanna that were freer from large herbivore competitors.

Changes contingent on latitudinal shifts probably had consequences for their social organization: territoriality in ♂♂, traditional home-ranges for herds of ♀♀, spatial segregation of bachelor ♂♂. Habitat changes were accompanied by morphological changes such as lengthening of the head and an increase in gape and the incisor–molar diastema, changes presumably well adapted for feeding on tufted perennial grasses. It has been suggested that the Roan Antelope's occupation of large home-ranges, dependence on water and relatively slow gait might all be symptomatic of derivation from a still larger, giant-sized ancestral stock (Kingdon 1997). Roan kept the typical hippotragine ability to walk long distances daily, which allows them to reach remote feeding grounds beyond the reach of most competitors; furthermore, being less water-dependent than many potential competitors, such as Kobs *Kobus kob*, they have access to good quality forage further away from water and away from other herbivores (with the exception, of course, of the Savanna Elephant *Loxodonta africana*).

Foraging and Food Roan Antelopes are considered to be predominantly grazers, taking only a small amount of browse. In their review of the dietary preferences of African bovids, Gagnon & Chew (2000) classified Roan as variable grazers, while studies involving stable carbon isotope analysis (from southern Africa only) are consistent with observations (e.g. Joubert 1976, Heitkönig 1993) that suggest that grass predominates in their diet (Sponheimer *et al.* 2003b). However, although Joubert (1976) found that browse did not contribute significantly to the diet (less than 5% of total intake), several other authors have mentioned that browse could play an important role during critical periods of the year, especially in the late dry season (Poché 1974, Wilson & Hirst 1977). In Zimbabwe, Child & Wilson (1964) showed that Roan Antelopes used to feed from browse plants such as *Diplorhynchus mossambicensis* (leaves), *Capparis tomentosa* (leaves), *Piliostigma thoningii* (fruit), *Diospyros kirkii* (fruit), *D. mespiliformis* (fruit) and bamboo (flowers). Schuette *et al.* (1998) studied the diet of Roan Antelopes in West Africa by means of microhistological analysis of faeces and found that Roan Antelopes switched from being predominantly grazers (>95% grass) in the wet season to mixed feeders (<50% grass) in the dry season.

Several studies, especially in South Africa, have shown that Roan Antelopes are quite selective, feeding only on a restricted number of grass species that represent as much as 90% of the year-round diet (e.g. Joubert 1976, Wilson & Hirst 1977, Heitkönig 1993, Dörgeleh 1998a,b, Perrin & Taolo 1999a), and remain so even under stressful conditions (Wilson & Hirst 1977). Studies in Kruger N. P. have found that these antelopes appear to be ecologically separated from common grazers where they feed selectively on tall grasses growing in the drainage line grassland during the critical dry months (Knoop & Owen-Smith 2006). Roan usually prefer inflorescent tips of mature grasses ranging in height from 5 to 30 cm, and favour taller and ranker perennial grasses. In Kruger N. P., Roan Antelopes selectively graze patches of nutrient-rich grasses (Wilson & Hirst 1977, Senft *et al.* 1987, in Kröger & Rogers 2005) in the boundary between savanna and wetland (Kröger & Rogers 2005). The greatest contributor to the diet throughout the dry and wet seasons is *Themeda triandra* (Joubert 1976). Other grass species most consumed in the dry season are *Eragrostis curvula*, *Melinis* spp., *Panicum maximun* and

Sporobolus fimbriatus, and during the wet season, *Hyparrhenia* spp. and *Heteropogon contortus*. Roan Antelopes would occasionally browse on trees and shrubs, particularly *Colophospermum*, *Grewia*, *Thylacium*, *Lonchocarpus* and *Kigelia*.

In the Nylsvley N. R., in South Africa's Limpopo Province, a spatial segregation exists between the breeding herd and bachelor ♂♂. During the wet season (Oct–Mar), breeding herds select the lower floodplain and the *Eragrostis pallens*–*Burkea africana* savanna where the mean grass height is the highest (around 45 cm). Selection of flood-plains may be partly explained by the fact that they contain higher levels of sodium than any other plant community (Dörgeleh 1998a). However, the drying of the floodplain in autumn with a corresponding decrease in forage quality and availability forces the Roan Antelope to move away. During winter (dry season, Apr–Sep) breeding herds select the *Aristida bipartita*–*Setaria sphacelata* grassland where there are large amounts of forage and a high calcium content for pregnant and lactating ♀♀ (the southern winter is the calving and lactating season, a period when ♀♀ have to maximize their intake of quality food to avoid calcium deficiency). Adjacent grassland dominated by *Tristachya rehmannii*–*Digitaria monodactyla* and the *Rhus leptodictya*–*Combretum apiculatum* complex were selected to a lesser extent (Dörgeleh 1998a). *Eragrostis pallens*–*B. africana* savanna is utilized to a large extent and may serve as a calving area in winter where the long grasses (mean = 48.3 cm) and woody plants (mean = 45.4%) provide cover for the newborn calves. Bachelor ♂♂ usually occur in suboptimal habitats, consisting of plants of low forage quality and high woody plant densities (Allsopp 1979, Esser 1980, Dörgeleh 1998a). Bachelor ♂♂ use the flood-plain in both summer and winter, and *Cymbopogon plurinodis*–*Combretum apiculatum* communities during winter (Dörgeleh 1998b). Differential utilization of plant communities between seasons as a consequence of reduced forage quality and palatability during the dry season has also been recorded in Dinder N. P. (Sudan) (Hashim 1987) and in Nyika N. P. (Malawi) where Roan leave the central plateau for miombo woodlands and valleys (though some remain when highly nutritive forage is maintained through dry season patch burning; Munthali & Banda 1992). On Nylsvley, Roan (both social groups) were highly selective of burnt areas, especially the flood-plain and the *A. bipartita*–*S. sphacelata* grassland, although spatial segregation between social groups could still be observed to some extent. The flood-plain showed the highest increase in percentage nitrogen, while the *A. bipartita*–*S. sphacelata* grassland and the *A. bipartita*–*S. sphacelata* savanna had the highest increase in calcium and phosphorus, respectively, when burnt (Dörgeleh 1998a,b).

Studies in Kruger N. P. and Nylsvley N. R. demonstrate the remarkable contrast that exists between the numerous studies on 'rare Roan' in southern Africa, and the very few studies on 'common Roan' in West and central Africa. In West and central Africa, the diet of the Roan Antelope might well comprise a slightly higher share of browse than documented in East and southern Africa, as suggested by the studies of Schuette *et al.* (1998) and De Stefano (2004). Interestingly, fewer browsers inhabit the West and central African regions, so that Roan Antelopes have comparatively less competition for browse than for grazing in these particular regions.

Limiting factors for Roan Antelopes are related to habitat quality, availability and utilization. Animals characteristically spend several

days at a time within an area of less than 5 ha (activity area) before moving on to another small section within their overall home-range. The activity areas of these antelopes vary from one month to another, the surface of which apparently bear little relation to the size of the herd using the area but is probably more closely related to the degree of food availability, food palatability and distance to water (Wilson & Hirst 1977).

By means of radio-tracking in W Transfontier Park, Cornelis *et al.* (2006) recorded Roan Antelopes making large daily movements (15–20 km), even where poaching pressure was low. Herds graze in the early morning and late afternoon and are for the most part inactive during the remainder of the day, ruminating, resting and socializing. They commonly drink in the late morning, but introduced animals in a park outside their natural range were frequently seen at water at any time of the day, though mainly towards mid-day (Perrin & Taolo 1998). Animals usually kneel while drinking, and display a preference for drinking on open banks. Similarly, ruminating and resting occurs in the shade of a tree preferably in open areas. Like Sable, Roan Antelopes regularly visit salt or mineral licks. Child & Wilson (1964) recorded an unusual observation of two Roan Antelopes feeding on *Equisetum* sp. in water 0.6 m deep, which, to reach, required the antelopes to totally immerse their heads (and see Gewalt 1987).

Social and Reproductive Behaviour The Roan Antelope is regarded as a semi-gregarious, generally sedentary, species. The social organization is dominated by a ♂, with nursery herds typically comprising 4–18 ♀♀ and young. In Comoé N. P., the average size of the herd varies depending on the time of year: at the beginning of the dry season (Oct–Dec) the herds average 2.5 and at the beginning of the wet season (Apr–Jul) 5.6 (Mühlenberg & Roth 1985). When density is high, herds reach about 20–25 individuals, and sometimes even up to 60 animals. Temporary aggregations of 150 animals are also known (Kingdon 1982).

The dominant ♂ evicts young ♂♂ at 2.5–3 years of age, and sometimes also ♀♀ as they reach sexual maturity. Evicted young ♂♂ either become solitary or form bachelor groups of two to more than 20 individuals, until they become socially mature at 6–7 years old. At this time ♂♂ then either remain solitary or are integrated into stable groups after taking over a female herd or ousting a dominant ♂. Lone ♂♂ remain outside of the main home-range, although occasionally an adult ♂ can temporarily join a splinter group of ♀♀ (Joubert 1970).

The alpha-female plays a leading role in initiating group activities such as feeding, drinking, moving and fighting, and even the dominant ♂ will follow her. This can lead to friction between the dominant ♀ and the next ♀ in line, which may gradually drift away from the main herd with her subgroup. These subgroups and the ejected young ♀♀ that form new herds assist dispersal within a population.

Males exhibit territorial behaviour (Joubert 1976). At low densities, Roan Antelopes are not strictly territorial, since a single ♂ can only defend an area of 200–600 m diameter around a mobile herd of cows. Allsopp (1979) studied two groups in the Lambwe valley, one of which comprised 45 individuals and the other 36, with home-ranges of 15–20 km² and 25 km², respectively, and which were probably the size of the male's territory. These results differed from those of Child & Wilson (1964) and Joubert (1970)

Roan Antelope *Hippotragus equinus*.

in southern Africa, where home-ranges were estimated at 48 km² and 60–100 km², respectively. In Waterberg N. P., Namibia, Erb (1993) estimated the home-range size of an introduced population at 48 km² for two clans and 12 km² for one ♂, using the minimum convex polygon method. Opinions differ on the degree to which home-ranges overlap. According to Joubert (1976), the various herds' home-ranges do not overlap, and marking is accomplished by both visual and olfactory means. Allsopp (1979) noted that mixing between herds may occur. Radio-collared Roan Antelopes in W Transfontier Park exhibited some temporary mixing of herds and overlapping of home-ranges (Cornelis *et al.* 2006).

Mating behaviour is initiated by the herd's dominant ♂ and includes dominance postures, sniffing the vulva area, an olfactory test of the female's oestrous status (flehmen), leg lifting (laufschiag) and mounting if the ♀ is receptive. Mounting duration is short and occurs many times before successful intromission. Low intensity fights are common within the bachelor herd and consist of head-long rushes, which usually stop just short of contact, but sometimes results in a clash of horns, followed by sparring from a kneeling position (Allsopp 1979). Such intra-specific aggression may lead to some fatalities (Wilson & Hirst 1977).

Females leave the herd to calve, but usually return the day after parturition. Newly born calves are hidden in dense vegetation and may be as far as 2 km from the herd for an extended period of up to six weeks (Wilson *et al.* 1974). This is a period of high mortality. The calf is almost odourless, effectively camouflaged and remains nearly motionless. The calf is left unattended throughout the day,

except in the early evening and early morning hours when suckling occurs (Beudels *et al.* 1992a). Most of the calves are weaned while food availability is declining (Beudels *et al.* 1992a). Communication between mother and calf is both visual and auditory, with slight but regular sharp shrills being emitted by both. Calves are kept in isolation for up to 4–6 weeks after which they join a group of a similar age within the main herd. When alarmed, these juvenile groups stay together, following the leadership of a single ♀ rather than joining their own mothers.

Roan Antelopes tend to avoid large concentrations of other grazing species (Joubert 1976), probably because they are susceptible to local competition (Wilson & Hirst 1977, Brown & Allen 1989, Harrington *et al.* 1999, Kröger & Rogers 2005). However, this may not be the prime reason, and Kingdon (1982) suggests that Roan Antelopes are absent from areas of high herbivore density because of the selective preference for these antelopes by more numerous predators. Large herds of Common Wildebeest *Connochaetes taurinus*, African Buffalo *Syncerus caffer* and Plains Zebras *Equus quagga* (their most likely ecological competitor), in particular, can keep the grass low and unsuitable for Roan Antelopes (Joubert 1976). For example, the Roan population of Kruger N. P. was almost driven into extinction in the early 1990s by reduction of grass cover through overgrazing (see Conservation) and in Kidepo Valley N. P. it was found that the distribution of Plains Zebras and Roan Antelopes rarely overlapped (Kingdon 1982). However, they are sometimes found associating with other grazers. For example, in Pendjari N. P., as

well as in W Transfrontier Park, Roan Antelopes may be associated with Western Hartebeest *Alceaphus buselaphus major* or Korrigums *Damaliscus lunatus korrigum* (Delvingt *et al.* 1989). In Central African Republic, Roan Antelopes may be seen with Lelwel Hartebeest *A. b. lelwel* or Giant Elands *Tragelaphus derbianus*, especially at saltlicks. Roan Antelopes may also be associated with smaller herds of oryx, Common Wildebeest, African Buffalo, Plains Zebras and Ostriches *Struthio camelus* in other regions.

Reproduction and Population Structure Roan Antelopes could be regarded as prolific breeders based on their reproductive potential (one calf every 10–10.5 months) (Joubert 1976). Single calves, with a birth-weight of 12–18 kg, are born after a gestation of 268–286 days (mean = 270) and 2–3 weeks after parturition ♀♀ enter a postpartum oestrus (Wilson & Hirst 1977). Females first conceive at two years of age (Joubert 1976). The calving season is not well defined: in Akagera N. P., a peak in births was recorded in May/Jun and Dec/Jan at the end of both wet seasons (Beudels *et al.* 1992a); in Central African Republic, the peak occurs in Apr and Dec (Delvingt & Lobão Tello 2004); and in South Africa's Limpopo Province most calves are born Jan–Mar (Wilson 1975).

Joubert (1976) counted 42 calves per 100 adult ♀♀ in Kruger N. P. where recruitment was calculated as 0.12 sexually maturing ♀♀ annually entering the breeding segment of the population. Also in Kruger N. P. the cow : calf ratio was about 0.5 while the population was stable (Mason 1990b), although this decreased to 0.42 on average between 1983–93 when the population was declining (Harrington *et al.* 1999), with an average adult female survival of 0.73 during the same period of decline (Harrington *et al.* 1999). In Nylsvley N. R., Dörgeloh (1998b) estimated recruitment at 0.33 sexually mature ♀♀ per breeding adult ♀♀. In Percy Fyfe N. R., Wilson *et al.* (1974) calculated a birth rate ranging between 0.32 and 0.47 calves per female per year (mean = 0.39). Factors influencing birth rate are essentially related to the quality and quantity of food.

In Akagera N. P., the highest juvenile mortality occurs at the beginning of each wet season when stable groups are most fragmented, and consequently when juveniles unaccompanied by adults may therefore be most vulnerable to predation (Beudels *et al.* 1992a). These authors calculated an annual calf survival of 0.89 for ♀♀ and 0.78 for ♂♂. In Nylsvley N. R., the mortality rates were estimated around 77% for calves aged 0–6 months, 70% for calves 6–12 months and around 81% for calves aged 0–12 months (Dörgeloh 1998b). In Kruger N. P., Joubert (1976) estimated a mortality rate of 67.5% during the first few weeks of life. Both studies showed no differences in mortality between sexes during the first two years. In Nylsvley N. R., the density and diversity of predators are not as high as in Kruger N. P., so the high mortality of calves during the first weeks may be due to other causes such as nutritional stress during winter when calves are born, or cytauxzoonosis, a disease caused by a blood parasite that causes high mortality among stressed Roan Antelopes (Wilson & Hirst 1977). Wilson *et al.* (1974) calculated a calf mortality rate of 80% within the first 12 weeks after birth in the Percy Fyfe N. R. and in other provincial reserves of N South Africa. Population viability analysis carried out on Nylsvley N. R. showed that newborn calf mortality was the most critical population parameter influencing extinction risk, especially in female calves (Dörgeloh 1998b).

In Kruger N. P., Joubert (1976) calculated male : female sex ratio among calves at 1 : 1.13 and 1 : 1.58 among yearlings. Mortality affects more subadult ♂♂, which should result in a biased adult sex ratio in favour of ♀♀. For example, the Roan Antelope population of Nylsvley N. R. presents an adult sex ratio of 1 : 1.89 (Dörgeloh 1998b), which is quite similar to the adult sex ratio found by Joubert (1976) in Kruger N. P. (1 : 1.8), although Munthali & Banda (1992) recorded an adult sex ratio of 1 : 0.83 in Nyika N. P.

Captive Roan Antelopes have lived to more than 25 years (Weigl 2005), although longevity is certainly shorter in the wild.

Predators, Parasites and Diseases The most significant predators are Lions *Panthera leo*, Spotted Hyaenas *Crocuta crocuta*, African Wild Dogs *Lycaon pictus* and Nile Crocodiles *Crocodylus niloticus*. Calves may also be preyed upon by Leopards *Panthera pardus* and Black-backed Jackals *Canis mesomelas*. There is one report of an adult Roan bull being killed by Cheetahs *Acinonyx jubatus* in East Africa (Spinage 1986). Juveniles unaccompanied by adults may be most vulnerable to predation (Beudels *et al.* 1992a). Lion predation has been implicated as a potential cause for the population decline observed in Kruger N. P. (Harrington *et al.* 1999).

In small protected areas artificially high densities build up, and, in the absence of dispersal opportunities, cause an increase in the rates of transmission of pathogens, thus contributing to some of the high mortalities seen among Roan Antelopes (Dörgeloh 1998b). In South Africa, mortality is sometimes attributed to tick overburdens brought about by good rains, in particular of the species *Rhipicephalus appendiculatus*, *R. evertsi* or *Boophilus decoloratus*. No fewer than four pathogens have been implicated in the death of juveniles: *Cytauxzoon* spp. (infection rates can reach 31.2% in young calves; the parasites are thought to be transmitted by *R. appendiculatus*), *Babesia*, *Chlamydia* and *Pneumocystis carinii*. Two helminth parasites were recovered from Roan Antelopes on Percy Fyfe N. R., namely *Skrjabinema ovis* and *Ostertagia* spp. (Wilson & Hirst 1977). Roan Antelopes are highly susceptible to anthrax, which can cause dramatic declines in the population (Pienaar 1960, 1961), and rinderpest (Chardonnet & Kock 2001), and they may be susceptible to malignant catarrhal fever (Gulland *et al.* 1989).

Conservation IUCN Category: Least Concern. CITES: Not listed.

As noted already, there are contrasts in the conservation status of the Roan Antelope throughout its distribution range. It currently remains common in some areas of West and central Africa, but is becoming increasingly rare in most areas of East and southern Africa. Overall, the Roan Antelope tends to disappear from transformed habitats and areas with human settlements and this helps explain its withdrawal from large parts of its historical distribution. Nevertheless, in West and central Africa, the Roan Antelope continues to thrive in areas where other antelopes are decreasing. This is probably due to its ability to withstand illegal hunting pressures better than many other large herbivores, especially the more water-dependent and more sedentary species, which are more exposed to poaching. However, some populations in West Africa are in decline, such as that in Comoé N. P. where numbers have declined by about 70% between 1978 and 1998 to

around 500 animals (Fischer & Linsenmair 2001a), and in Mole N. P. (Ghana), where numbers have declined from an estimated 1010 in 1993 to 160 in 2004 (East 2006). Elsewhere, Roan have disappeared from several areas because of the opening up of farms, fencing and settlement, and poaching. Illegal hunting probably contributed to the demise of the Roan Antelope in Masai Mara National Reserve in Kenya in the 1970s (Hofer *et al.* 1996). In the Karoi area, in Zimbabwe, Roan Antelopes were systematically exterminated by government tsetse control hunters: 2862 Roan Antelopes were shot on tsetse control between 1924 and 1945 (Best *et al.* 1970).

Harrington *et al.* (1999) have proposed different explanations to understand the decline of the Roan population and its lack of subsequent recovery in South Africa, specifically in the Kruger N. P. (450 animals in 1986 to around 30 in 2001; Grant *et al.* 2002): (i) extreme deterioration of habitats caused by a long period of low rainfall; (ii) substantial influx of Plains Zebras and Common Wildebeest into Roan range, increasing competition for grazing resources; and (iii) enhanced predation by Lions, following the influx of Plains Zebras and Common Wildebeest. Despite the high-density conditions, and the probable competition for resources, predation pressure following the influx of grazers seems to be the main factor responsible for the drastic decline of Roan Antelopes in Kruger N. P. (Knoop & Owen-Smith 2006; and see McLoughlin & Owen-Smith 2003). Evidence seems to suggest that ecological disturbances set off by 'ecosystem manipulation' through the extensive provision of water-points in this region facilitated the build-up of Plains Zebra and Common Wildebeest numbers. The increase of common grazing ungulates might explain the decrease of uncommon grazing ungulates relying on a feeding strategy based upon the selection of the highest quality plant parts in the most remote areas from water sources. Although the closure of 13 artificial water points (including one large dam) within the Roan Antelope's range in Kruger N. P. in 1995–96 resulted in an initial recovery in the Roan population, this recovery has not continued and the population still remains well below historical numbers (R. Harrington pers. comm.), suggesting that other factors in addition to those mentioned above may be influencing the population. Kröger & Rogers (2005) suggest that fine spatial scale dietary resource requirements (wetland boundary) by Roan Antelopes may make them experience the effects of habitat deterioration first, before other ungulates.

Dörgeloh (1998b) proposed that, in South Africa in particular, habitat management and calf mortality should be primary issues in designing a management plan for the Roan Antelope. Management procedures must aim at modifying or supplementing missing habitat factors. Management recommendations include, in South Africa, the maintenance of the important plant communities, mainly flood-plains and the *Aristida bipartita*–*Setaria sphacelata* grassland type. The hydrology of the flood-plain should be maintained to supply sufficient quality forage throughout the wet season. Bush encroachment onto the latter plant community should be controlled. Patch-burning throughout the dry season will increase the forage quality for the Roan Antelope. The carrying capacity can be increased by enlarging protected areas. It can also be increased by introducing an artificial feeding programme, which should enhance the condition of animals during winter and

control their parasite load. Another management option could be to reduce the population size, which will improve the population growth rate, and may also improve calf survival and the condition of animals (Dörgeloh 1998b). The decrease of the Roan population in Kruger N. P. shows that protected areas are not necessarily the 'safest' option and that the risk of extinction should be minimized by having populations in different areas with different management strategies (Dörgeloh 1998b). Interestingly, the highest densities and largest populations of Roan Antelopes appear to remain in West and central Africa with light management interventions, while the conservation status of Roan Antelopes is degrading in southern Africa with intensive management.

The current strongholds of Roan Antelopes are predominantly focused in West and central Africa: Dulombi, Corrubal and Boé areas (Guinea-Bissau); all the northern regions of Guinea (only occurs seasonally in National Park of Upper Niger, according to Brugière *et al.* 2005); Niokolo-Koba N. P. and Falémé Hunting Zone (Senegal); Comoé N. P. (Côte d'Ivoire); Arly and W National Parks and Nazinga Game Ranch and all surrounding gazetted Hunting Areas (Burkina Faso); Mole N. P. and Digya N. P. (Ghana); Pendjari and W National Parks and surrounding gazetted Hunting Zones (Benin); W N. P. and Tamou Faunal Reserve (Niger); Waza, Faro, Bénoué and Bouba Ndjida National Parks and all surrounding gazetted Hunting Zones (Cameroon); Manovo–Gounda–St Floris and Bamingui–Bangoran National Parks and the very extensive areas gazetted as Hunting Areas (Central African Republic); and Zakouma N. P. (where the population was estimated at about 1300; Mackie 2004), Siniaka-Minia Faunal Reserve and Aouk Hunting Areas (Chad). In the remainder of the range, among the largest surviving populations are those in the North and South Luangwa and Kafue National Parks (Zambia), Nyika N. P. (Malawi) and in N Botswana (East 1999).

In extreme situations with small populations, the planned exchange of animals between reserves might be needed to counter inbreeding. However, in the early 1990s another threat appeared in the mixing of distinct taxa of Roan Antelope, notably the importation of Roan Antelopes from West and central Africa to southern Africa where this species is one of the most expensive wild animals for sale, reaching prices as high, and even higher, than Black Rhinoceros *Diceros bicornis*. In May 2000, the South African Minister of Environmental Affairs and Tourism requested a moratorium on the importation of non-indigenous subspecies of Roan Antelope, in view of the dangers that hybridization poses to the threatened South African subspecies *H. e. equinus*. The trade of Roan Antelopes in southern Africa is also a threat to West and central African wildlife where this particular antelope is one of the few distinct major natural assets. Long-term conservation of the Roan Antelope in West and central Africa relies on safeguarding its value for all stakeholders. For local communities, attention needs to be paid to management that brings tangible benefits (notably employment by safari operators and returns from sustainable use of wildlife). For government agencies that must plan land-use, their decisions need to be based on the most efficient rural development tools (e.g. cotton farming is making rapid encroachment on Roan natural habitat), while for private operators with monetary motives, the depletion of a large antelope such as the Roan acts as a disincentive for investment in all kinds of wildlife tourism.

Measurements*Hippotragus equinus*

HB (♂ ♂): 2593 (2360–2840) mm, n = 19
 Sh. ht (♂ ♂): 1459 (1370–1610) mm, n = 19
 WT (♂ ♂): 277.8 (232.0–313.0) kg, n = 19
 N Benin (Coatmellec 2004).

TL (♂): 2730 mm, n = 1
 TL (♀): 2630 mm, n = 1
 T (♂): 540 mm, n = 1
 T (♀): 530 mm, n = 1
 HF c.u. (♂): 620 mm, n = 1
 HF c.u. (♀): 600 mm, n = 1

E (♂): 310 mm, n = 1

E (♀): 290 mm, n = 1

Caprivi (Rautenbach 1982)

In E Zambia, Wilson (1968) gave the mean weight for 12 ♂ ♂ as 280.0 kg (range 241.0–298.1) and for 8 ♀ ♀ as 258.2 kg (range 222.4–280.0)

Maximum recorded horn length is 99.0 cm for a pair of horns from Tokwe Valley, Zimbabwe (Rowland Ward)

***Hippotragus niger* SABLE ANTELOPE**

Fr. L'Hippotrague noir; Ger. Rappenantilope

Hippotragus niger (Harris, 1838). Athenaeum 535: 71. 'The great mountain range in the county of Mataveld', and 'On the northern side of the Cashan range of mountains, about a degree and a half south of the tropic of Capricorn', since specified as South Africa, North West Prov., Krugersdorp and Rustenburg, Magaliesberg (Grubb 1999).

Sable Antelope *Hippotragus niger*.

Common name derived from a heraldic colour and the black pelage of adult ♂ ♂. Not to be confused with a fur-bearer of the weasel family, the Sable *Martes zibellina*.

Taxonomy Polytypic, with four recognized subspecies. Mitochondrial DNA studies by Pitra *et al.* (2002) and Pitra *et al.* (2006), involving more comprehensive sampling than that undertaken by Matthee & Robinson (1999b), confirmed the distinctness of the subspecific lineages, the boundaries of which broadly conform with recognized subspecies boundaries (Ansell 1972). The most recent genetic research by Jansen van Vuuren *et al.* (2010) not only confirms that all four subspecies are significantly differentiated from each other, but clearly demonstrates that the western Zambian sable, despite the close resemblance of some individuals to the Giant Sable in facial markings and coat colour, is not referable to *H. n. variani*. Most striking is the fact that none of the haplotypes detected in the western Zambian sable specimens were shared with those from Angola, nor were *H. n. niger* haplotypes detected in the Angolan population. Had there ever been interbreeding between the two populations, it should be revealed in the mtDNA analysis (Jansen van Vuuren *et al.* 2010). Instead, the most closely related haplotypes to *variiani* are found in the southern region of central Tanzania (a distance of some 2000 km). This suggests that the peripheral populations of *H. n. niger* in Angola and STanzania were founded during the Pleistocene by episodic long-distance colonizations from a common source population (Pitra *et al.* 2002, 2006).

Synonyms: *anselli*, *harrisi*, *kaufmanni*, *kirkii*, *niger*, *roosevelti*, *variiani*. Chromosome number: 2n = 60 (Wurster & Benirschke 1968, Claro *et al.* 1993). Despite very different phenotypes, and subtle differences in chromosomes (Fordyce-Boyer *et al.* 1995) the Sable Antelope and the Roan Antelope *H. equinus* may be genetically close enough to produce viable hybrids (Robinson & Harley 1995). In the latter instance, a hybrid ♀ was born into a Sable herd in the Satara area of Kruger N. P. (South Africa) in the late 1980s. A Roan bull had joined this herd in about 1987, though it was unclear where the bull came from as there were no Roan herds in that area. As it was clearly a hybrid, the animal was captured and put in a large enclosure (1 km × 1 km) in the Pretoriuskop area of the Park

where no other Sable or Roan Antelopes were present. This was to prevent her from breeding with the pure Sable stock of the Park (though it is fairly certain that she was sterile). The animal died in early 2006 at an estimated 19 years of age (Estes & Whyte 2006). Subsequently, multiple instances of hybridization have occurred in Cangandala N. P. in Angola (Vaz Pinto 2006, Walker 2010; and see Conservation).

Description A large, heavy-set antelope with long, arched horns, narrow pointed ears and sexually dimorphic colouration. Brown or black bridge to the nose bordered by a preorbital patch of white connecting with a white stripe that extends to the white upper lip. Narrow dark orbital stripe down the side of the face separates this white stripe from the white forecheek and chin. Inside surfaces of the elongated ears have white hair; backs are light russet-brown. Muzzle elongated, mouth with wide gape and diastema, and a small dewlap under throat. Neck is thick, with an upstanding mane. Short, glossy pelage, ♀♀ and young sorrel to chestnut, becoming deep black in adult ♂♂. Similar contrasting white markings in both sexes, including rump patch, belly and facial markings. Mane and tail hairs black. Conspicuous pendant penile sheath white with black tip. Calves up to two months are tan with indistinct markings. Rudimentary preorbital glands are present under the white 'eyebrows', and there are pedal glands on all feet, the constituents of which have been examined by Wood (1998); inguinal glands are absent.

Horns are well developed in both sexes, but thicker, longer, more sickle-shaped in ♂♂. Horns are laterally compressed and strongly ringed for most of their length. The pattern of horn growth in relation to age for known-age individual Sable Antelopes has been quantified for *H. n. roosevelti* in the Shimba Hills by Ross (1984). Age determination based on patterns of tooth eruption is discussed by Grobler (1980a), the first permanent tooth (M_1) erupting at 6–10 months and the first premolars at about 34–42 months.

Geographic Variation

H. n. niger (Black-black Sable): south of the Zambezi R. in Mozambique, Zimbabwe, NE South Africa, N Botswana, Caprivi Strip (NE Namibia), Zambia west of Zambezi and SE Angola. The only race in which ♀♀ become nearly black, mimicking the main male secondary character; young begin turning dark as yearlings.

H. n. kirkii: north of the Zambezi R. in Mozambique, Malawi, Zambia, SE DR Congo, E Angola and W Tanzania, west of the Eastern Arc Mts. Highly significant genetic separation between W Tanzania populations and Kenya/East Tanzanian populations (*H. n. roosevelti*) suggests long isolation of the different lineages on either side of the Eastern Arc Mts (Pitra *et al.* 2002).

H. n. roosevelti (Roosevelt Sable): patchy distribution in coastal hinterland of Kenya and Tanzania, associated with extension of miombo-type woodland into Kenya, where now found only in Shimba Hills National Reserve. Isolated relict populations in Tanzania except in and adjacent to Selous G. R., its one stronghold (estimated population of 3900 in 1998). The population is highly differentiated along approximately the 38th degree of longitude. Usambara Mts and Pangani R. are obvious geographic barriers cutting across the northern parts of its range and the Rufiji R. further south. The Eastern Arc Mts appear to mark the western boundary of its range,

Lateral view of skull of Sable Antelope *Hippotragus niger*.

but clear morphological differences across this genetic divide have yet to be found.

H. n. variani (Giant Sable): limited to two reserves in C Angola south of Malange – Cangandala N. P. and Luando Integral Reserve of the Giant Sable. Distinguished from other races by facial mask lacking white stripe bordering the nose and retention of tan hocks by adult bulls. 'Giant' designation derives from male's horns, which average ca. 30 cm longer than in other races.

Similar Species

Hippotragus equinus. Sympatric through most of the southern savannas.

The Roan Antelope is less of a woodland and more of a grassland/tree-savanna species, tolerating taller grassland and higher elevations (Estes 1991a, Dörgeleh 1998a). Averages 40 kg heavier with a conspicuous black and white mask, but grey to rufous coat that is similar in both sexes; robust curving horns in both sexes are much shorter (average = 75 cm) and heavier than those of the Sable.

Distribution Endemic to Africa. Confined to the southern savanna regions of the continent, with a particular association with the miombo (*Brachystegia*) woodland communities.

Historical Distribution Their natural distribution extends from the Caprivi Strip and E and SE Angola, west throughout Zambia, and south of the Zambezi R. in N and NE Botswana, throughout Zimbabwe, Mozambique (except the extreme south-east) and northwards through SE DR Congo, Malawi and W, NE and SE Tanzania (East 1999). The northern limit of Sable distribution formerly extended near or to the Somalia border (I. Parker pers. comm.) in a 5000 km² expanse of miombo-like *Diospyros* lowland woodland lying inland from the Kenya coast, extending west to the border of Tsavo N. P. (Estes & Estes 1969a). In South Africa, they occurred in the bushveld and lowveld areas of the North West, Limpopo and Mpumalanga Provinces; the historical southern limit was the Komati R., at ca. 26° S (Pienaar 1963) and the Magaliesberg Mts. An isolated population (the Giant Sable) occurred in C Angola, between Cuanza and Luando R. and north of the Cuanza R. (East 1999, Crawford-Cabral & Veríssimo 2005).

Current Distribution Sable Antelopes have been eliminated from large parts of their former range and now survive mainly in protected

areas and on private land. Their range reduction has been particularly marked in Mozambique, where they survive in good numbers only in Niassa G. R. in the north, and in the western Gaza province. In SE DR Congo, they have been eliminated from most of their range (but survive in Upemba N. P. and Kundelungu N. P.). Similarly, they have been eliminated from much of their range in NE Tanzania, but still survive at low to moderate densities in the miombo woodlands of W and S Tanzania; the population in the Selous ecosystem probably represents the largest free-ranging population in Africa. The northerly limit of their range now extends to SE Kenya (Shimba Hills National Reserve).

Sable Antelopes have been reintroduced to many parts of their former range, but have also been introduced to areas where they never naturally occurred, including to Swaziland (Mkhaya Private Reserve; Monadjem 1998), widely on private farmland (and to the Waterberg Plateau Park) in Namibia, and various provinces in South Africa (Free State, KwaZulu–Natal, Eastern Cape, Northern Cape) (East 1999).

Habitat Apart from Lichtenstein's Hartebeest *Alcelaphus buselaphus lichtensteini*, no large mammal is more closely identified with the miombo woodland zone than the Sable Antelope. This broad-leaved, deciduous open woodland is dominated by *Brachystegia*/*Julbernardia*/*Isoberlinia* spp. growing on leached granitic and sandy soils. Currently covering a large part of the interior of southern Africa, this vegetation type is maintained by annual fires that burn off the grasses and much of the undergrowth. These woodlands are open enough to support an understorey of grasses and forbs and are interspersed with edaphic grasslands and flood-plains. The Sable Antelope is an 'edge' species that frequents the woodland/grassland ecotone. It spends the wet season in woods open enough to support an understorey of grasses no more than 30 cm high on well-drained soils, and in the dry season emerges onto the grasslands in search of green grass and forbs.

Sable Antelopes occur in three drier vegetation types south of the miombo ecotype (Wild & Barbosa 1967):

- Rhodesian teak (*Baikiaea plurijuga*) woodland, associated with *Pterocarpus angolensis*, *Guibourtia coleosperma* and *Ricinodendron* and sparse grass cover of tall *Aristida* spp., *Triraphia schlechteri*, *Tristachys rehmannii*, *Digitaria* spp. and *Eragrostis* spp.
- Dry early deciduous savanna woodland (lowland). Mopane woodland mixed with *Kirkia acuminata*, *Sterculia africana*, *Commiphora* and *Combretum* spp. in varying proportions. Associated grasses include *Stipagrostis uniplumis*, *Digitaria milinjiana*, *Panicum kalaharens* and *Pogonarthria squarrosa*.
- Deciduous dry tree savanna (on Kalahari sand). Dominant trees include *Baikiaea plurijuga*, *Colophospermum mopane*, *Dialium englerianum*, *Erythrophloeum africanum*, *Pterocarpus angolensis*, *Ricinodendron rautanenii* and *Azelia quanzensis*. Important grasses: *Aristida stipitata*, *A. pilgeri*, *Tristachya rehmannii*, *Eragrostis* spp., *Andropogon schirensis*, some *Hyparrhenia dissoluta* and *H. filipendula*.

Sable populations currently reach their highest densities (4/km²) in W Zimbabwe and N Botswana, in the transition zone between mopane and mixed deciduous savanna woodland, growing on Kalahari sands (type c above), where the average rainfall is 625 mm or less, falling Dec–Mar (Wilson & Hirst 1977).

The miombo woodland zone receives an annual rainfall of 750–1125 mm in a single wet season lasting 6–7 months. However, from Zambia to Botswana the climate becomes progressively drier, as noted above. The southern limit of Sable distribution in Botswana coincides quite closely with the 500 mm rainfall isohyet, in *Terminalia* deciduous tree-savanna. Summer temperature and humidity are high (up to 40 °C) in the region and winter temperatures frequently drop below freezing in Zimbabwe and Botswana.

The Central African plateau lies at an altitude of 1000–1500 m, but most of the miombo woodland grows on an ancient upland plateau with little relief. In the Southern Highlands of Tanzania and the Chimanimani Mts of E Zimbabwe, Sable Antelopes occur in montane grassland; also in wooded hills of Mozambique's Gorongosa N. P., and among low hills fronting the Cuanza R. in the Luando Reserve, Angola. At their north-eastern limit they inhabit Kenya's coastal Shimba Hills, which consist of a forest/grassland mosaic.

Abundance The most recent estimate of total population size is 53,365 animals, although correcting for undercounting bias in aerial surveys gives a slightly higher estimate of 75,000 animals (East 1999). The largest populations survive in Zimbabwe (>19,690), Tanzania (>10,680), Namibia (7100) and Mozambique (4270) (East 1999). According to an unsubstantiated report of the Kissama Foundation printed in the December 1997 issue of *Safari Times*, newsletter of the Safari Club International, at least 253 and probably many more Giant Sable Antelopes survived the 25-year civil war, greatly reduced from an estimated 2000–3000 in the late 1960s (Estes & Estes 1974, East 1999).

Like other ungulates of the miombo woodlands, the Sable Antelope occurs at low density in comparison with ungulate densities in semi-arid savanna. In what Wilson & Hirst (1977) considered the best Sable habitat in southern African, the Matetsi area of SW Zimbabwe, the estimated density was 4/km². In Kenya's Shimba Hills National

Reserve, the estimated year-round density was $1.4/\text{km}^2$ (Estes & Estes 1969a, Sekulic 1977). However, this island population now numbers less than 200 individuals (Ross 1984, K. Ross pers. comm.). A density of $4/\text{km}^2$ was estimated in Zambezi N. P., Zimbabwe, in the 1969 dry season, but represented the concentration of animals from a much wider area (Estes & Estes 1969b). Earlier road-strip counts by Dasmann & Mossman (1962) in this Park also gave a density of $4/\text{km}^2$. In the Luando Reserve, the wet season range of a herd of 32 Sable Antelopes observed for a year was ca. 20 km^2 , a density of $1.6/\text{km}^2$; its dry-season range was ca. 12 km^2 , amounting to a density for the year of $1/\text{km}^2$ (Estes & Estes 1974). Density estimates based on aerial surveys are much lower, usually ranging from 0.01 to $0.10/\text{km}^2$, reaching 1.2 – $1.3/\text{km}^2$ in areas where Sable Antelopes are particularly common (East 1999).

Adaptations According to Kingdon (1982) the Sable and Roan Antelopes share arid-adapted ancestors with *Oryx* and *Addax*. Thus, the adaptive radiation of species from North African biomes extended into the northern and southern savannas, and, according to Hernández Fernández & Vrba (2005), most likely followed a dry period in the mid-Miocene. A diverse array of semi-arid savanna ungulates left little room for large, arid-adapted antelopes. However, the broad-leaved deciduous woodlands and grasslands of the mesic savanna were occupied by few ungulates and hardly any the size of Roan or Sable Antelopes. So, like the oryxes and *Addax*, which occupy deserts and sub-deserts where they have no competitors among large antelopes, Roan and Sable Antelopes found niches in the mesic savanna, thereby avoiding competition with most other large antelopes. Here there were also fewer Lions *Panthera leo* and other large predators, which could have been another factor promoting their choice of these less-productive and mineral-depleted ecotypes (Kingdon 1982).

In the process of adapting to the mesic savanna, *Hippotragus* gave up nomadic habits and became dependent on habitats that provide free water. They adopted the social organization typical of a sedentary life-style, with territorial ♂♂, female herds resident in traditional home-ranges and segregated bachelor ♂♂. Actually, these changes were not as radical as might be supposed, for Gemsboks *Oryx gazella* will drink and bulls will stake territories where water is available – and in the Kalahari even where it is not (Williamson & Williamson 1985b). More radical were the morphological changes that culminated in the *Hippotragus* phenotype. Perhaps most significant was the lengthening of the head and the increase in gape and the incisor–molar diastema, which are well adapted for feeding on tufted perennial grasses.

It is plausible to suppose that the Roan Antelope, which has a much wider geographic range and occupies more open savannas, evolved before the Sable, which is limited to the southern savanna and closely linked to the miombo woodland zone. The Roan Antelope's relatively small degree of sexual dimorphism would seem to place it closer to *Oryx* and *Addax* and their arid-adapted, nomadic ancestors. As the only member of the tribe with conspicuous sexual dimorphism, the Sable Antelope is arguably the most recent and niche-specialized hippotragine. However, the Black-black Sable (*H. n. niger*) affords an example of how selection can lead to reduced sexual dimorphism when socio-ecological circumstances warrant. This race lives in the driest region of the species' range, extending south of the miombo biome. During a Pleistocene dry epoch both natural and sexual

selection favoured female mimicry of male colouration as a means of reducing aggression toward male offspring and allowing them access to scarce green pastures. Had this counter-selection continued and the population become increasingly migratory, it could have led to unimorphism and sexually integrated herds, as among oryxes and the *Addax*, where minimal sexual dimorphism is seen as the end result of this process of female mimicry of male secondary sexual characters (Estes 1991b, 2000).

Foraging and Food Studies from several areas have confirmed that Sable Antelopes are both graminivorous and folivorous (Glover 1969, Estes & Estes 1969a, b, 1974, Grobler 1974, 1981a, Wilson 1975, Sekulic 1977, Wilson & Hirst 1977, Ross 1984). About 15–20% of the diet consists of herbs, forbs and woody vegetation, and Gagnon & Chew (2000), in their review of the dietary preferences of African bovids, classified the Sable Antelope as a variable grazer. For example, the leaves of *Diplorhynchus condylocarpon*, an understory shrub abundant in miombo woodland, especially on termite mounds, is a favourite browse plant in all studied miombo woodland habitats (Estes & Estes 1974). However, grass forms the primary component of the diet, as borne out by studies involving stable carbon isotopes, which suggest that they are almost entirely grazers (Cerling *et al.* 2003, Sponheimer *et al.* 2003b).

Studies of Sable Antelope food habits by Wilson & Hirst (1977) indicated that, like the Roan, the Sable is highly specific in choice of food plants, specializing on a small number of available species at any one time. Marked preferences were shown for *Setaria perennis*, *Themeda triandra*, *Eragrostis gummiflua* and *Heteropogon contortus*. The last-named was most utilized, followed by *Themeda triandra*. Grobler (1981a) noted that the Sable Antelopes he observed in Matopos N. P., Zimbabwe, preferred a grass sward below 160 mm and cropped plants between 40 and 140 mm above ground.

A grazing herd keeps moving from tuft to tuft of preferred grass and usually shifts feeding grounds from day to day. After staying in a small part of the home-range for several days at a time, a herd will likely move 2–4 km and settle in another area. In the Matetsi area of NW Zimbabwe, Sable Antelopes foraged in an area of 37 ha inside a 260 ha annual home-range during the dry season (Wilson & Hirst 1977). In Zambezi N. P., a herd of 125 Sable Antelopes remained on Chamabonda Vlei within an area of about 250 ha from early Jun until at least late Jul and could usually be found less than 1 km from the previous day's location (Estes & Estes 1969b); the following summary of Giant Sable seasonal feeding habits also applies to other populations (Estes & Estes 1974).

The Sable Antelope's preference for bunch grasses at a tender growth stage largely determines its seasonal habitat preferences. Preferred grasses and browse are found in woodland during the rains, especially on termite mounds and on the woodland/grassland border. Here the grasses stay short, the ground remains comparatively firm and there is little undergrowth. In Apr upland woodland grasses begin to dry, and the Sable Antelopes then move onto the edaphic vlei and drainage-line grasslands (*mulolos* = *dambos* of Zambia, = *mbugas* of East Africa), where pastures are still green. As the rains end in May, bringing low humidity and freshening winds, the drying trend accelerates. Woodland grasses have all dried up and most trees have shed their leaves. Only lower parts of the catena around marshes, swamps and springs, along streams and drainage lines retain enough

moisture to support growth. Tall *Hyparrhenia* grass species become dominant in these pastures late in the rains. A Sable Antelope grazing bunch grasses gathers in a clump of blades with dextrous lip movements, then bites off and chews a length up to 36 cm. Herds subdivide as Sables move between patches, still seeking clumps of green grass they can crop in mouthfuls, rather than trying to select green shoots sprouting from bases of otherwise dry tufts. In Jun fires burn woodland undergrowth and adjacent *anhara* grasslands. The woods remain barren until the next rains, but the *anhara* grasslands flush within a fortnight, attracting Sables into the open starting in late Jun and early Jul. They may feed on post-burn flushes of 5 cm or even less (however, Sable Antelopes in the Shimba Hills only moved onto burn flushes when they reached 15 cm high, meanwhile continuing to feed on standing hay; Estes & Estes 1969a). Finally, the grasslands lowest in the catena burn and quickly respond with new growth, the wetter the ground the lusher the growth. A succession of herbs and shrubs springs up once the grasses are removed (Estes & Estes 1974).

The extended burning season produces a mosaic of pastures at different stages of regrowth. If not for fires, the Sable Antelopes would have to hunt harder and harder for green pasture until forced to subsist on dry hay (and see Parrini & Owen-Smith 2009). The Giant Sables stayed in good condition with sleek coats even at the end of the dry season, whereas Sables observed in Zambezi N. P. a year earlier, subsisting on dry grass, were mostly in fair to poor condition with staring coats. However, in Shimba Hills National Reserve, where the grasslands are burnt repeatedly as a management tool, Ross (1984) noted that such regular annual burns favour fire-resistant grass species in the long run. Over time these grasses become less palatable, and have a significantly lower mineral and protein content than grasses that are burnt less frequently. Whilst the post-burn green flush is attractive to Sable Antelopes, the grasses become unpalatable within six months and the Sables then move on to areas that have not been burnt. This emphasizes the need for patchy burns to create a grassland mosaic, and shows the benefit of having coarse-grass feeders such as zebras *Equus* spp. and African Buffalo *Syncerus caffer* present, whose choice of grass length benefits Sable Antelopes by removing the taller clumped grasses thus making available the short green leaves that Sables prefer (Ross 1984).

Although Sable Antelopes are considered water-dependent, some live in areas that are waterless for much of the dry season (P. Vaz Pinto, pers. comm.). However, most drink daily, and even during the rains they visit waterholes frequently. Sables prefer to drink from pans and waterholes rather than flowing rivers (Estes & Estes 1969b). Their feeding peaks are typical of most African ungulates, being early morning and late afternoon. Herds settle to rest and ruminate by 09:00h. Herds of Giant Sables were observed to stop feeding at dusk and move some distance in the dark before lying down to ruminate. After resting for several hours, they fed up until about midnight and sporadically afterward (more on moonlit, less on dark nights), but were inactive the last couple of hours until dawn. Daily ranging in the order of 1–2 km while on green pasture increased in the dry season, often involving movements up to 10 km as herds searched for remaining patches of green grass. Sable Antelopes often visit waterholes and salt licks after the morning and before the late-afternoon feeding peak.

Sable regularly chew bones (producing a white froth) in the Shimba Hills (Sekulic & Estes 1977). All populations frequent mineral licks

at the bases of termite mounds and saline pans. Sterile soils deficient in essential elements such as potassium, calcium, iron, selenium and salt would account for these habits (detailed in Wilson & Hirst 1977, Sutton *et al.* 2002). Samples collected at five different licks used by Giant Sables tested very high in calcium, medium-high in phosphorous, medium-high to very high in magnesium, and very low to high or very high in potassium, ammonia, nitrate and aluminium (Estes & Estes 1974).

Sable Antelopes in Zambezi N. P. fed on a prostrate perennial herb, *Blepharis bainesii*, which resembles and is as prickly as a thistle, and which grew abundantly among the annual grasses they were consuming at the time. A Sable Antelope would gingerly close its mouth over a flowering head, grip the wiry stem with its lips and pluck it. Then, standing with head outstretched and tilted to one side, mouth gaping, it would proceed to ensalivate the ball until it was soft enough to swallow. At the same time, *Brachiaria* grass the Sables were eating often came up by the roots with an attached clod of dried clay, which they removed with vigorous head shakes or ejected by gaping and pushing with their tongues (Estes & Estes 1969b).

Social and Reproductive Behaviour Sable Antelopes are gregarious with three different classes: breeding herds of ♀♀ and young, bachelor herds, and territorial ♂♂. In addition, ♀♀ with hidden calves may form maternity subgroups. Numbers in breeding herds vary: in *H. n. niger*, 21 (maximum 125, from an average of 57 herds in eight different Parks of Zimbabwe, Botswana and South Africa [Estes & Estes 1969b]); in *H. n. kirkii*, 15.2 (average of 93 nursery herds all over Zambia, sighting records of Zambia Dept of Wildlife, Fisheries and National Parks, 1957–1968); in *H. n. roosevelti*, 19.6 (range 7–48, average of five herds [Estes & Estes 1969a]); and in *H. n. variani*, 22.5 (range 13–69, average of 13 herds). Numbers in bachelor herds are usually under ten ♂♂ (rarely up to 25) from 3 to 5 years old.

Breeding herds comprise what are presumably related ♀♀ occupying a traditional home-range with an age-graded dominance hierarchy. The senior cow usually leads herd movements and is the most vigilant individual (except for low-ranking peripheral ♀♀). Dominance is frequently reinforced with aggressive behaviour ranging from simple supplanting, rubbing head/horns on the opponent's body, lateral-presentation, medial- and low-horn presentation, prodding and chasing (Estes 1991a, Thompson 1993). Individual distances of 3–4 m are maintained even in a resting herd. Large herds frequently subdivide and may range separately for hours, days and even weeks. Mothers and calves may end up in different groups. When different, unrelated herds meet, as at water-holes, they are mutually hostile.

Home-ranges vary greatly in area in different populations and among herds of the same population, depending on the nature of the habitat and herd size. In the Shimba Hills open grassland habitat, several herds remained the whole year in ranges of 10–25 km², which overlapped by up to 20%. A herd of 70 animals had the largest range. In typical miombo woodland, herds may be separated by kilometres of unoccupied but perfectly suitable-looking habitat. For example, in the Luando Reserve, spacing between nearest neighbours for six known herds averaged 7.5 km (range 5–10 km) (Estes & Estes 1974). Four herds studied for 27 months in Matopos N. P. had annual home-ranges of 2.4–2.8 km² (Grobler 1974), whereas two herds in different South Africa nature reserves had ranges of 9.2 and 17.7 km²

Sable Antelope *Hippotragus niger*.

(Wilson & Hirst 1977). Joubert (1974) recorded home-ranges of only 0.2–0.4 km² in Kruger N. P. In contrast, using GPS collars, Rahimi & Owen-Smith (2007) recorded much larger annual home-range sizes covering 118 km² and 65 km² for two herds numbering 15 and 6 animals (excluding adult bulls), respectively, in the same park. One Giant Sable herd stayed the whole year in an area of ca. 12 km², while its neighbour 'migrated' 15 km from the grasslands where both herds spent the dry season to a separate wet-season range in wooded habitat (Estes & Estes 1974).

The seasonal grouping and movement patterns of Sable Antelopes may be summarized as follows (Estes & Estes 1974): (1) concentration during the dry season in the open, within 2–4 km of water; (2) break-up early in the rains into smaller sections, which sooner or later settle down in relatively stable groups in a wooded part of the home-range; (3) increased movement at the end of the rains and fragmentation of herds prior to the calving season; and (4) reformation of stable herds of ♀♀ after the new calves leave concealment.

The amplitude of seasonal movement is related to climate and water distribution. In general, Sable Antelopes move further in low than in high rainfall areas. Where their needs are adequately met, herds may remain the whole year in small home-ranges, as noted above. But the Sable Antelopes in Gorongosa N. P. had entirely different dry- and wet-season ranges: at the height of the dry season most herds stayed on the Rift Valley floor, then withdrew to the miombo woodland on the higher, dissected plateau during the rains (Tinley 1977). Verheyen (1951) observed movements of 40 km between wet- and dry-season ranges in Upemba N. P. (DR Congo). In NW Zimbabwe and adjacent Botswana, wet-season dispersal covers a still larger area. Herds of up to 100, putatively representing wet-season dispersers, were seen in the Kisuma Pans area 65 km south-west of Victoria Falls in early Jun (Estes & Estes 1969b).

To participate in breeding, ♂♂ must own territories, but are only ready to compete for space when they mature at five or six years (Estes & Estes 1974). Territory size ranges from 4 to 9 km² in the Shimba Hills National Reserve (Sekulic 1978, 1983). Grobler (1974) estimated the size of defended territories at 0.25–0.4 km². In Zambezi N. P., minimum spacing between territorial bulls was 1–2 km and 2–3 km among six territorial Giant Sable bulls in the study area (Estes & Estes 1974). Between the time they are driven away from the breeding herds by territorial bulls as three-year-olds, subadult bulls often roam alone if there is no bachelor herd in the area. In any case, a young adult prospecting for a territory tends to isolate himself from other ♂♂ and to haunt a particular locality, which he proceeds to patrol and demarcate by scraping the ground with his forefeet then defecating, on a patch of bare ground or on a road, and by thrashing small trees with his horns. In time he lays claim to a piece of land wherein he may mate with any receptive ♀♀ that enter.

Very little information on territorial tenure is available. Two known bulls in Matopos N. P. occupied the same pieces of real estate for at least two years (Grobler 1974). In Shimba Hills National Reserve, where large territories were maintained with very low turnover, eight territorial ♂♂ were known to occupy the same territories between two and four or more years, with an average of 2.8 years (Sekulic 1978). There is a link between territory size and habitat quality, as noted by Ross (1984), with prime territories being smaller than those in more marginal habitats, and equally territorial tenure is shorter in the prime locations.

Sable territoriality is unusual in that not all territorial bulls are equal. As observed both in the Shimba Hills National Reserve and in the Luando Reserve, there are 'master bulls' that can invade and supplant their neighbours (Estes & Estes 1974, Estes 1991a). For example, a known bull without a herd invaded a herd that was accompanied or tended by a neighbouring ♂ and, after intense displays and a brief fight (in kneeling attitude), took over the herd. However, he only stayed for a day before returning to his own territory and the displaced bull came back. In other instances, a bull whose efforts to prevent a herd from exiting his land by threat and dominance displays and chasing were unavailing, crossed over with them and the neighbour bull acknowledged subordinate status by keeping a respectful distance. The most likely explanation for such territorial inequality is dominance based on seniority: younger territorial bulls continue to acknowledge the dominance of seniors who intimidated them in their bachelor days. In Matopos N. P., Grobler (1974) divided territorial ♂♂ into three different classes: central, peripheral and outer territorial ♂♂. Only the central ♂♂ were in regular contact with the female herds.

All observed territories included woodland, into which bulls often withdrew when alone. They are surprisingly inconspicuous standing in the shade, considering how a bull stands out in a herd of ♀♀ and young, especially while actively herding, urine-testing and dominating the cows and adolescent ♂♂. When his herd is on the move, the bull brings up the rear but can dictate the direction by performing such dominance and threat displays as lateral presentation, head-shaking, horn-sweeping and low-horn presentation (head lowered, chin in, horns pointing towards opponent) (Estes 1991a). But when a herd is resident for an extended period in one territory, the proprietor is often absent, either patrolling and marking his boundaries or remaining solitary in the woods.

Research in the Shimba Hills National Reserve noted that female and calf Sable herds typically moved through the territory of 8–10 different bulls during their annual foraging through their home-range (Ross 1984). As noted, bulls have access to oestrous ♀♀ only when they are within their own territory. Ross (1984) quantified the amount of times different ♀♀ were in the territory of different bulls, since herds often split up into smaller groups that ranged in different areas of their home-range. Certain ♀♀ exhibited distinct 'territorial preferences', spending a disproportionate amount of time with a 'preferred' bull. Most interestingly, such ♀♀ returned to their 'preferred territory' to give birth. Since ♀♀ in the Shimba Hills exhibit postpartum oestrus, these ♀♀ are mated immediately by the resident bull. It seems likely that this preference allows the calf and mother greater protection from the bull, since in all likelihood the calf is the offspring of the territorial bull (Ross 1984).

When a herd bull's urine testing detects a cow in pro-oestrus, he begins courtship displays, following her in lowstretch (neck and chin outstretched), lateral presentation of the body in the erect posture, and laufsclag (or foreleg lifting). Should the ♀ prove unreceptive, running away or circling to avoid contact, a bull may become aggressive, hitting her with his horns and chasing her, even roaring. Cows, when persistently chased, scream their distress and end by lying prone in total submission (Estes & Estes 1974). Such unusually aggressive behaviour was also observed by Grobler (1974), Kingdon (1982) and in a captive herd by Buechner *et al.* (1974). A receptive cow stands performing the submissive head-in display with

tail out in response to foreleg lifting, whereupon the bull mounts and completes copulation within a few seconds (Estes & Estes 1974).

Urine-testing, which enables ♂♂ of most ungulates to monitor female reproductive status, is also performed very frequently by ♀♀ and even young calves in this species (likewise in Roan Antelopes and probably in the whole tribe). Research into the behaviour and reproductive physiology of captive ♀♀ has shown that urine testing can serve to synchronize reproduction among associated individuals (Thompson 1995, Thompson & Monfort 1999).

Behaviour of Sable Antelope mothers and calves is typical of the 'hider' system prevalent among antelopes (Estes 1991a). A cow preparing to calve typically seeks seclusion and grass tall enough to conceal a calf during the 2–3 week hiding period. Exceptionally, however, a cow may remain in her herd and calve on bare ground (Sekulic 1978). A mother remains on guard within the area where the calf is hiding but may not know its exact location and has to search for it when retrieving and suckling it two or more times a day (Thompson 1996). Following these activity periods, during which a calf may have social contact with other calves if the mother leads it to her herd, it seeks and remains in a new hiding place until retrieved again. Calves are sometimes found hiding together (Grobler 1980b). After calves join the herd at 2–4 weeks (Thompson 1998), they associate together in crèches and only seek out their mothers to nurse. They have even less contact after weaning but continue to associate with their peers in definable subgroups. The bond between calves is so much closer than the maternal bond that calves often end up separated from their mothers, a situation promoted by the tendency of crèches to lag behind the rest of the herd (Estes 1991a). Calves born after the annual peak may not join a crèche but instead rest with the herd (Thompson 1998).

Usually silent, ♀♀ and young exchange surprisingly high, bird-like calls when searching for one another. When hotly pursued by a bull, ♀♀ and young ♂♂ emit a harsh scream, and bulls emit a braying roar when chasing other Sables. Sable Antelopes are rarely found closely associated with other ungulates.

Reproduction and Population Structure The Sable Antelope is an annual, seasonal breeder throughout most of its range, which lies almost wholly in the single wet-season zone. Mating occurs toward the end of the dry season and calving occurs over a period of several months at the end of the rains. As fecundity is strongly influenced by nutrition, mating should occur when the breeding population is in peak condition. Recorded conception rates have been nearly 100% (Wilson & Hirst 1977). Yet Sable Antelopes unable to find green pasture at the end of the dry season are likely to be in only fair to poor condition. One natural and one anthropogenic occurrence may raise the Sable's nutritional plane: the regrowth of foliage a month or more before the rains in the miombo 'spring' and green pasture resulting from burning. Calving late in the rains is a time of plenty, when tall grassland provides secure hiding places during the concealment period. Most calves (ca. 80%) are born during a two-month calving peak: Feb–Apr in Zimbabwe (Child & Wilson 1964, Grobler 1974, Wilson 1975); Jan–Feb in N Botswana (Child 1968); Feb–Mar in Kruger N. P. (Fairall 1968); and May–Jun in Giant Sable reserves (Estes & Estes 1974). In Kenya, with two wet seasons characteristic of the equatorial region, the Sable Antelope has no fixed breeding season. Like the Roan, ♀♀ have a postpartum

oestrus and may reproduce every 9–10 months (Sekulic 1978, Ross 1984). Males are fertile all year round (Wilson & Hirst 1977).

Gestation period has been given as 240–248 days (Wilson & Hirst 1977) and 259–272 days (mean = 266; Grobler 1980b). Mean birth mass for ♂♂ has been recorded as 19 kg (range 13.5–19.8; n = 26) and for ♀♀ 20.3 (range 13.5–22.5; n = 22) (Grobler 1980b). The faded tan colour and markings of newborn calves change to the adult form within two months, by which time the horns are 2–3 cm long. Both sexes of *H. n. niger* begin to darken in their first year and become progressively darker with age, to the point where mature cows can be mistaken for bulls. In the other races ♀♀ may become a richer, chestnut colour with age, but only ♂♂ turn black, beginning in their fourth year and proceeding from forequarters to hindquarters. The horns grow straight up, becoming twice ear-length in yearlings and beginning to curve in the second year. Calves are weaned at about eight months; the milk composition of free-ranging Sable Antelopes has been investigated by Osthoff *et al.* (2007), and seems comparable to that of ovines.

Males become adolescent and capable of breeding by 1.5 years (Wilson & Hirst 1977). Their horns are thicker than those of ♀♀ but do not become longer and more curved until the third year, by which time (2.5 years) ♀♀ are fully grown and pregnant (although ♀♀ in captivity may calve at two years). Males continue growing for another two years, becoming larger and dominant over ♀♀ and developing much thicker, longer horns of more pronounced curvature.

As in virtually all sociable, territorial bovids, the adult sex ratio is skewed in favour of ♀♀, in consequence of male sexual competition and selective predation. The fact that female offspring are philopatric while ♂♂ are driven from the maternal herd and home-range when they develop obvious male secondary characters is the main reason. For instance, the adult sex ratio in a subpopulation of 415 animals in Victoria Falls was 36 : 64 (Estes & Estes 1969b). In Matopos N. P., Grobler (1974) calculated a 1 : 1 yearling sex ratio, compared with a 1 : 2.18 to 1 : 2.38 overall adult sex ratio. Territorial ♂♂, spaced out on their territories, typically comprise 10–12% of the population (R. D. Estes pers. obs.).

Survival and recruitment rates, based on percentage of immature animals to adult ♀♀ were assessed in the Shimba Hills National Reserve, Victoria Falls and Luando Reserve during a two-year study (Estes & Estes 1969a, b, 1974):

| | Shimba Hills | Victoria Falls | Luando |
|---------------|--------------|----------------|--------|
| Calves (%) | 86.5 | 47.5 | 75.2 |
| Yearlings (%) | 37.8 | 35.0 | 53.1 |
| 2-yr-olds (%) | 18.9 | 26.4 | 39.8 |

Weigl (2005) gives a longevity record for *H. n. niger* in captivity of 22 years and three months. Females more than ten years of age have been recorded calving (Grobler 1980b).

Predators, Parasites and Diseases Predator density is low in the miombo woodland zone, reflecting the low density of prey species. Leopards *Panthera pardus* and Spotted Hyaenas *Crocuta crocuta* are the main predators, followed by African Wild Dogs *Lycaon pictus*, mainly through predation on calves and juveniles. The tendency of the young to associate in crèches, which regularly lag behind the herd, increases their vulnerability. In the southern, drier parts of the

Sable Antelope's range there are more Lions, Spotted Hyenas and African Wild Dogs, but the presence of abundant and preferred prey species such as Plains Zebras *Equus quagga* and Common Wildebeest *Connochaetes taurinus* usually buffers the Sable – though apparently not in Kruger N. P. (Pienaar 1969a). There may also be some hesitation to take on the adults, as the Sable can defend itself more effectively than most antelopes, especially by stabbing backward and sideways with its scimitar horns, a fighting technique rarely deployed against conspecifics except in sparring matches (Estes 1991a). If it proves to be a habit, moving from feeding grounds to a resting/ruminating spot after dark could be an additional anti-predator strategy (Estes 1991a).

In the Shimba Hills National Reserve (Ross 1984), a Sable bull was observed defending a calf from a Leopard attack. By roaring loudly and charging the Leopard, the bull successfully frightened the Leopard off the calf, which only sustained a few scratches. The incidence of 'female territory preference' described earlier suggests that the bull could in fact have been defending his own calf, despite the fact the Sable herds typically move so freely through different territories in the course of the year (Ross 1984).

The tall grasslands utilized by Sable Antelopes in the dry season are often heavily infested with ticks, especially clusters of hundreds of larval 'pepper ticks' in the inflorescences. Various species of ixodid ticks have been recorded from Sable: in the Central Province of Zambia, Zieger *et al.* (1998b) recovered five species from a single animal, namely *Amblyomma variegatum*, *Boophilus decoloratus*, *Rhipicephalus appendiculatus*, *R. evertsi* and *R. lunulatus*.

Sable Antelopes react to the alerting calls of associated oxpeckers (*Buphagus* spp.), which play an important role in reducing tick loads, especially concentrations around the tail, ears and neck. Observations of different Sable populations in Zimbabwe suggested that the more oxpeckers present the less heavy tick loads and associated sores were in evidence. In Zambezi N. P., where there were few oxpeckers compared to Hwange N. P., tick loads were noticeable especially in lactating ♀♀, which were in the poorest condition. Some animals had missing eartips, probably caused by infected tick bites (less likely due to occasional freezing temperatures). In Matopos N. P., where oxpeckers had been largely eliminated through cattle-dipping and reduced wildlife in surrounding areas, the Sable Antelopes were not only in mostly poor condition but some were seriously infested with ticks and had large sores resembling mange (Estes & Estes 1969b).

The parasites of Roan and Sable Antelopes were investigated in Percy Fyfe N. R. by Wilson & Hirst (1977). Four protozoal parasites of the blood and organs were implicated in the deaths of juvenile Sable and Roan, including *Cytauxzoon* sp. and *Babesia* sp., both tickborne diseases, *Chlamydia* sp., a chronic disease of domestic calves, and *Pneumocystis carinii*. A rapid loss rate of calves only a few days old from cytauxzoonosis infection was explained by the finding that *Cytauxzoon* sp. could be transmitted by the mother via the placenta. Helminthiasis (eight species identified) was only a secondary problem and not an important factor by itself in Sable mortality. Exceptional worm burdens could lead to some loss of condition but were far outweighed by primary deficiencies in diet. However, infection by *Haemonchus* spp. was suspected as a main cause of mortality in Sable Antelopes in Zimbabwe under particularly moist conditions (Grobler 1981b). Thomas *et al.* (1982) report

infections of Sable Antelopes by *Babesia*, *Theileria* and *Anaplasma* spp. Sable Antelopes have been reported to be more resistant to anthrax (caused by *Bacillus anthracis*) than are Roan (Pienaar 1961).

Conservation IUCN Category: Least Concern (*H. n. variiani* – Critically Endangered A2cd; C2a(i)). CITES: Appendix I (*H. n. variiani* only).

Distribution and numbers of Sable Antelopes have been reduced by loss of habitat (to settlement, cultivation, development schemes) and poaching. Range and numbers were severely reduced during Mozambique's civil war, while the effects of recent wholesale poaching in Zimbabwe are not yet fully known or realized. A 2004 aerial survey of Liuwa N. P. and surroundings in SW Zambia (Barotseland) indicates that both Sable and Roan Antelopes have been eliminated from the region (P. Viljoen pers. comm.). A former stronghold of Sable in N Botswana, near the Caprivi border, has been severely impacted by the construction of the Northern Buffalo Fence, which has affected their access to water, causing significant mortality.

Of the total Sable population estimated by East (1999), about half were estimated to occur in and around protected areas. Major protected populations of the species occur in Selous (probably the largest in Africa), Moyowosi-Kigosi, Ugalla River, Katavi-Rukwa, and Ruaha-Rungwa-Kisigo-Muhesi Game Reserves (Tanzania); Kafue N. P. (Zambia); Liwonde N. P. (Malawi); Niassa G. R. (Mozambique); Hwange N. P. (Zimbabwe); Chobe N. P., Moremi and Okavango-Linyanti Game Reserves (Botswana); and South Africa's Kruger N. P. (where in decline either due to habitat degradation or high predation pressure; Grant & Van der Walt 2000, Owen-Smith *et al.* 2012) (East 1999).

In Kenya, the only major population (representing Roosevelt Sable) occurs in the Shimba Hills National Reserve. A nucleus herd from this population could be translocated as foundation stock to create a second reserve in one of the places where Sable Antelopes formerly occurred. Possible sites include Mwangea Hill near Vitengeni west of Malindi, Jombo Hill or Mrima Hill south of the Shimba Hills, and the South Coast near Lunga Lunga. In addition to reducing the risk of having only one population in the limited area of the Shimba Hills National Reserve, protecting another example of the indigenous fauna and flora of the *Brachystegia/Diospyrus* ecotype of the coastal hinterland would be highly desirable for the preservation of Kenya's biodiversity.

Sable have been widely reintroduced on private land and provincial nature reserves in South Africa, Swaziland, Zimbabwe, Botswana and Namibia (East 1999). Many of these reintroduced populations are small, and this poses a genetic threat to Sable. In a survey of 136 ranches in Zimbabwe with Sable Antelope, 35% had fewer than 50 individuals and 20% of all populations had less than 10 animals (du Toit, R. F. 1992). Consequently, inbreeding, evidenced by increased calf mortality, is a major risk in many of the smaller, privately owned herds (Grobler & Van der Bank 1994).

Luando Reserve and Cangandala N. P. are the essential strongholds for Giant Sable. Expeditions mounted in 2002 and 2004 established that herds still survived in both protected areas – despite near-to-total absence of protection during and after Angola's 28-year civil war (Estes 2002b, Goering 2002, Walker 2004, Baldus 2005, O'Keefe 2005, Vaz Pinto 2006). However, now that peace has come

to Angola, the Giant Sable may be more threatened than ever (Estes 2002b, Walker 2004). Virtually all of the 25,000 or more people who lived in the Luando Reserve during the mid-1970s moved out and took refuge in cities and towns during the fighting. By 2002, Angolans were flooding back into the areas they had evacuated. Unless the government can strictly limit the number of people coming back into Luando and other protected areas, the habitat available to wildlife will be increasingly limited. Unscrupulous foreign trophy hunters prepared to pay almost any price to hunt Giant Sable may come in considerable numbers. The best hope for the Giant Sable's survival is a National Park that encompasses both the Luando Reserve and Cangandala N. P., wherein conserving Sable habitat has top priority (Estes 1983). Unless the Angola Government underwrites this alternative in the near future, it may be too late for this iconic animal.

Although instances of hybridization with the congeneric Roan Antelope are extremely rare in the wild (see Taxonomy), camera-trap photos taken in Cangandala N. P. in 2005 revealed the presence of hybrids of the Critically Endangered Giant Sable with Roan. Hybrid animals were identified by their unusually long, floppy ears and uncharacteristic facial markings. In Jan 2006, a Roan bull was seen leading the Sable herd, further evidence that cross-breeding between the single Roan bull and the Sable cows was taking place, apparently in the absence of a mature Sable bull and/or absence of Roan cows (Vaz Pinto 2006). Survey work revealed that only 10, elderly Giant Sable cows survived in Cangandala N. P., and that they produced only hybrids (called robles) after 2005. A total of 10 robles were born up until 2010 at the rate of one every six months or so. The hybrids included two ♂♂, which developed into large bulls. In 2009, a 400-ha captive-breeding enclosure was established in Cangandala N. P. and in Jul and Aug of 2009, the nine surviving Sable cows (the tenth had since died of old age) – of estimated ages 8–14 years – were transferred to a holding boma in the enclosure, later to be joined by a bull airlifted 100 km from the Luando Reserve. Unfortunately, expectations that the captive cows would produce a bumper crop of calves were dashed when only three calves were born in 2010.

In 2010, photographic evidence of a two-month-old hybrid calf in Cangandala N. P., accompanied by its hybrid mother, proved that hybrids were fertile after all, although it was unclear whether hybrids were breeding among themselves, or whether the calf was the outcome of a Sable or Roan backcross with a hybrid. This spurred a second capture operation in 2011, which included doubling the size of the fenced sanctuary to 3400 ha, hopefully large enough to

enable two herds with two territorial bulls to coexist. In Jul and Aug, a capture team logged over 100 helicopter hours flying over the Luando Reserve and Cangandala N. P. and found no Sable in the southern part of Luando, where Unita troops based at Mulondo had probably killed all resident herds (numerous poachers camps indicated continuing heavy commercial poaching). However, four different herds (the largest numbering 24) were recorded in the northern part of the Luando Reserve near Cunga Palanca, each accompanied by a territorial bull. In addition, three, solitary, territorial bulls were sighted, yielding a total of 60 animals (7 bulls, 21 cows, 11 calves, 12 yearlings and 9 two-year-olds). Three ♀♀, one two-year-old ♂ and one solitary territorial bull were translocated to the enlarged sanctuary in Cangandala N. P. At the same time, in Cangandala N. P., all of the known hybrid robles were darted one at a time. The two mature bulls and a sub-adult ♂ were castrated, and the six roble cows had their udders removed to prevent them rearing young. In summary, fewer than 100 Giant Sable, and more likely 60–70 animals, are all that survive in Luando Reserve. Thus, the *in situ* captive-breeding efforts in Cangandala are do or die for the Giant Sable.

Measurements

Hippotragus niger

HB (♂♂): 1924 (1877–1985) mm, n = 4

T (♂♂): 465 (425–515) mm, n = 4

HF c.u. (♂♂): 524 (457–550) mm, n = 4

E (♂♂): 237 (225–265) mm, n = 4

WT (MM): 191.0, 260.0 kg, n = 2

Botswana (Smithers 1971)

Haltenorth & Diller (1980) give Sh. ht. as 1270–1430 mm for ♂♂ and 1170–1350 mm for ♀♀. In E Zambia, Wilson (1968) gave the mean weight for 15 ♂♂ as 234.7 kg (range 212.0–262.7) and for 10 ♀♀ as 217.9 kg (range 203.9–231.0). Grobler (1974) estimated the mass of six ♂♂ darted in Matopos N. P. at between 155.0 and 270.0 kg

Maximum recorded horn length is 164.8 cm for a pair of horns of a Giant Sable from Angola (Rowland Ward)

GENUS *Addax**Addax*

Addax Laurillard, 1841. In: d'Orbigny, Dict. Univ. Hist. Nat. I, p. 619.

Addax is a monotypic genus containing the *Addax nasomaculatus*, a desert antelope that originally ranged so widely over the Sahara that it represented a single gene-pool and even the most assiduous splitters have been unable to argue convincingly for recognition of subspecies. This taxonomic detail is a good biological indicator of the absence of physical or ecological boundaries in open deserts, even when that desert is as extensive as the Sahara. It is also an indicator of the extent of movements made by these animals and of their former great numbers. Of course, there have been more humid periods when the Sahara became a mosaic in which stretches of arid land became interspersed with more savanna-like habitats. At such times there may well have been some tendency for subpopulations to become distinct; none the less, these periods would seem not to have lasted long enough to allow subspeciation.

Both morphological and genetic studies cluster *Addax* and members of the genus *Oryx* (e.g. Hassanin *et al.* 2012), with the latter speciating more recently; indeed, these genera have been known to hybridize (Ruhe 1993), presumably with sterile offspring. The *Addax* is known to have taken adaptation to heat-stress, solar radiation and total drought further than any other large antelope and this implies that its lineage must have made a very early start in making the necessary physiological modifications (the Arabian *Oryx leucoryx*, which most resembles the *Addax* in size and colouring, may well match it in resistance to heat and drought, but these adaptations are more recently evolved). Molecular clocks suggest that the *Addax* and *Oryx* lineages diverged about 5 mya (Hernández Fernández & Vrba 2005), which broadly corresponds with the later Messinian (6.5–5.3 mya) when the Mediterranean dried out and deserts, especially the Sahara, spread as the world became cooler and drier. Within the hippotragines, which first appear in the African fossil record at about 6.5 mya, the joint *Addax*–*Oryx* lineages' divergence from *Hippotragus* has been calculated

at over 10 mya (Hernández Fernández & Vrba 2005; and see discussion under Hippotragini). Although the latter are not desert animals today, there is much to suggest that all hippotragines share a common arid-adapted heritage, possibly beginning in Asia as the large-bodied branch of a proto-caprine lineage (Kingdon 1982). The *Addax* could, therefore, represent the culmination of some 10–14 million years of life in arid lands.

The many remarkable characteristics that are so authoritatively described in the profile of *Addax nasomaculatus* imply that even at the beginning of the 'Messinian Crisis', the ancestors of this species were probably already the best equipped large herbivores to adapt to a prolonged 'ordeal by drought'. Their survival, until very recently, in the driest fastnesses of the Sahara represents a period of refinement to the many challenges of the Sahara that is probably as old as the desert itself, so much so that no other free-ranging large mammal can approach it for efficient utilization of the Sahara's scarce and scattered resources.

While concern was voiced in the 1930s about impending extirpation of this unique genus (In Tanoust 1930, Brocklehurst 1931), the crass ineptitude of deaf colonial powers has been augmented by their successors and by many contemporary international policy-making bodies, notably those concerned with promoting livestock and so-called 'development'. Together with the armed, motorized men that have done most of the killing, all these institutions suffer a selective myopia towards the ecological and evolutionary processes that have enabled useful and beautiful organisms to make their livings in the remotest and most difficult regions of the world. The casual emptying of naturally adapted life out of the Sahara exposes the shallowness and brutality of our cultures and institutions; it will be among the many severe indictments of our generation.

Jonathan Kingdon

Addax nasomaculatus ADDAX

Fr. *Addax*; Ger. *Mendesantilope* oder (*Addax*)

Addax nasomaculatus (de Blainville, 1816). Bull. Sci. Soc. Philom., Paris 1816: 75. No type locality given. Lydekker (1914: 148) stated it was 'probably Senegambia', but Grubb (2005) noted that it was more probable that British hunters or collectors obtained *Addaxes* from the Tunisian Sahara, to which he restricted the type locality.

The *Addax* probably takes its name from the vernacular Arabic *agas* or *adas*. The specific name *nasomaculatus* – meaning 'spotted nosed' – refers to the contrasting white patches on the otherwise darker head.

Taxonomy On the basis of differences in pelage between museum specimens from Tunisia and Sudan, Lydekker (1908) suggested the possibility of two subspecies, *A. n. nasomaculatus* and *A. n. addax*. However, this was rejected by Flower (1932) on the basis of observed seasonal differences in pelage throughout the *Addax*'s range, and although Allen (1939) attempted to reopen the debate, the issue was put to rest by Ellerman & Morrison-Scott (1951) and Setzer (1956) following examination of original and current specimens. Ansell

(1972) treated the *Addax* as monotypic. Synonyms: *addax*, *gibbosa*, *mytilopes*, *suturosa*. Chromosome number: 2n = 58; the first pair of autosomes are submetacentric, while all other chromosomes are acrocentric (Wurster & Benirschke 1968). Their chromosomes share many common features with other Hippotragini (Claro *et al.* 1996). *Addax* and Scimitar-horned *Oryx* *Oryx dammah* hybrids are known and reported to resemble *Addaxes* in European zoos (Ruhe 1993). Hybrids born at Bou-Hedma N. P. in Tunisia (believed to be sired by an oryx ♂) were large bodied like oryx, with typical oryx horn shape, but with obvious *Addax* body colouration and body shape (R. Molcanova pers. comm.).

Addax *Addax nasomaculatus*.

Description A predominantly white, stocky-bodied, medium-sized antelope inhabiting the sand seas and gravel plains of the Sahara. Head light grey or beige, with contrasting white patches in front of the eyes, linked across the bridge of the muzzle. Small white patches behind the eyes. Nose beige, lips and chin white. Crown and forehead sporting a prominent, wig-like tuft of dark brown hair. Ears white with a long basal tuft of pale hairs. With the exception of the throat and chest, which are beige, overall body colour is bright matte white. During the hot season (Apr–Oct) pelage is short, but in the colder months (Nov–Mar) it lengthens on the neck, chest, shoulders, back and flanks, becoming greyer, a characteristic especially obvious in Addaxes held in zoos with cold winter climates (Renshaw 1902). Adults of both sexes develop a beige fringe of variable length on the lower neck. Legs white with beige patches on knees. Hooves broad and splayed. Tail short and white, sporting a sparse tuft of dark terminal hairs. Other than slight differences in size, weight and horn development in adults, sexes are essentially similar. Pedal glands are present on all four feet.

Both sexes bear corkscrew-shaped horns, which grow upwards and outwards, reaching over one metre in length. The horns of the adult ♂ are stockier than those of the ♀, often having two to two-and-a-half turns to the female's one-and-a-half to two. Horns are heavily annulated over the first two-thirds of their length in both sexes. Over time, and with violent sparring, the horns of the ♂ may become lost, damaged or blunted.

Geographic Variation None recorded (and see Taxonomy above), although Addaxes inhabiting colder, North African climates tend to maintain a longer and darker pelage than sub-Saharan populations, a characteristic shared by animals kept in northern zoos.

Similar Species The Addax's size, colouration and habitat preferences leave little chance of misidentification in the field. However,

Lateral and palatal views of skull of Addax *Addax nasomaculatus*.

lack of familiarity with the animal due to its rarity, together with long flight distances, makes comparison desirable with the Scimitar-horned Oryx *Oryx dammah* and the Dama Gazelle *Nanger dama*, both of which have in the past been sighted in close proximity to Addaxes.

Oryx dammah. Now extinct in the wild. Larger, averaging 150 kg; off-white with rusty-red neck and cape instead of pure white; scimitar-shaped horns; occupies sub-desert steppe rather than true desert.

Nanger dama. Smaller (60 kg); white and rusty rather than pure white colouration; short, lyrate horns; occupies sub-desert steppe and wadis rather than true desert.

Distribution Endemic to the Sahelo-Saharan region of Africa, west of the Nile Valley. As with other ungulates of the Sahelo-Saharan fauna, the Addax has undergone an unprecedented reduction in its geographical range over the past century, and although the issue's gravity is only just being seriously considered by the international conservation community, authors in the 1930s (In Tanoust 1930, Brocklehurst 1931) had already raised the alarm, identifying excessive offtake and motorized hunting as the prime cause of the Addax's decline.

Historical Distribution Their presence in prehistoric times is reflected in rock engravings and paintings (Hugo & Bruggmann 1999), as well as on walls of tombs in the Nile Valley from the Sixth Dynasty (In Tanoust 1930, Heim de Balsac 1931), although there is no solid proof of the Addax occurring east of the Nile R. (Manlius 2000b). They are depicted in North African mosaics from Roman times. Historically widespread, and present in suitable habitats in all countries sharing the Sahara Desert (Nachtigal 1879–89, In Tanoust 1930, Kock 1970, Newby 1984a, Beudels-Jamar *et al.* 2005a). The coastal Atlantic deserts of Mauritania and ex-Spanish Sahara, extending as far north as the Moroccan Drâa Valley and the southern edge of the Atlas Mts formed the western and north-western limits to the Addax's distribution (Marçais 1937, Morales Agacino 1950, Valverde 1957, Loggers *et al.* 1992). In the central Sahara, the great ergs and hamadas (Lhote 1946, Walter & Breckle 1986, Kowalski & Rzebik-Kowalska 1991) and further east, the Western Desert of Libya and Egypt (Hufnagl 1972, Osborn & Krombein 1969, Osborn & Helmy

1980), were all former Addax strongholds. In the southern Sahara and bordering Sahelo-Saharan steppes, the Addax was formerly numerous along a several thousand kilometre front, stretching from Mauritania to C Sudan via Mali, Niger and Chad (Brocklehurst 1931, Shaw 1945, Lhote 1946, Brouin 1950, Audas 1951, Monod 1958, Gillet 1969, Kock 1970, Wilson 1980, Lamarche 1987, Heringa 1990).

Current Distribution Although already long extinct in Morocco, Tunisia (1932) and Egypt (ca. 1900), and extremely rare in Libya and Algeria (Lavauden 1926a, Brocklehurst 1931, Cabrera 1932, Flower 1932, Bigourdan & Prunier 1937, Blancou 1958a, b, Dupuy 1967, Hufnagl 1972), the Addax was still present in fair numbers in Mauritania, Mali, Niger and Chad up until the late 1960s and early 1970s (Monod 1958, Hue 1960, Edmond-Blanc *et al.* 1962, Gillet 1964). Massed herds, drawn together by exceptional grazing, could then still be found in Chad, Mauritania and Mali (Newby 1978a, Lamarche 1980). Monod (1961, 1990), on his fourth voyage across Mauritania's Majabat sand sea in 1960, counted the tracks of more than 5000 Addaxes in a single day and over 11,000 in the space of a week.

Today, the Addax is confined to two to three sparsely inhabited areas of E Niger and W Chad, lying between the Termit/Tin Toumma area of the former and the Djourab of the latter (Grettenberger & Newby 1990, Thomassey & Newby 1990, East 1999, Mallon & Kingswood 2001a, Claro & Sissier 2003, Monfort *et al.* 2004, Newby *et al.* 2004, Planton & Ascani 2004, Wachter *et al.* 2004a, Beudels-Jamar *et al.* 2005a, Wachter *et al.* 2008, 2009, Wachter & Newby 2010). Possible rare vagrants from these areas may be seen in N Niger, S Algeria and Libya. They are rumoured to persist in former strongholds straddling the Mali–Mauritania (Majabat Al Koubra) frontier and in Egypt, but there is no recent supporting evidence (Hoath 2003, F. Claro pers. comm.). Aerial and ground surveys carried out in the Erdis and Mourdi of NE Chad in late-2005 recorded no Addaxes. In early

March 2007, the fresh tracks of about 15 Addaxes were seen in C Mauritania, in an area where they had not been seen for over 20 years (R. Vernet pers. comm.).

Habitat The most desert-loving large ungulate, frequenting areas of extreme temperature (range -5 to $+60^{\circ}\text{C}$) and aridity (less than 100 mm annually). With the exception of truly mountainous areas, the Addax has been recorded from all major Saharan habitat types, ranging from gravelly and sandy plains, to dune fields, sandy basins and depressions, pans and wadi systems (In Tanoust 1930, Newby 1978a, Lamarche 1980, Giazzi 1996). Their preference is for harder, packed sands and flatter areas within and between dune fields that support perennial vegetation. Although not a mountain species, Addaxes use wadi beds to penetrate Saharan massifs in search of food and shade. Their local distribution is heavily influenced by the presence of suitable pasture and shade during the hottest months (Apr–Aug), when Addaxes may move into the more wooded sub-Saharan grasslands during periods of drought, or when attracted by rainfall and any resulting pastures (Gillet 1964, 1965, Newby 1978a).

Abundance Probably fewer than 300 animals survive in the wild, distributed unevenly along a narrow, 600 km-long band lying between Termit/Tin Toumma in Niger and the Djourab sand sea in Chad. The main population is in Niger, probably numbering around 200 individuals. Otherwise, they are found in widely separated small groups, typically singletons or small herds of 2–3 animals (Ama *et al.* 1998, Lamarche & Hamerlink 1998, Barmou & Oumarou 2000, Scholte 2001, Amadou 2002, Monfort *et al.* 2004, Wachter *et al.* 2004a). In the Termit/Tin Toumma area, M. Ascani (pers. comm.) reported the tracks of a group of 57 Addaxes during the cold season of 2001–2002. In the same area, Claro & Sissier (2003) observed 34 in 2002 (and see Claro 2004) and a systematic survey carried out by Wachter *et al.* (2004a) recorded 26 Addaxes and estimated a population size of 227 (with 95% CI between 93 and 555) for the area of 8814 km² sampled. In September 2004, a total aerial count of some 93,000 km² of prime Addax habitat to the east of the Termit Massif returned a total of 128 Addaxes (Keita 2004, Planton & Ascani 2004). Ground and aerial surveys in 2005 in N Chad (Beudels-Jamar *et al.* 2005a) turned up only one, all-adult group of nine Addaxes. In May 2007, more than 60 animals were again spotted in the Termit/Tin Toumma area of Niger (T. Rabeil pers. comm.). In November 2007, 71 Addax were spotted in Tin Toumma during a combined ground and air survey. Statistical treatment of data suggests a population size of around 200 animals (Wachter *et al.* 2008, 2010).

Addaxes have been reintroduced to fenced sectors of protected areas in Tunisia (Bou-Hedma N. P.) and Morocco (Souss-Massa: 70 animals released 1994–97 increased to ca. 550 by 2007; Cuzin *et al.* 2007). During 2007, 33 Addax from Bou-Hedma N. P. and zoos in Europe and the United States were introduced to enclosures in Tunisia's Djebel and Senghar National Parks in the Great Eastern Erg (Molcanova & Wachter 2010). Addaxes from Souss-Massa N. P. in Morocco have also been released into a small, 600-ha enclosure at Safia just north of the Morocco–Mauritania border (T. Abaigar pers. comm.).

In comparison with the situation in the wild, *ex situ* presence and status is healthy, with over 600 Addaxes in Europe, North America, Japan and Australia in managed breeding programmes. At least 1000

more individuals are held in private collections and ranches in the United States and the Middle East (Engel & Brunsing 1999, D. Noble pers. comm., T. Correll pers. comm.).

Adaptations The Addax displays a large number of morphological, physiological and behavioural adaptations to life in a hot, dry environment, including pale colouration to reflect radiant heat, pelage length and density to assist with thermoregulation, barrel-bodied shape to reduce surface area/volume ratio, and large, splayed and spongy hooves for moving in a hot and sandy environment.

The Addax has a highly efficient moisture extraction and retention system. The rumen and omasum are important in water economy and conservation (Ruckbush & Thivend 1979), and faeces are exceptionally dry. Consumption of plants, such as *Boerhavia repens* or *Limeum viscosum*, may be the source of the fine mucilaginous film coating the faeces that assists ejection (Gillet 1965). The Addax likely exhibits physiological heat and moisture control measures described in other large desert-living mammals, including urine concentration (Monod coined the term 'addaxite' for the rock-hard aggregation of sand and Addax urine!), osmoregulation and sodium retention, high tolerance to thermal stress, low metabolic rate, high switch-on point for sweating and the presence of an efficient blood temperature cooling system in the nasal sinuses (Taylor 1969, Taylor & Lyman 1972, Cloudsley-Thompson 1977, Schmidt-Nielsen 1979, Louw & Seeley 1982). Research on free-ranging Arabian Oryxes in Saudi Arabia (Ostrowski *et al.* 2003) has demonstrated a high degree of heterothermy, up to $4.1 \pm 1.7^\circ\text{C}$ per day, permitting an estimated water economy of more than 0.5 l per day in thermoregulation. It is likely that a similar adaptation exists in the Addax.

Behavioural adaptations include feeding during cooler hours and at night, and sheltering and resting during the heat of the day. Seasonal distribution and frequency of traditional resting sites is often influenced by presence of shade (Newby 1981). Animals have been recorded excavating shelter behind vegetation or on the shade side of dunes using both hooves and horns (Lamarche 1980, Dragesco-Joffé 1993).

Foraging and Food The Addax is a grazer, the diet of which is based almost exclusively on the small number of plants able to prosper under the desert's harsh regime. Staples include the xerophytic grasses *Stipagrostis vulnerans* and *S. acutiflora*, and the prickly succulent *Cornulaca monacantha*. *Stipagrostis vulnerans* and *C. monacantha* are particularly favoured, their distribution and quality often defining the Addax's local presence, foraging behaviour and movements (Monod 1958, Gillet 1964, Lamarche 1980, Monfort *et al.* 2004, Wachter *et al.* 2004a). Addaxes may remain for weeks or months in areas of good grazing. As plants dry out, or begin to green after a period of drought, Addaxes will clamber on to tussocks, pawing away sand and dead vegetation to reach new or remaining green shoots and leaves.

As temperatures in the open desert rise (shade temperatures during the hot season regularly exceed 45°C), or the quality of vegetation diminishes, Addaxes will move towards the sub-desert steppes or mountainous areas where surface rainfall run-off or subterranean seepage allow the growth of vegetation and the maintenance of sparse trees and shrubs. At times like this, plants such as *Panicum turgidum*, *Aristida mutabilis*, *Moltkiopsis ciliata* and

Indigofera spp. are eaten. As with all Sahelo-Saharan ungulates, as well as Ostriches *Struthio camelus*, the succulent, but bitter, wild melon *Citrullus colocynthis* is especially sought, containing as it does a rare source of moisture. It is at these times that Addaxes will also browse on shrubs, such as *Leptadenia pyrotechnica*, *Capparis decidua*, *Maerua crassifolia* and *Acacia tortilis*, eat the long fleshy parasite *Cistanche phelypaea* (Lamarche 1980, Wachter *et al.* 2008) – a habit that may have given rise to the belief held by the bedu that the Addax eats snakes – and strip *P. turgidum* grasses of their seed heads (Gillet 1964).

Although tropical rainfall in the Addax's domain is a rare event, it does happen occasionally, giving rise not only to temporary standing water but also to rich, ephemeral pastures known as *jizu* or *eshoob* by the Arabs. Jizu pastures, which are often extensive, are composed of only a small number of perennial species (such as *S. acutiflora*, *Astenatherum forskalii*, *Limeum* sp., *Heliotropium* sp., *Cyperus conglomeratus* and *Tribulus* sp.), but are highly attractive to Addax and other desert fauna (Newby 1978a, 1984a, Wilson 1978, Poilecot 1996). The Sahara is also prone to winter rainfall from Mediterranean weather fronts. If insufficient to leave standing water, the combination of drizzle plus cold night-time temperatures (regularly as low as $1\text{--}2^\circ\text{C}$) favours plant growth and the greening of perennials. Since the Addax very rarely has access to free water, its diet must provide both food and moisture. With adequate grazing, animals are able to survive for long periods, possibly years, without drinking. However, under conditions of poor grazing and high temperatures they lose condition and eventually succumb. On occasions when it is available, Addaxes will drink water in large quantities.

Social and Reproductive Behaviour The Addax is nomadic, wandering over large areas in search of grazing. Movement and duration of stay within any one locality is dictated by quality of grazing, and in the hotter months, to a certain extent by shade. It will remain in the general vicinity of good grazing for long periods. Although not a migrant in the true sense of the word, the Addax undertakes local, seasonal movements in relation to vegetation and climatic conditions. In the relatively uniform desert and sub-desert lands of the Sahel, movements tend to be north–south in direction, i.e. from the more arid desert to the less arid sub-desert and Sahel (Gillet 1965, Newby 1978a). In C Niger, movement may also be east–west, i.e. from the open desert towards the better-wooded and more varied habitats of the Air and Termit mountains (Hue 1960). In Mali and Mauritania, seasonal movements are north-west to south-east, between the dunes of the Mreyye and the better vegetated Aklé (Lamarche 1980, 1987).

Addaxes generally live in small herds of up to 15 animals, comprising ♂♂ and ♀♀ of all ages (Lhote 1946, Lamarche 1980, Walters 1981, Mackler 1984). The larger groups observed in the past, sometimes numbering several hundred, were probably the result of many smaller herds congregating seasonally and temporarily in areas of exceptional grazing (Nachtigal 1879–89, In Tanoust 1930, Monod 1961, Newby 1978a). With increasing persecution, and as a result of mortality due to the severe droughts of the past four decades, average Addax herd size today is rarely more than half a dozen (Dragesco-Joffé 1993). In Niger, between 1980 and 1991, average herd size was 2.2 (range 1–5, $n = 27$) (Rapant 1992, Poilecot 1996). In the wild, herds are generally led by an adult cow (Lamarche 1980), although Mackler (1984) observed male dominance under captive

conditions. During the rut, the alpha-male interacts aggressively with challengers, engaging in long bouts of horn wrestling, and chasing off younger ♂♂ (Newby 1978a, Lamarche 1980, Mackler 1984). In captivity, ♂♂ have been observed to engage in flehmen and lausschlag to assess oestrus in ♀♀ and to elicit receptivity for copulation (Mackler 1984).

Shortly before parturition, the ♀ moves away from the herd, possibly to avoid the attentions of the dominant bull. The young is born in a shallow scrape, often in the shelter of vegetation if available, the cow and calf joining the herd after 3–4 days. For the first few days, the cow leaves her calf to join the herd to feed, often moving considerable distances in doing so (In Tanoust 1930, Lamarche 1980).

Reproduction and Population Structure In the wild, frequency of births and resulting calving periods depend on pasture condition. Under good conditions ♀♀ demonstrate postpartum oestrus and can breed throughout the year (Dolan 1966a, Dittrich 1986). In times of severe drought or periods of poor grazing, reproduction is disturbed and ♀♀ may either abort, abandon young calves, or not calve at all until pasture improves (Newby 1978a, Lamarche 1980). In general, however, ♀♀ have one young per year, usually calving during the cooler months (Sep–Mar).

The gestation period is between 34.5 and 38.5 weeks, and a single calf is born weighing between 5.0 and 8.6 kg (mean = 7.0; n = 96 from animals in captivity, Ferrell *et al.* 2001; see also Puschmann 1989, Engel & Brunsing 1999). Calves are rusty-beige at birth, progressively taking on the adult pelage over the first year of its life (Lamarche 1980). Calves are weaned after 6–10 months and reach sexual maturity between 24 and 30 months (Densmore 1986, Dittrich 1986). In captivity, the reproductive behaviour of Addaxes has been well studied (Manski 1991) as has their reproductive endocrinology (Asa *et al.* 1996, Hall-Woods *et al.* 1999). Mean oestrous cycle length at St Louis Zoo was 32.3 days. Longevity under zoo conditions is in the order of 25–28 years (Jones 1993, Weigl 2005).

Predators, Parasites and Diseases A healthy adult Addax has no natural predators. Young calves are harassed and taken by Golden Jackals *Canis aureus* (Lamarche 1980, J. Newby pers. obs). Other potential predators, before their almost total extirpation in the Sahara, included Cheetahs *Acinonyx jubatus*, Striped Hyenas *Hyaena hyaena* and African Wild Dogs *Lycan pictus*.

Diseases in the wild are little known, although Addaxes are reported to be susceptible to rinderpest (Brouin 1950). In captivity, Addaxes have been identified as the hosts of a wide range of bacterial, viral and intestinal organisms, including Johne's disease (Burton *et al.* 2001), yersiniosis (Raverty 2002), encephalomyocarditis (Citino 1995), clostridium (Gulland & Parsons 1987) and roundworms (Craig 1993).

Conservation IUCN Category: Critically Endangered A2cd; C1+2a(ii). CITES: Appendix I. CMS: Appendix I.

Along with other large Sahelo-Saharan mammals, including the Slender-horned Gazelle *Gazella leptoceros* and Dama Gazelle, the plight of the Addax has been largely overlooked by the conservation community. The Scimitar-horned Oryx *Oryx dammah* is already 'Extinct in the Wild' and the species mentioned above are all down to highly fragmented populations of less than 500 individuals at best. With the notable exceptions of a CMS project, funded by the French

government (FFEM) and the European Union, and the establishment in 2004 of the Sahara Conservation Fund (SCF), direct support for conservation to the region is extremely limited.

The decline and extirpation of the Addax, along with the other large ungulates of the Sahara and Sahel, can be attributed primarily to a murderous combination of the motor vehicle, the modern rifle and man's cupidity (Newby 1980, 1981, 1982, 1988). The further impacts of civil war, severe drought (1969–72, 1983–84) and the extension of pastoralism into desert lands, thanks to the increase in wells, have also taken a heavy toll on wildlife. During the recent past, a new and potentially disastrous threat from hunters from the Gulf states has also emerged (*Le Sahel* 2002, BBC 2003, *El Watan* 2003, UNEP/CMS 2004), a phenomenon earlier addressed by Newby (1990a) and Cloudsley-Thompson (1992). Lastly, the exploration for oil (and the construction of wells and pipelines for its exploitation) in Niger's Tin Toumma desert is having a major impact on Addax distribution and access to grazing, as well as leaving them vulnerable to opportunistic hunting by military detachments providing security to the oil workers (Sahara Conservation Fund 2010).

Establishment of protected areas for the Addax and other Sahelo-Saharan species, and designating the Addax as a strictly protected species in all range states, has been a case of too little too late. Although massive reserves, such as the Ahaggar (4,400,000 ha) and Tasilli (1,140,000 ha) in Algeria, the Aïr/Ténéré (7,736,000 ha) in Niger, the Ouadi Rimé–Ouadi Achim (7,795,000 ha) in Chad, and the newly established Wadi Howar N. P. in Sudan cover areas where the Addax formerly occurred, they are under-resourced or no longer harbour Addaxes (Newby 1982, 1984b, 1991, UNESCO 1998, Monfort *et al.* 2004, Newby *et al.* 2004). In early 2012, Niger established the Termit and Tin Toumma National Nature Reserve, a 97,000 km² tract of desert and sub-desert land specifically designed and managed to protect Addax and other threatened species. In the short term, the only way of saving the Addax from extinction in the wild is to multiply efforts on the ground to protect it and its remaining critical habitat. Given the terrain and the political instability in the Addax's remaining range, this is a significant task. Continued support for gazetted reserves in Chad and Niger, together with the establishment of new protected areas, especially along the Mali/Mauritania frontier (Majabat) and Chad (Bodélé, Eguey), will only succeed if adequately supported and combined with programmes to create incentives for the local people to protect wildlife wherever it is found (Newby *et al.* 1987, Newby 1990b, 1992, 2002). Addax, together with other Sahelo-Saharan ungulates, should be the subject of a binding, inter-governmental, regional agreement and action plan under the Bonn Convention. International efforts and diplomacy are needed to ensure that foreign hunters behave responsibly, respect local and international laws, and contribute to wildlife conservation and restoration programmes. To combat the threat from oil activities, far better communication and cooperation between ministries and operators in the same country are essential.

In Morocco and Tunisia, reintroduction schemes are beginning to bear fruit (Engel & Brunsing 1999, Cano *et al.* 2001, Wakefield & Molcanova 2001, Anonymous 2003, Molcanova & Wachter 2010), and these are providing valuable lessons and experience needed for reintroduction and local captive-breeding initiatives in countries where the Addax is still extant (Dixon *et al.* 1991). Luckily, a number of zoos in Europe and the United States are maintaining genetically robust stocks of Addax ready for reintroduction. Like

Addax *Addax nasomaculatus*.

all reintroductions, however, efforts will come to nothing unless the root causes for the Addax's extinction are addressed beforehand (Spalton *et al.* 1999, Dunham 2001).

Ultimately, as In Tanoust (1930) said in his authoritative work on Saharan wildlife, the desert itself is the Addax's best protection: 'l'addax est une pauvre bête, facile à tuer, et qui n'a qu'une protection: le desert' [the addax is a sorry beast, easy to kill, and with only one protection: the desert itself].

Measurements

Addax nasomaculatus

HB (♂ ♂): 1600, 1700 mm, n = 2

HB (♀ ♀): 1540, 1580 mm, n = 2

T (♂): 340 mm, n = 1

T (♀ ♀): 260, 280 mm, n = 2

HF c.u. (♂ ♂): 95, 95 mm, n = 2

HF c.u. (♀ ♀): 95, 100 mm, n = 2

E (♂ ♂): 200, 200 mm, n = 2

E (♀ ♀): 175, 185 mm, n = 2

Sh. ht (♂ ♂): 1060, 1140 mm, n = 2

Sh. ht (♀ ♀): 1060, 1080 mm, n = 2

WT (♂ ♂): 101.0, 125.0 kg, n = 2

WT (♀): 82.0 kg, n = 1

Air Mts, Niger (Brouin 1950)

WT (♂ ♂): 94.4, 104.0 kg, n = 2*

WT (♀ ♀): 94.7 (87.1–108.9) kg, n = 3*

WT (unsexed): 104.0 (91.0–115.0) kg, n = 4**

Captivity (*St Louis Zoo [Fischer *et al.* 1993]; **The Living Desert [T. Correll pers. comm.])

Maximum recorded horn length from the native range is 91.4 cm from the Sudan, although an animal in Texas, USA, had horns measuring 103.2 cm (Rowland Ward)

Note: A wealth of information on the dimensions of the skull, skeleton and brain of the Addax can be found in von Oboussier (1974)

John Newby

GENUS *Oryx*

Oryxes

Oryx de Blainville, 1816. Bull. Sci. Soc. Philom., Paris 1816: 75.

The genus *Oryx* embraces several forms of desert antelope, including the Gemsbok *Oryx gazella*, the Arabian Oryx *O. leucoryx* and the Scimitar-horned Oryx *O. dammah*. Until recently, the north-east African Beisa Oryx *O. beisa* was commonly subsumed as a subspecies of the Gemsbok, but most authors now regard Beisa as a distinct species (Grubb 2005; and see Osmers *et al.* 2012). The latter course has been followed in this work.

The genus *Addax* has many resemblances with *Oryx*, but the two lineages diverged some 5.3 mya (Hernández Fernández & Vrba 2005). It would appear that while *Addax* became specialized to exploit the driest areas of the Sahara, *Oryx* maintained sufficient versatility to adapt to (literally) more marginal areas of the four great desert regions of Afro-Arabia. Thus, the Scimitar-horned Oryx formerly flourished in a broad swathe around the Sahara, both to the north and to the south. The Beisa Oryx inhabited extensive areas

of semi-desert around the Horn of Africa, and the Gemsbok spread widely throughout the Namib and Kalahari arid region. The Scimitar-horned Oryx is, perhaps, the more wholly desert-adapted of the three African species, sharing its white colouring and diminished size with both the Arabian Oryx *Oryx leucoryx* and the Addax *Addax nasomaculatus*.

As animals from regions where predators are few, young oryxes seem to be consistently susceptible to heavy predation in spite of occasional examples of protective threats by adults (Tilson *et al.* 1980, Mills 1990, Molcanova *et al.* 2001, M. Stanley Price pers. comm.). It can be suspected that there are similar vulnerabilities to parasites and diseases to which other antelopes are immune. Thus, desert-acquired susceptibility to predators and diseases are likely to be major selective forces confining *Oryx* to dry open areas with few other antelopes or carnivores and where recruitment can keep up with mortality.

Whether the Arabian Oryx ever occurred on the African mainland, west of Sinai, has been a matter of some conjecture. This species formerly occurred through most of the Arabian Peninsula, north to Kuwait and Iraq, but the last populations were hunted out by 1972. A concerted reintroduction programme was initiated in 1982 (Stanley Price 1989). The probable presence of this species in the Sinai during prehistoric times (see Osborn and Osbornová 1998) raises the question as to whether the species could have got through the Isthmus of Suez and colonized the Egyptian deserts to the east of the Nile R. In reviewing the question of whether the Arabian Oryx occurred in Egypt during pharaonic times, Manlius (2000c)

focused attention on a desert hunting scene depicted in a fresco from the walls of Neferhotep's tomb of Drab Abul Neggah, near Thebes. Neferhotep lived during the XVIIIth Dynasty, from 1427 to 1392 BC. The hunting scene depicts an oryx whose morphology and coat colouration closely resembles that of an Arabian Oryx. This is not irrefutable evidence of the presence of Arabian Oryxes in the Eastern Desert, and the pharaonic fresco might equally be evidence that Egyptians went hunting in Arabia (T. Wachter pers. comm.).

Jonathan Kingdon

Oryx gazella GEMSBOK (SOUTHERN ORYX)

Fr. Gemsbok; Ger. Südafrikanischer Spiessbock

Oryx gazella (Linnaeus, 1758). Syst. Nat., 10th edn 1: 69. 'India'; understood to be South Africa (Thomas 1911: 152).

Gemsbok *Oryx gazella*.

The origin of the name Gemsbok is obscure, but appears to be a combination of the German word 'gems' for the European chamois and the Dutch word 'bok' for buck.

Taxonomy Monotypic species including only those animals from southern Africa (following Kingdon 1997, East 1999, Grubb 2005, Osmers *et al.* 2012), and excluding forms *beisa*, *gallarum*, *annectens* and *callotis* (and other allied forms) from the East and north-eastern parts of Africa (contra Ansell 1972, Grubb 1993c).

Synonyms: *aschenborni*, *bezoartica*, *blainei*, *capensis*, *nec*, *onyx*, *oryx*, *pasan*, *recticornis*. Chromosome number: $2n = 56$ (Hsu & Benirschke 1968, Wurster 1972, Gallagher & Womack 1992, Kumamoto *et al.* 1999). One male $2n = 57$ specimen deviated from the normal complement due to aneuploidy; this animal died from maternal

Lateral view of skull of Gemsbok *Oryx gazella*.

neglect on the day of birth, although post-mortem investigations did not reveal any congenital abnormalities (Kumamoto *et al.* 1999). The X chromosome is a large acrocentric and the Y chromosome is a small acrocentric (Kumamoto *et al.* 1999). Gray (1972) reports hybridization in captivity between the Beisa Oryx *Oryx beisa* and Gemsbok, which produced viable offspring.

Description A large, thick-necked, monomorphic antelope with long straight horns aligned with the muzzle, large and oval ears, and a distinctly marked body pattern. Muzzle tip white with characteristic bold black facial strips extending from the horns to the dark muzzle ring, all set on a white background. Belly bright white, with a contrasting black flank strip that extends to the elbow and hindquarters; lower legs have characteristic white stockings and black hooves. Remaining upper body a distinctive pale cream-grey, with a thin dark brown mane from shoulders to mid-back, widening after into saddle above rump and narrowing again towards tail. Tail is long, black and hangs to below the hocks. Pelage short and sleek, body hairs about 35 mm long. Like all oryx species, neck and shoulders are enveloped in an exceptionally thick, inelastic and dense skin. Distinctive dewlap at throat, with a dark brown line down the mid-line to between the forelegs. Newly born Gemsbok pelage is light brown to reddish in colour without any distinctive markings. Juveniles start to develop adult colouration at six months, when horns also start to become more prominent. Pedal glands are present on all feet; the constituents of these glands have been investigated by Wood (1997b); preorbital and inguinal glands are absent. Sexes are difficult to tell apart, except that adult ♂♂ are heavier set.

Horns present in both sexes, ♂♂ with shorter, stockier horns. The first third of the cylindrical horns is ribbed, remainder being long, smooth and ending in notably sharp tips.

Geographic Variation There is no obvious geographical variation, but Angolan animals are distinguished by their narrower black markings.

Similar Species

Oryx beisa. Allopatric, occurring in East Africa only. Slightly smaller, with a more brown-grey coat colour and less prominent flank strips and upper leg markings, and lacks a black muzzle ring. A particular subspecies, *O. b. callotis*, in SE Kenya and NE Tanzania has prominent black-haired ear fringes.

O. dammah. Saharan species, now extinct in the wild. Smallest of the African species; characteristic apricot-brown forequarters and white body coat, with no dark facial or flank patterning; long, characteristically arched horns.

Distribution Endemic to southern Africa, south of the Cunene and Zambezi Rivers, formerly with a marginal intrusion into SW Angola.

Historical Distribution Formerly occurred widely in the semi-arid and arid bushland and grassland of the Kalahari and Karoo and adjoining regions of southern Africa (East 1999). Gemsboks ranged well south of the Orange R. in South Africa into Namaqualand and the central Karoo and marginally into Limpopo Province of South Africa. They ranged throughout Namibia and Botswana, though largely absent from parts of N and NE Namibia (including the Caprivi Strip) and within and to the north of the Okavango Delta in Botswana (as well as parts of the south and south-east). Extended peripherally into NW Zimbabwe, at the eastern limit of the Kalahari sand areas north and south of Hwange N. P. (Smithers & Wilson 1979) and SW Angola, north to about 75 km inland of Benguela (Crawford-Cabral & Veríssimo 2005).

Current Distribution Gemsboks remain widely, albeit patchily, distributed in south-western southern Africa, although populations in SW Angola are now considered extirpated, even from the former stronghold in Iona N. P. (East 1999). The species does not range as far south into the Karoo and Namaqualand as it once did, but it has been reintroduced in parts of its former range in the Northern Cape, largely onto private land and some national reserves such as Karoo N. P. There have been widespread reintroductions elsewhere within the former range, and Gemsboks have also been introduced in several areas, including onto private land in Zimbabwe (some of these populations may now have been extirpated) and in Limpopo Province of South Africa (East 1999).

An apparently viable population has become established on the White Sands Missile Reserve, New Mexico, USA.

Habitat Gemsboks prefer open arid to semi-arid grasslands with intermittent wooded or karroid shrublands receiving less than 500 mm annual rainfall. In Botswana and Namibia, they occur in open savanna and light woodlands, but at the arid extreme of their distribution they range into extensive dune fields and arid mountainous areas. In the arid Kalahari system, they prefer *Acacia*-

Oryx gazella

dominated savannas in combination with scattered pans. The pans and dry river beds are particularly important for their mineral licks sites, which offer important mineral supplements to the animals' generally poor-quality Kalahari diets. Furthermore, it has been suggested that the mineral licks may also be an important source of clay, crucial in neutralizing the effects of acidosis, in addition to minimizing the effects of plant secondary compounds in the rumen (Kreulen & Jager 1984). Gemsboks penetrate moister *Baikiaea* and Mopane *Colophospermum mopane* woodlands in the eastern areas of their range.

Abundance In the southern Kalahari, Gemsbok densities ranged between 0.45 and 0.87 animals/km². With the demise of migratory Common Wildebeest *Connochaetes taurinus* and Red Hartebeest *Alcelaphus buselaphus caama* populations in the Kalahari, there appears to have been an increase in Gemsbok numbers in the central Kalahari system; their independence of surface water and non-migratory behaviour seems to have helped them survive the adverse effects of the veterinary cordon fences that have had such a detrimental impact on populations of migratory game (Spinage & Matlhare 1992). In 1997, the Gemsbok population in the southern Namib was estimated to be 10,400 strong, at a density of 0.17 ind/km², which appeared to be down from the estimate of 0.53 ind/km² in 1984 (Kilian 1997). Population estimates are available for almost all of this species' range, with Namibia (187,000), Botswana (125,000) and South Africa (13,000) collectively harbouring about 320,000 of a combined total population of 330,000 animals. However, actual numbers are probably higher because of an unknown level of undercounting bias in aerial surveys. East (1999), assuming an average correction factor for undercounting bias of 1.3, produced a total population estimate of 373,000.

Adaptations Gemsboks are extremely well adapted to surviving in hot and arid environments. Their pelage is well suited to reflect radiant heat, there is evidence that they show adaptive heterothermy

in extreme desert conditions, they are able to conserve body water more efficiently than virtually all other artiodactyls, they can regulate their brain temperature, and they have a range of thermoregulatory behaviours.

Taylor (1969) proposed that brain temperature regulation, especially during exercise, was achieved by counter-current heat exchange between the cool venous sinus blood derived from the nasal veins and the network of carotid artery blood vessels, known as the carotid rete situated at the base of the brain. Recent work by Maloney *et al.* (2002) on free-ranging Gemsboks has demonstrated that brain cooling, as in all other ruminants that have been studied, is a component of routine thermoregulation. The system completely shuts down during times of extreme exercise or stress, and is triggered most often in the late afternoon when the animal's body temperature is in the rising phase of its circadian rhythm. Its effect may be to reduce evaporative water loss. During exercise the animal rids itself of excess heat through panting (which increases the air flow over the capillaries of the veins in the nasal passages) or sweating.

Behavioural adaptations are a key part of the Gemsbok's ability to survive in arid environments. It is able to survive without drinking water by selecting for higher quality foods through its more selective feeding on succulent plant parts (facilitated by its relatively narrower muzzle than expected for an animal of its size), shifting to better quality browse in the dry months, making extensive use of water-rich melons and tubers, and by feeding predominantly in the cooler evenings (Knight 1991, 1995b). Furthermore, they lie up in cool sand and make extensive use of shade, spending up to 40% of the day in the shade, 10% more than Common Wildebeest in the Kalahari. Gemsboks also reduce water loss while foraging during daylight hours by actively orientating their body in such a way as to reduce the surface area directly exposed to the sun's rays. This behaviour was noticeably more common in the hot dry season. Gemsboks are also up to 13% less active than Common Wildebeest, which in itself saves both energy and water. Moreover, it appears that activity budgets and feeding rates of Gemsbok are shaped more by external factors such as air temperature, vegetation height and group size, than by sex and reproductive differences (Ruckstuhl & Neuhaus 2009).

Water turnover rate is the lowest known (85 ml/kg per day) (Macfarlane *et al.* 1971). The Gemsbok's kidneys are relatively efficient in their water retention ability as reflected in their ability to handle water with 1.8% total dissolved salts (Giddings 1990). Furthermore, the stomach of the Gemsbok also shows morphological adaptation to conserving water. The colon ascendens makes up 80% of the length of the colon; this is the main site of water reabsorption and reduces water content from 82% in the proximal gut to 56% or less in the faeces (Reiðig 1995). Finally, the Gemsbok can moderate its breathing to reduce the loss of moisture in the respiratory tract.

Foraging and Food Gemsboks have a great capacity to digest high-fibre diets—a further adaptation to surviving in their arid environment (Hofmann 1973, Reiðig 1995). Although they are predominantly grazers (80–93% of diet), they broaden their diets in the dry season to include a greater proportion of browse, ephemerals and *Acacia* pods, which make up 6% of their diet at this time (Knight 1991). In the Kalahari, they prefer productive short-grass habitats associated with pan edges and dry river beds in the wet season, moving into the taller, less palatable longer grasslands in the dry season.

Gemsbok tend to be rather generalist in their selection of grasses and forbs, feeding on *Stipagrostis ciliata*, *Eragrostis lehmanniana* and *Tribulus terrestris* throughout the year, but switching to more resilient and fibrous *S. amabilis* and *S. uniplumis* and water-rich Tsama Melon *Citrullus lanatus*, when available, during the dry season. They appear to avoid the prolific annual grass *Schmidtia kalahariensis* when it is green during the wet season, probably because of a chemical irritant produced by this grass, but they do feed on it in the dry season. Gemsboks also feed extensively upon protein-rich pods of *Acacia erioloba* and *A. haematoxylon* during the dry seasons. Overutilization of *A. erioloba* pods is known to cause prussic poisoning in Gemsboks. By virtue of their narrower muzzle and use of browse, Gemsboks are able to select for a better quality diet, particularly in the dry season, than similar-sized, broad-mouthed grazers such as Common Wildebeest.

Stomach contents have a very high moisture content (82%), so much so that Bushmen used the rumen juice as a source of water, squeezing and straining the liquid through grass into skin containers (Skinner & Chimimba 2005). To supplement their required daily water intake (which Knight [1995b] estimated at 2.5–4 litres depending on weather conditions), Gemsboks make extensive use of water-rich fruits such as the Tsama Melon in the Kalahari and Nara *Acanthosicyos horridus* in the Namib. They also excavate the tuber of the astringent-tasting Gemsbok Cucumber *A. naudinianus* during the dry months, as well as others such as *Brachystelma* spp., *Cucumella cinerea*, *Neorautanenia brachypus* and *Talinum tenuissimum* (Williamson 1987, Knight 1995b). The Gemsbok Cucumber appears to be a more predictable source of water than the Tsama Melon, which varies considerably between areas and years in its abundance. Dieckmann (1980) recorded Gemsboks digging for the roots of *Grielum humifusum* during the dry season in Namaqualand. When freshwater is available individuals will drink up to 21 litres every five days (Dreyer 1987). Introduction of drinking water to the South Africa side of the Kgalagadi Transfrontier Park appeared to result in a higher density of Gemsboks than the adjacent, but waterless, Botswana side of the Park. As an energy-saving tactic, Gemsboks are considerably less active than other large herbivores such as Common Wildebeest. Daily foraging distances average 9 km for both sexes.

Social and Reproductive Behaviour Gemsboks are gregarious, occurring in mixed herds (averaging about eight animals) and nursery herds, although solitary ♂♂ are also common. Herds are usually relatively small, up to 30, but larger herds of as many as 300 can form in the wet season (Knight 1991). Although the ♂♂ are territorial, they show some degree of tolerance towards other adult ♂♂. Solitary territorial bulls have territory sizes ranging between 14 and 30 km² in the southern Kalahari, while adult female home-ranges vary between 260 and 530 km² depending upon environmental conditions (Knight 1991). Some territories have been held by the same individual for as long as three years (Knight 1991). By contrast, non-territorial bulls may range over areas of 3600 km². In the absence of access to drinking water, home-ranges of adult ♀♀ vary between 1400 and 3074 km² (Knight 1991). In the central Kalahari G. R., female home-ranges varied from 52 to 212 km²; five ♂♂ (probably territorial) had annual ranges of 10–16 km² (Williamson & Williamson 1988). In Namaqualand in the Northern Cape, the mean size of territories was 7.6 km², and tended to be delimited by drainage lines and kopjes (Dieckmann 1980).

Adult ♂♂ mark their territories with piles of dung that they deposit in a characteristic low crouch. The dung piles are often left under or adjacent to large trees or bushes, predominantly around the periphery of the territory (Dieckmann 1980, Knight 1991). The territories appear to be patrolled on a regular basis. The ♂♂ defend their territories from other ♂♂ through threat-like behaviour that includes ground pawing, horning of shrubbery and head-on clashes (Dieckmann 1980). Such aggressive behaviour constitutes about 20% of all social interactions. In comparison with other antelopes, Gemsboks appear to show relatively high levels of aggression as reflected in the high incidence of broken or damaged horns. The most dangerous fighting movement is an over-the-shoulder horn thrust, made when contestants are standing alongside each other, and it can result in death. The territorial bull will herd mixed and/or nursery herds into his territory. Non-territorial ♂♂ do not form bachelor groups but remain with mixed herds. When approached by adult ♂♂, subadults normally hang and shake their heads in submission and move off. Under lower rainfall regimes (less than 100 mm of rain) the territorial system is replaced with a 'following' system with ♂♂ tagging onto breeding herds. However, in favourable habitats, such as along the vegetated dry river beds in the Namib, adult ♂♂ are more sedentary. Adult ♂♂ with symmetrical horns appear to be more successful in maintaining their territories and breeding, as are adult ♀♀ in breeding (Møller *et al.* 1996).

Courtship and mating is the prerogative of the territorial bull and occurs throughout the year; non-territorial ♂♂ very rarely succeed in mating. Males test the reproductive status of ♀♀ regularly and exhibit flehmen after inserting the nostrils into the stream of a female's urine. If the ♀ is in oestrus, lauschlag may follow and if the ♀ is receptive she will stand and allow the ♂ to copulate. The ♀♀ stay with the herd during parturition or leave to give birth. The young are hidden for up to six weeks after birth, after which time the mother and young will join either a mixed or nursery herd. The effectiveness of their hiding behaviour led early colonists to think that the calves were born with horns (the horns growing some 200–300 mm during the period of concealment). Nursing of young tends to follow periods of rumination.

Reproduction and Population Structure Although single calves are born at any time of the year, there tend to be peak periods such as Aug–Sep in the Kalahari (Knight 1991) and North West Province (Skinner *et al.* 1974) and May–Jul in the Namib, which coincides with the peak wet season (J. W. Kilian pers. comm.). Gestation period is about 8.5 months; Fringe-eared Oryxes *O. b. callotis* have a postpartum oestrus, but it is not known whether the same holds true for Gemsboks. Calves are weaned at about five months. Females become sexually mature at the age of two years and first conceive at 29–33 months (Dieckmann 1980). Maximum longevity in captivity has been given as just less than 24 years (Weigl 2005). Adult ♂ to ♀ sex ratios averaged 1.0 : 1.4; adult ♀ to calf ratios averaged 1 : 0.28 (Knight 1991).

Predators, Parasites and Diseases Lions *Panthera leo* and Spotted Hyaenas *Crocuta crocuta* are the main predators of adults and calves, although Cheetahs *Acinonyx jubatus* will also prey on calves. Mills (1990) found Gemsboks made up between 32% and 52% of Lion and Spotted Hyaena kills, respectively, and Gemsboks were also

the most important food item in the overall diet of two groups of Spotted Hyaenas studied in the Namib Desert by Tilson *et al.* (1980). Spotted Hyaenas' success rate is higher (82%) for Gemsbok calves vs. 14% for adults. Adult Gemsboks often back into *Acacia* thickets as a defence strategy against attack by Spotted Hyaenas.

Simpson (1978) recorded serological evidence of bluetongue antibodies in Gemsboks in Botswana. Gemsboks are also prone to ticks in wetter areas, which may account for their inability to survive in higher rainfall areas. The ticks notably attack the udder regions in adult ♀♀. Horak *et al.* (1992a) examined 48 Gemsboks from Etosha N. P. and Hardap Dam G. R. in Namibia and recorded four ixodid tick (*Hyalomma marginatum*, *H. truncatum*, *Rhipicephalus evertsi* and an unidentified *Rhipicephalus* sp.) and two lice (*Haematopinus oryx* and *Linognathus oryx*) species. Boomker *et al.* (1986) recorded a number of helminths from an animal taken in Kgalagadi Transfrontier Park, including a number of new host records: *Haemonchus contortus*, *Longistrongylus meyeri*, *Paracooperia serrata*, *Impalalia nudicollis* and *Agriostomum equidentatum*, and Boomker (1986) later also added *Trichostongylus auriculatus*. Boomker & Durette-Desset (2003) remark on the presence of *Teladorsagia hamata* in the species.

In response to reports from game farmers regarding mortalities among Gemsboks that had been introduced in Free State, Fourie & Vrahimis (1989) conducted a study on Tussen-die-Riviere G. R. and established that the Karoo paralysis tick *Ixodes rubicundus* was responsible for paralysis and mortalities amongst the Gemsboks. The mean burden of female Karoo paralysis ticks on paralysed subadult Gemsboks was 0.83 ticks/kg host body mass (range 0.26–2.12) compared with a burden of 0.12 ticks/kg host body mass (range 0.03–0.18) on healthy adult animals. Gemsboks with high tick burdens were therefore more likely to suffer paralysis compared with Gemsboks with lower tick burdens. Paralysed animals were found during May and Jun of each year, corresponding closely with the peak period of activity of the Karoo paralysis tick.

Conservation IUCN Category: Least Concern. CITES: Not listed.

Despite having experienced a range contraction and decline in numbers in the nineteenth and twentieth centuries, Gemsboks remain widespread and are present in a number of well-managed protected areas (about 35% of the population), including Etosha N. P. and Namib-Naukluft N. P. (Namibia) and the mega Kgalagadi Transfrontier Park between South Africa and Botswana. Furthermore, about 45% of the entire population resides on private land (East 1999). In Namibia alone the population on private land increased from 55,000 in 1972 to >164,000 in 1992, indicative of the important role this sector of society is playing in the conservation of the species (East 1999). The Gemsbok's ability to meet its survival needs within a relatively small area of semi-arid or arid savanna, even during severe droughts, enables it to occupy much smaller mean annual ranges than migratory species such as the Common Wildebeest and Red Hartebeest. Furthermore, their independence of surface water and non-migratory behaviour have enabled it to largely escape the adverse effects of veterinary cordon fencing (East 1999). The Gemsbok's future is secure so long as protection within southern African reserves and private lands continues. Provided illegal hunting is controlled, the Gemsbok's desirability as a hunting trophy could promote further increases in population size and might extend the species' distribution.

Measurements*Oryx gazella*

HB (♂ ♂): 1995 (1220–2460) mm, n = 14

HB (♀ ♀): 2140 (1700–2400) mm, n = 15

T (♂ ♂): 418 (320–520) mm, n = 14

T (♀ ♀): 435 (400–525) mm, n = 15

HF c.u. (♂ ♂): 510 (460–580) mm, n = 14

HF c.u. (♀ ♀): 508 (450–545) mm, n = 15

E (♂ ♂): 191 (180–205) mm, n = 14

E (♀ ♀): 199 (185–225) mm, n = 15

WT (♂ ♂): 240.0, 245.0 kg, n = 2

WT (♀ ♀): 200.0, 230.0 kg, n = 2

Kalahari (Smithers 1971, M. Knight pers. obs.)

Maximum recorded horn length is 125.7 cm for horns of a ♀ from the Northern Cape, South Africa (Rowland Ward)

Key References Dieckmann 1980; East 1999; Knight 1991.**Michael Knight*****Oryx beisa* BEISA ORYX (FRINGE-EARED ORYX)**Fr. *Oryx beisa*; Ger. Eritrea-Spiessbock (Swahili Choroa)

Oryx beisa (Rüppell, 1835). Neue Wirbelt. Fauna Abyssin. Gehorig, Säugeth., p. 14, pl. 5. Eritrea, 'in den Niederungen der Küstenlandschaft bei Massaua' (Red Sea coast west of Massawa).

Beisa Oryx *Oryx beisa*.Lateral view of skull of Beisa Oryx *Oryx beisa*.

Taxonomy The Beisa Oryx has frequently been treated as a subspecies of the southern African Gemsbok *Oryx gazella* (Ansell 1972), but has since been restored to full species status (Kingdon 1997, Grubb 2005), a view supported by karyotypic (Kumamoto *et al.* 1999) and molecular data (Osmers *et al.* 2012). Two morphologically recognizable subspecies of *O. beisa* are found on either side of the Tana R. in East Africa: the Beisa Oryx *Oryx beisa beisa* to the north and the Fringe-eared Oryx, *O. b. callotis* to the south (see

below). Molecular genetic investigation based on mtDNA control region and cytochrome *b* sequences from 21 *O. b. beisa* from Samburu and Marsabit in Kenya and 39 *O. b. callotis* from S Kenya and Tanzania confirmed significant genetic differentiation and historical isolation of the two subspecies, but with the complication that overall three equally distinct genetic lineages can be detected within modern East African oryx. One lineage clearly corresponds to Fringe-eared Oryx. The other two lineages are found together within oryx of Samburu and Marsabit, interpreted as evidence that what we call *O. b. beisa* today represents an ancient introgression between two of three originally differentiated subpopulations of East African oryx (Masembe *et al.* 2006). Synonyms: *annectens*, *aschenbonni*, *callotis*, *gallarum*, *reticornis*, *subcallotis*, *typica*. Chromosome number: $2n = 58$; the X chromosome is a large acrocentric and the Y chromosome is a small acrocentric. The two subspecies have indistinguishable karyotypes (Claro *et al.* 1996, Kumamoto *et al.* 1999). Gray (1972) reports hybridization in captivity between *O. gazella* ($2n = 56$) and *O. beisa*, which produced 'viable' offspring.

Description A large, thick-necked, brownish to greyish antelope with long straight horns and distinctively patterned head and ears. Face boldly striped in black and white in adults. Muzzle tip white, with black mask over bridge of nose and a black shield-shaped blaze mark on forehead overlaying a whitish background (or pale sandy buff in Fringe-eared Oryx). Mask and blaze may or may not be joined by a narrow black line and fine details of face-mask pattern are often individually distinctive at close range. Vertical black facial stripes extend from horn bases across eye to corner of mouth. Narrow black line extends down centre of throat to chest. Body

colour pale brownish-grey and pelage is dense, short and sleek. Tight, inconspicuous mane of the same colour extends from head to mid-back. Belly white (usually sandier in Fringe-eared Oryx), with a narrow black flank-stripe from elbow to just above knee. Lower legs white (sandier in Fringe-eared Oryx), and hooves and false hooves black; prominent black markings above knees of forelegs. Tail matches body colour, carrying an extensive brush of black hairs. Mature Fringe-eared Oryxes display distinctive terminal ear tassles, sometimes very prominent. Occasionally, hair loss in old Fringe-eared Oryxes may lead to extensive mottled patches of blackish skin colouration showing through on flanks and body. Hair loss may also result in appearance of all-black ear linings with no fringes. Sexes are superficially similar in the field, especially among younger age classes. Adult ♂♂ have thicker necks and deeper shoulders than ♀♀. Mature ♂♂ may sometimes be recognized at a distance by a combination of the massive neck, heavy horns and weary head-low gait adopted when walking in a typical 'controlling' position just behind a moving group. Mature ♂♂ develop a relatively enlarged scrotum compared with subadult ♂♂. For reliable separation from the more round-bellied, lighter-necked and thinner-horned ♀♀, ♂♂ are distinguished by the black penis sheath under the mid-belly or the scrotum (seen from between the hindlegs). Pedal glands are present on all four feet; preorbital and inguinal glands are absent.

The newborn calf has a uniform sandy or orange-brown body colour (almost cinamon-toned when very young) with weakly developed face pattern in tawny and buff, and a dark brown tail tuft. Body colour and pattern develops to adult tones in a continuous process from 2–6 months of age. Notably the face mask is last to develop full adult colouration, with the blaze patch at the base of the horns retaining tawny colouration longest, becoming fully black typically between 24 and 36 months of age in the Fringe-eared Oryx (Wacher 1986).

In adults, the cylindrical horns are annulated over the basal third to two-thirds of their length, but become progressively smoother and end in very hard and sharp, black shiny tips. Horns are rather straight (a more female trait), or slightly backswept (more masculine trait). Male horns are thicker and, in older individuals, often shorter, than those of ♀♀. Observation of known individuals (Arabian Oryx *Oryx leucoryx* and Fringe-eared Oryx) over time shows that full grown horns may shorten with age. This applies particularly to ♂♂, the result of splintering, breaks and tip damage in fighting, and also perhaps from wear accruing as the result of the specific behaviour of stabbing at termite mounds and soil: conceivably this serves to sharpen (and incidentally clean) the horns as well as perform a display function. Broken, misshapen horns may occur, resulting in asymmetrical, sometimes bizarre, shapes and single-horned animals, especially under managed conditions.

At birth, horn buds are present but scarcely observable in the field. At four months of age horns are approaching ear length, and have grown to match head length by about nine months. Through this period the horns typically lack annulations and appear smooth and blunt tipped, being encased in a fibrous keratinous sheath. This keratinous layer is most obvious when flaking off patchily to reveal the hard sharp adult horn material beneath. The period of this exfoliation occurs variably among individuals and in some cases for relatively extended periods between 6 and 24 months of age (Wacher 1986).

Inspection of the incisiform dentition on a series of known-age skulls (n = 46) and known-age live Fringe-eared Oryxes (n = 76

observations made on 40 or so individuals) on the Galana Ranch in Kenya indicated full sets of milk teeth up to 12 months of age. Successive eruption of the permanent incisiform dentition follows, commencing between 12 and 18 months of age, with completion occurring between 2.5 and 3.5 years of age (Wacher 1986).

Geographic Variation

O. b. beisa (Beisa Oryx): arid parts of Ethiopia and Horn of Africa, extreme SE Sudan and Kenya. Ears with small black tip; body colour tends to greyer cleaner tones (e.g. Samburu).

O. b. callotis (Fringe-eared Oryx): SE Kenya (south of the Tana R.) and NE Tanzania. Ears with long, pendulous, black-haired tips that are variable in size, developing with age; body colour tends to duller, sandier tones (e.g. Tsavo).

Similar Species

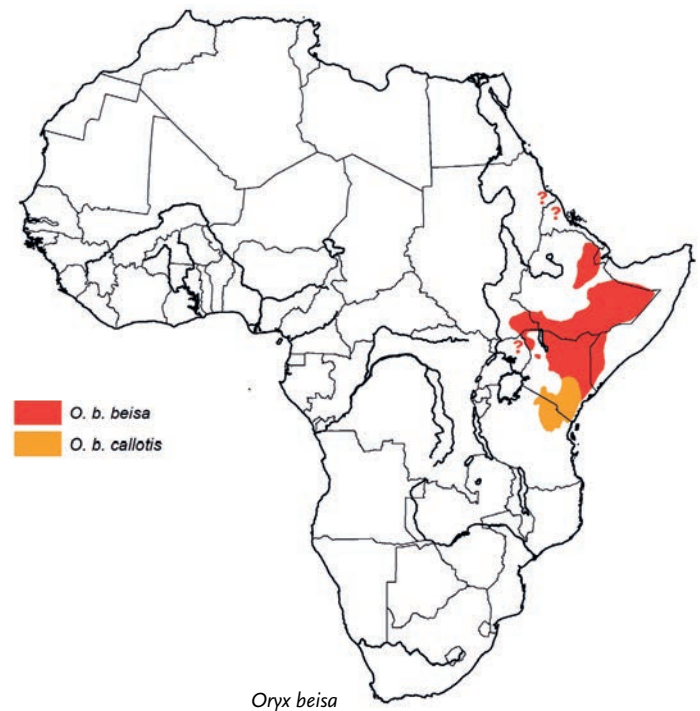

Oryx dammah. Allopatric Saharan species, now extinct in the wild. Smallest African member of genus, with characteristic apricot-brown forequarters and white body, much less contrasting facial and flank patterning, and long, characteristic arched horns.

O. gazella. The most similar species, but allopatric, occurring in south-west Africa only. Larger and brighter, with more extensive black markings, particularly on hindlegs, and a diagnostic dark patch over the upper rump; more rounded ears; horns typically more widespread.

Hippotragus equinus. Marginally sympatric in some areas (for example, SE Sudan). Much larger, somewhat redder antelope with shaggy coat and heavy curved horns

H. niger. Probably only marginally sympatric where the southern range of the Fringe-eared Oryx meets the northern part of the range of the Sable. Similar-sized antelope with reddish or black body colour and white belly and facial markings; arched horns.

Distribution Endemic to Africa.

Historical Distribution Formerly widespread in north-east Africa, from NE Sudan throughout arid areas of Eritrea, Ethiopia, NE Uganda and Kenya to Djibouti, Somalia and NE Tanzania.

Current Distribution The distribution of the species has declined markedly, especially at the margins of its range (East 1999). There is no current information on the population status of Beisa Oryxes in NE Sudan, but they survive in the south-east, mainly in Boma N. P. Likewise, in Eritrea there is no reliable recent information on their status. In Djibouti, they were restricted to the Gammaré Plateau on the Ethiopia border by the mid- to late 1980s. In Somalia, they were believed to be eliminated from the coastal plain north of Mogadishu by the late 1970s (T. Thurow pers. comm.) and survive only, as far as is known, in the south, where a population was noted in the Lag Dhere area in the 1980s (J. Sale pers. comm.). Beisa Oryxes still occur widely in Ethiopia and N Kenya. They are possibly extirpated in Uganda, although formerly common in the Bokora Corridor and Metheniko Game Reserves.

Fringe-eared Oryxes are distributed entirely south of the Tana R. in E Kenya and NE Tanzania, with a major centre of distribution in Tsavo (East) and the Galana Ranch region (Cobb 1976), spreading west and south to Mkomazi, Amboseli and sporadically appearing in Serengeti N. P. (Walther 1978c).

Habitat Beisa and Fringe-eared Oryxes prefer arid and semi-arid grasslands and bushlands, but avoid tall grass in the wet season and dense dry bush in the dry season. The condition of grazing and state of the soil influence seasonal movements. They move out of waterlogged and soft-soiled depressions and up onto higher ground during the rains, but make many cyclic peregrinations in some parts of their range. During the driest periods, and in the most arid parts of their range, movements are irregular. They occur to altitudes of 1700 m in Ethiopia (Yalden *et al.* 1996).

A radio-tracking study of range and habitat use by Fringe-eared Oryxes in the eastern lowlands of Kenya, on the Galana Ranch and Tsavo East N. P. boundary area (Wacher 1986), found significant differences in range use between some largely solitary adult ♂♂ (apparently occupants of territories) and the rest of the population (which ranged more widely) (see Social and Reproductive Behaviour below). In a generally flat landscape, characterized by a habitat sequence from lateritic and bushy red soils down through wooded and bushed grasslands on grey soils to black cotton grassland-drainage lines, analysis of radio locations on a 1 km² grid indicated a significant general association with those grid cells characterized by a mixture of habitats. This suggests that oryxes tend to remain close to the ecotone between major red soil and grey soil habitat associations in this region. Both mixed-sex herds and solitary ♂♂ showed a significant tendency to use open grassland habitats during feeding bouts in morning and evening, while moving into denser habitats to find shade in the hot middle hours of the day. Oryx herds used the open grassland habitats more in seasons of green growth while bushier red soils were frequented more often in the dry season. Individual animals made extensive movements to new grazing zones (up to 45 km recorded directly) in response to rainfall at the end of dry periods, although known solitary ♂♂ observed in these periods did not move.

During dry months, radio-collared Fringe-eared Oryxes on the eastern border of Tsavo East N. P. showed interesting behaviour in

relation to their need for water. At this time, the Galana R. becomes the main available surface water for a few weeks following the drying up of waterholes. Under these conditions herds tend to drink towards mid-day and show great caution wherever riverine thickets overlook the sand banks most favourable for drinking, but with a potential for ambush from Lions *Panthera leo* or Leopards *P. pardus*. After a trek of 10–15 km to the Galana R. bank, members of the herd stagger their drinking so that some animals are alert and always have their heads up, while others kneel to drink. Groups do not loiter or rest in such an area, rather they remain the minimum possible time and set off to march directly back within a couple of minutes of arriving, just as soon as drinking is complete. By contrast, herds visiting the open, nearly treeless banks of the artificial Aruba Dam in neighbouring Tsavo East N. P. were noted spending time resting beside the water. Solitary adult ♂♂ are also known to come to the river to drink at dusk (B. R. Heath pers. comm.) and, indeed, this was noted in the case of a radio-collared territorial ♂, who during one dry season once visited water at dusk (arriving back on his territory 12 km north at 23:00h). However, this single instance is contrasted with six other daytime excursions when the same individual arrived to drink in the middle of the day and returned to his territory before dusk. This same territorial ♂ and two adult ♀♀ with calves were observed daily throughout the late dry season month of Mar 1983. During this period all three animals were based ca. 10 km north of the river around Lali hills but never associated in the same social group. Observations confirmed that the territorial ♂ and adult ♀ with older calf trekked to the river and back once every 4–5 days throughout the month, maintaining the 10 km distance from the river during all non-drinking days. By contrast, a ♀ with a young calf and lactating more heavily, moved progressively closer to the river during the same period, and drinking intervals became shorter, diminishing from five to three days through the month. At the onset of rainfall towards the end of the month all movements to the river ceased for all three animals, as widespread small water pools became available. It has also been noted that managed oryxes supplied with water on a daily basis may also drink only at 4–5 day intervals (Stanley Price 1985b).

Abundance Densities are typically low, with aerial surveys giving densities of 0.05–0.1/km² in the Awash Valley and 0.15–0.2/km² in areas such as Mkomazi G. R. and Tarangire N. P. (East 1999; and references therein). Higher local densities were recorded in known centres of distribution in the 1970s: 0.26/km² for Marsabit in the 1970s (aerial survey KREMU data), 0.31–0.69/km² in Tsavo East N. P. (ground survey by Leuthold & Leuthold 1976), 0.54/km² in Isiolo in Kenya (Leuthold & Leuthold 1976) and up to 1.2–1.4/km² for Fringe-eared Oryxes (aerial survey of Galana Ranch in the 1970s; M. Stanley Price pers. comm.). However, it is notable that more recent estimates for some of these key areas have reported lower figures, for example, 0.05–0.1/km² in Tsavo in the 1990s (Butynski *et al.* 1997a).

Correcting for an undercounting bias in aerial surveys, East (1999) used an average density of 0.05/km² to estimate a total population of 50,000 Beisa Oryxes and 17,000 Fringe-eared Oryxes.

Adaptations Taylor (1969) studied oryxes to investigate their adaptation to arid environments and showed that these antelopes

have various physiological devices to reduce heat stress. Such adaptations have been shown to be widely shared by many, less obviously arid-adapted antelope and livestock species (King 1983), but are well developed in oryxes and gazelles. In dry conditions, dehydrated oryxes are known to conserve body water by allowing the body temperature to rise, storing heat through the day instead of sweating (Taylor 1970a). The brain is protected by a counter-current heat exchange system between the blood vessels draining the nasal mucosa and those travelling toward the brain (the carotid rete), which is believed to sustain the brain at normal temperature while the rest of the body warms. Under experimental conditions dehydrated oryxes are reported to have successfully sustained body temperatures in the vicinity of 45 °C for several hours (Taylor 1970b). More recent studies of this phenomenon in free-ranging oryxes are reported by Maloney *et al.* (2002).

Fringe-eared Oryxes were subject to unusually detailed research in the 1970s and 1980s at the Galana Game Ranch Research Project in SE Kenya, where a series of studies on physiological and behavioural traits were conducted on captive and semi-free-range animals kept in the heart of the species' natural distribution. These studies established that Fringe-eared Oryxes are comparatively efficient in managing their water economy. In trials, animals drank from 2.2 to 3.6 litres per head per day (Stanley Price 1985a), with individuals typically obtaining their water intake by drinking once every 4–5 days. In a comparative trial with five other species – camels, cattle, Common Eland *Tragelaphus oryx*, sheep and goats – body water turnover rate measured in free-ranging Fringe-eared Oryxes using injections of tritiated water was the lowest, measured at 35 ml/kg per day compared with the next lowest (camels) at 41 ml/kg and was highest in goats at 94 ml/kg (King *et al.* 1975, King 1979, 1983). These antelopes probably function without access to free water for protracted periods in some parts of their range, managing on moisture from food selection alone. There is currently no scientific confirmation of this with the Beisa Oryx, but it has been speculated on in older literature (Taylor 1968a), and given the survival of these oryxes during particularly long and widespread droughts their ability to go without surface water is probably tested periodically in the drier parts of their range. There is also evidence that the combined effect of unusually efficient body heat management and water economy, sets oryxes at an advantage. They can remain active and graze their fill during hot daytime periods more easily compared with other species (Lewis 1975).

Behavioural adaptations also help explain the ability of oryxes to survive aridity. For example, like many other mammals, they pant when water is available and are able to survive without drinking surface water by selecting comparatively succulent species or the most succulent parts of plants when feeding or the best times to feed (see Food and Foraging). They also reduce temperature and water loss by 'shading' and orientating their body to minimize areas exposed to the sun and possibly by scraping away hot surface soil and materials before lying down. The strong, splayed triangular hooves are adapted for both sandy and hard stony ground, but are ill suited to soft, muddy ground.

The peculiar facial and forequarter markings come into great visual prominence during a highly ritualized run that is characteristic of oryxes and has been dubbed the 'tournament' (Kingdon 1982) or 'runplay' (Lewis 1974). This performance starts with one or more

Beisa Oryx *Oryx beisa* head-wags and hackney gait during 'tournament' display.

animals running round the herd in broad circles. A galloping spurt builds sufficient momentum for the runner to suddenly switch into a long, high-stepping pace like a hackney pony. Simultaneously, the animal pulls its bunched neck back, throws its chin into the air and jerks its head from side to side in perfect opposite rhythm with the pace of the forelegs, an action that further emphasises the length of the horns and body colouring highlights. Bouts of high-stepping/head-flagging may simply slow and break into a normal run or they may climax in a sudden feint or actual clash of horns with a standing individual in the herd, usually followed by instantly darting away in a normal run to prevent escalation. The individual may then return to circling round, breaking back into the extended gait and initiating the sequence again, perhaps with a different member of the herd. Sometimes, excitement can spread and many members of the group may run around their herd with frequent, but mostly brief, horn clashes or feints. Oryxes of all ages may be observed using this gait, younger animals may be particularly prone to it, and on occasion comparatively young oryxes may initiate interaction with older and larger animals in the course of these displays (Wacher 1986).

Lewis (1975) noted that outbreaks of the displays in semi-captive oryxes seemed to be associated with sudden changes in environmental conditions (for example, after showers of rain early in the wet season and shortly after release from the night boma at the same time of

year). The displays are infrequently observed in wild oryxes, but on Galana Ranch have also been associated with bright mornings in the early wet season or on one occasion directly following a brief, but heavy, shower of rain. Speculation on possible functions of this display include a ritual testing of rank order (minimizing the risks of damage in such dangerously horned animals) or possibly a device for focusing attention on landmarks as an aid to navigation (Kingdon 1997). But data are lacking and further research is needed.

Connected to fighting and conflict, both Beisa and Fringe-eared Oryxes show marked sexual dimorphism in skin thickness over the forequarters and over the forehead and front of the face. The skin of a male Fringe-eared Oryx forms a 'dermal shield' up to 2.5–3 cm thick over the neck and shoulders, while the equivalent area on an adult female hide is also slightly thickened relative to the rest of the body, but only to about 1 cm depth (Wacher 1986). In terms of body mass, the skin of oryx ♂♂ was found to comprise 8.7% of live weight (substantially the highest proportion among 11 antelope species reported, including heavier species such as Waterbuck *Kobus ellipsiprymnus*, Common Wildebeest *Connochaetes taurinus* and Common Eland), but only 4.8% in ♀♀ (Ledger 1968). This adaptation is not unique to oryxes, and is quite widespread in horned ungulates (e.g. Jarman 1972a), but appears to be unusually well-developed in this fiercely armed species. As well as increasing protection against stabbing horn tips during fighting, the heavy dermal shield presumably also serves to increase bulk, visual display and weight for ♂♂.

Foraging and Food Both Beisa and Fringe-eared Oryxes are preferentially grazers, and they eat a wide range of grass species and growth stages, taking a succession of small cropping bites. Recorded grasses include species of the genera *Aristida*, *Sporobolus*, *Setaria*, *Brachiaria*, *Schoenfeldia* and *Chrysopogon*, but the actual number of species is probably very great (Kingdon 1982). In the dry season oryxes browse more often (Cobb 1976), taking species of the genera *Grewia*, *Indigofera*, *Acacia* and, reportedly, *Adenium*, which is known to be a very poisonous plant. It has been suggested that by means of selective feeding by time of day (and particularly at night) oryx may take advantage of free water obtained hygroscopically from the atmosphere by food plant species such as the dwarf shrub *Disperma* sp., which under the right conditions of temperature and humidity can increase in water content from 2% to 40% (Taylor 1968a).

Direct observations of tame Fringe-eared Oryxes feeding in natural habitat reported diet selection consisting of 83.3% grass items, 8.5% herbs and 7.9% browse (Field 1975). When grazing they were observed to be more selective of protein-rich leaves than larger-mouthed species such as African Buffalo *Syncerus caffer* and cattle. Grasses form a higher proportion of the diet in drier conditions and important species taken by oryx at Galana Ranch include *Brachiaria deflexa*, *Schoenfeldia transiens* and *Botriochloa* spp. in wetter conditions, with *Enneapogon cenchroides* and *Chloris roxburghiana* increasingly important in the dry season. Fringe-eared Oryxes were also noted making use of the moisture-rich herb *Commelina* sp. when available. Low level of browse use is persistently observed, but most notably towards the end of rainy periods when dwarf shrubs such as the legume *Indigofera schimperi* and shrubs such as *Grewia tristis* are utilized (Field 1975).

An analysis of their diet, based on stable carbon isotopes, again reported that although oryxes are primarily grazers (with 88% C₄ diet), they also take a small, but significant, fraction of browse (Cerling *et al.* 2003). Food intake rates in comparative feeding trials were measured at 2.2–2.5 kg/day (Stanley Price 1985a). During droughts they will occasionally walk long distances to water but may also dig deeply for potentially water-rich tubers and swollen underground stems of *Thunbergia guerkeana* and gouge the hugely swollen surface stems of *Pyrenacantha malvifolia* with horn and hooves before consuming broken off pieces (Root 1972). Fringe-eared Oryxes have also been seen on rare occasions chewing on bleached animal bones (osteophagia), presumably in response to mineral needs (Field 1975). In comparative trials at the Galana Ranch it was noted that oryx preference for abundant grasses coupled with physiological tolerance to heat allowed them to flourish under a daytime-only foraging regime (no opportunity for nocturnal feeding) imposed by a domestication management trial, in contrast to the browsing and heat-sensitive Common Eland (Lewis 1975).

Where conditions are favourable, oryxes can remain in a limited locality over several seasons, but cyclical movements over long distances and nomadism have been recorded in several areas (Percival 1928, Cobb 1976). Large numbers congregate in a locality one year, only to switch to another in other years. They avoid flooded areas during the wet season, when they prefer higher, drier ground. In the dry season they often join other herbivores on the black cotton soils that were avoided in the rains, the principal attraction being grassy regrowth.

Individually known adult female and herd-living male Fringe-eared Oryxes were measured moving over ranges measuring 250–300 km² during the course of 1–2 years of radio-tracking at Galana Ranch, with indications that with longer data sets individual home-ranges could be much larger (Wacher 1986). Female and non-territorial male oryxes move around these ranges in a series of stages, settling in locally smaller areas for periods of days or weeks. Some of the longest transitions between areas coincide with the onset of rains when exploration for fresh pasture is undertaken.

Social and Reproductive Behaviour The Beisa Oryx is a gregarious species and herds commonly number 20–60 animals of mixed sex, although temporary aggregations of more than 200 have been observed (Kingdon 1982). Solitary individuals are generally ♂♂ (although ♀♀ that have recently given birth spend much time away from herds). Very expansive wandering is known to take place, but the extent of such movements, principally by young ♂♂, has yet to be studied in detail.

Radio-tracking studies of wild Fringe-eared Oryxes on Galana Ranch (Wacher 1986) indicate that they live in a relatively complex social environment, characterized by socially dynamic mixed-sex herds of variable size and composition. In green conditions and at high local densities, groups may occur in loosely structured assemblies, typically with the majority of all of the younger animals aggregated in one group, perhaps resting, while older animals are grouped at a distance feeding. Long-term social relationships between individuals are likely to exist, but hard to detect. Observations from this population are summarized below, but it should be noted that this location represents one of the most resource-rich habitats used by any oryx species, and therefore reflects behaviour exhibited under relatively benign and high-density conditions.

Beisa Oryx *Oryx beisa*.

Adult ♀♀ spend the majority of their time in herds. Relatively brief periods of constant group composition are regularly disrupted by episodes of splitting or fusion with group-size changing regularly even within 24 hours in high-density populations. Major factors influencing group size and composition for ♀♀ are the time elapsed since calving, and season (Wacher 1986). On Galana Ranch the largest aggregations of oryx (100–300) were recorded exclusively in wet season periods on large areas of fresh grazing. Mean group size from a count sample of oryx groups over all seasons averaged 10–11, but group size experienced by individuals ranged from 1 to >200 for all radio-collared ♀♀ followed longer than a few months. Although large aggregations occur in seasons of green grass growth, ♀♀ that calve in green conditions usually still persist in isolation and form consortships in the immediate postpartum period.

At calving, experienced adult ♀♀ tend to isolate themselves to give birth to a cryptic calf that adopts a solitary hiding defence strategy over the first 2–3 weeks of life. In the Fringe-eared Oryx this behaviour was observed consistently in radio-collared wild animals, and in the semi-captive Galana herd it was notable that adult ♀♀ showed a sharp peak in tendency to run away back to the wild in the month of calving. Most ♀♀ come into postpartum oestrus within 1–2 weeks, and so often attract the attention of adult ♂♂. Small group sizes of 1–3 individuals (typically some combination of a lactating cow, neonate and consorting adult ♂) are most typical (but not invariable) in this period and calving interval data indicate that there is a high probability that healthy adult ♀♀ will conceive within this period. Females may also intermittently join herds while the calf lies out (Kingdon 1982). During the period 2–6 months postpartum, adult ♀♀ are most likely to be found in mixed-sex herds (10–15% adult and subadult ♂♂) of variable size, with a range of calves and younger age groups also present. Crècheing among calves and cohorts of young may be apparent, and on occasion a lactating cow may move as far as 10–12 km away from her own calf and back again in the course of a single day when, for example, travelling to a water source to drink in the dry season. During the period 6–9 months postpartum, adult ♀♀ become more likely to be found in mixed groups composed mainly of adults and subadults only, with a marginally higher proportion of ♂♂ (20–30%). This is not an absolute change, but it appears that progressively less time is spent in the immediate company of her own or other young in the period of later pregnancy leading up to isolation for birth of the next calf. A tendency of Fringe-eared Oryx herds to form group types characterized by the presence or absence of young was also noted independently in Tsavo East N. P. (Leuthold & Leuthold 1975b).

The majority of maturing, and some fully adult, ♂♂ are also found in mixed-sex herds and information from individuals suggests that their ranging and foraging behaviour operates on a similar wide scale to that seen in ♀♀ (see above). All-male groups of Fringe-eared Oryx bulls were only identified on six occasions in the course of a three-year study (setting aside the common phenomenon of solitary adult ♂♂). Known radio-collared territorial bulls were present on five of these occasions, confirming the group was a temporary association. On the sixth occasion, the largest all-male group recorded (five individuals found walking to the river) included a tagged wild ♂ who was known to have been a member of a mixed-sex group of 96 animals the day before and who was next seen in a mixed-sex group of 57 two weeks later.

However, some adult ♂♂ behave very differently, distinguished by spending the majority of their time alone and in comparatively restricted areas. In the Galana–Tsavo border zone, the best documented solitary male home areas (territories) were placed along the ecotone between red and grey soils, straddling grassland and woodland habitats preferred by herding oryxes. Two radio-collared solitary bulls in this area restricted their movements to separate 5–8 km² zones over study periods of 1–3 years. They were seen to patrol boundaries in parallel with neighbouring adult ♂♂ with some evidence for a degree of spatially determined reciprocal dominance between neighbours. These ♂♂ make visual displays by a ritualized sequence of squatting defecation, associated only with adult male oryxes (castrated adult male oryxes did not develop this behaviour on Galana Ranch). This involves walking directly to a known dung site, scenting the ground and/or older dung piles, scraping the ground or dung pile with a front hoof before squatting low on the haunches while defecating, in the process creating a strikingly vertical visual display apparent at long range to other oryxes. Dung piles were not usually dropped exactly on top of one another, but scattered around a patch of bare soil. Sometimes 3–4 dung sites may be visited and re-marked in direct succession in the course of a morning ‘patrol’. Midden sites (n = 61 observations of active dung site use at 50 different dung site locations) mapped for one radio-collared bull were found to be scattered throughout his area of residence, with no indication of clustering towards the margins (Wacher 1986). More than 80% of sites had been used previously with 3–6 older dung piles (maximum ten) evident at most sites when inspected immediately after use.

Tellingly, the most common social grouping of solitary ♂♂ when not alone was to be seen in groups with a single adult ♀ (with or without new calf present), although larger mixed-sex groups move through territories fairly frequently, when the local resident may or may not join them temporarily. Consortships between solitary ♂♂ and oestrous ♀♀ are normal, often lasting 3–5 days and sometimes as long as three weeks. Radio-collared cows with neonates mostly consorted with 2–3 different ♂♂ over the postpartum period. Solitary bulls attempt to herd and control movement of consorting ♀♀ using passive body positions and posture, and active horn threats, chases and lunges. This usually results in the ♀ remaining near the centre of the territory, but not always. Oestrous ♀♀ can and do escape to another solitary bull, or even back to herds on some occasions. Under these conditions, with dams in view on a neighbouring territory, it is notable that on three separate occasions one well-known, solitary, radio-collared bull was seen vigorously herding and threatening single calves (on one occasion galloping at full speed to head off the running calf) to prevent them moving towards their dams and retain them on his own side of the boundary. On one of these occasions a ♀ was seen returning to her calf on the radio-tracked male’s territory. Adult ♂♂ have frequently been noted to be attentive to young calves, whether encountered in small or larger groups. In most situations this takes the form of herding and nudging the calf towards its mother (but in Arabian Oryx calves have been seen tossed through the air with a rough sweep of the adult male’s horns). Whilst these activities may confer a certain protective advantage to these calves in normal situations, it seems probable that a prime motivation of the ♂ is to manipulate the calf as a means of influencing movements of the mother while she is receptive to mating.

Relations between solitary and herd-living ♂♂ visiting the territory can be surprisingly calm and tolerant in the absence of receptive ♀♀. Territorial bulls may exert dominance to newly arrived ♂♂ by means of a head-low march followed by ritualized lateral head-nod or 'ear-point' display across the front of the recipient (Walther 1978c, and see full description below). On other occasions they may not even bother to approach a mixed-sex visiting group in plain view on the territory. Prolonged and serious clashes between adult ♂♂ do occur, but are relatively rare. In the Galana study, this was only seen between pairs of ♂♂ unknown to the observer. A limited number of observations of a well-known resident solitary bull dealing with mixed-sex groups on his area that included a sexually receptive ♀ suggested that the resident bull had little difficulty retaining social dominance and probably mating advantage also over the visiting herd ♂♂. On such occasions, active herding and chasing is directed primarily at the ♀, but also at other members of the herd by the resident bull. Visiting ♂♂ may also attempt to court and mount the ♀ while the resident is occupied or elsewhere. On one radio-collared male's territory, mountings by all adult male oryxes made during herd visits to the territory were scored as 'successful' or 'unsuccessful' depending on whether the ♀ involved stood still or walked forward as intromission was attempted. Summing over five different occasions when receptive ♀♀ were courted by both the resident and visiting ♂♂ in groups on the territory, the resident bull was scored 'successful' on 5/22 mountings observed while the visiting ♂♂ achieved 0/20 successful mountings and were commonly seen to be submissive when approached and threatened by the resident bull. The circumstances of these observations raise interesting questions about female options to control mating and mate choice.

However, because the social system is dynamic and flexible it seems very probable that not all ♀♀ mate exclusively with solitary territorial ♂♂. Receptive ♀♀ in large mixed-sex groups are sometimes observed, and the level of harassment and chasing by several ♂♂ on one cow can be intense on such occasions. This suggests that solitary territoriality is unlikely to be the only mating strategy used by oryx at Galana. In drier areas, used by Beisa Oryxes in N Kenya and Ethiopia, and at the margins of the oryx range, it seems even more probable that alternative, more mobile, or herd-based mating strategies might be expected to predominate.

In Serengeti N. P., one herd of 15 Fringe-eared Oryxes travelled 17 km in one day, and a lone bull walked 4 km in a straight line within one hour; on the other hand, another Serengeti herd remained localized in a 20 km² area for three weeks (Walther 1978c). In these conditions it is possible that ♂♂ may attempt to detain ♀♀ groups when local grazing conditions allow, but may alternatively attach themselves to more determinedly mobile groups if food or other resources do not attract sufficient isolated calving ♀♀ to their chosen areas. It is therefore possible that oryxes are able to adjust social relations to resident or nomadic conditions and observed mating activities appear to exhibit features of both resource-defence and mate-defence options. It is also noted that in more recent studies of reintroduced Arabian Oryxes in harsh desert conditions of S Saudi Arabia, the oldest adult ♂♂ developed very large-scale spatial segregation relative to each other, where they were comparatively sedentary, not emulating younger ♂♂ who wandered widely in search of dispersing ♀♀ following rare rainfall events. These

observations hint at an unproven possibility that male oryxes may adjust their mating strategy according to circumstance, age and perhaps body size.

Studying free-ranging groups of Fringe-eared Oryxes in a semi-domesticated and resident state, Stanley Price (1978b) found that some of these groups had a closed membership that was of long standing. In such groups there was an alpha-male and often a beta-male immediately below this dominant individual. All adult ♀♀ were arranged in a hierarchy below these ♂♂, but they were dominant over any other adult ♂♂. The ability of ♀♀ to hold social status in this way allows them to control their immediate grazing space effectively among conspecifics in mixed-sex herds. Besides providing a level of defence against predators (see below) this may be a further selective advantage for the existence of fully developed horns on ♀♀ in oryxes generally. Oryxes are notable as a group for specializing in habitats where resources can be scattered and rare, ♀♀ are adapted to breed at a high rate with simultaneous lactation and early pregnancy commonplace, and effective intra-specific defence of energy resources via social status may be at a premium.

The vivid markings may well facilitate social interactions in that even the slightest gestures are amplified by the patterning. Thus, when an adult ♂ expresses routine dominance to subordinates using the 'head nod' or 'ear point' display he walks across the front of the target animal with head and horns held high, slightly turned to one side and ears forward. At the last moment the horns are tilted over in a ritualized (but undelivered) slow motion lateral 'blow' to the air in front of the recipient, the main gesture being created by movement of the brightly marked head, with profile of neck and shoulders clearly shown off. The ritualized submissive response also emphasizes head movement; the receiving animal stands at first with head low, horns pressed protectively down along the neck, before half jumping, half turning away with a shake of the head as the stylized 'blow' is delivered. Captive ♀♀ in this situation have been seen to lie down and bawl (Kingdon 1982).

In addition to these ritualized exchanges, low-key social signalling is an ongoing feature at a range of intensities among oryx groups. Individuals may use a selection of simple stares, positional displacements and avoidance, horn and head gestures in incremental intensities while interacting during grazing or movement. In this context it is notable that adult ♀♀ make use of horns and gestures to maintain status and position while grazing in a similar way to ♂♂. The occurrence of dramatic prancing 'tournaments' is described above. At close range, frequent soft grunts may be heard, notably from cows approaching young calves, or between courting pairs, while calves may bawl vociferously when denied suckling.

In conflict, horn-to-horn clashes may develop with increased intensity among older animals. Fighting takes place face to face with antagonists alternatively 'kneeling' and standing to push against each other between sharply delivered head blows and horn swipes. With rising intensity fighting oryxes may swing round and lean together in a side-to-side position with horns crossed and over-the-shoulder stabbing actions aimed at the neck and shoulder region of the opponent. Fights usually end with one individual breaking away and running, pursued for a short distance by the victor who often then turns away and may indulge in a squat defecation display a short time later. But fatal outcomes do occur in other oryx species (Arabian Oryx) and may also be expected as a rare event in Beisa and Fringe-eared Oryx.

Courtship consists of prolonged bouts of nose-to-tail circling, the ♀ initially repeatedly stepping away from the male's attempts to press his forequarters to her hindquarters, sniff and rub the female's perineal area, kick (laufsclag) or mount. Females may also respond by producing urine, which the courting ♂♂ will sample through typical flehmen. Unreceptive ♀♀ may on occasion repel the ♂ with repeated frontal clashes or may also lie down to discourage attention. But ♂♂ may also initiate courtship bouts by pawing at lying ♀♀ to get them to their feet during rest periods. As circling intensifies the pair break into occasional excursive and rather slow circular or figure-of-eight marches led by the ♀ to and from a more or less fixed point, as the bull follows directly behind. Mounting is rapid, with the male's head held high to avoid the female's horns and intromission is achieved with a single firm thrust.

Reproduction and Population Structure Births occur throughout the year, but well-defined birth peaks may emerge in some conditions (Leuthold & Leuthold 1975b). As ♂♂ tend to mate ♀♀ during their postpartum oestrus, and the gestation period is in the region of 8.5 months (see below), the timing of birth peaks remains difficult to understand (Kingdon 1982). Birth months were not synchronized among six radio-collared breeding ♀♀ captured from the same population on Galana Ranch where newborn calves were found in all seasons and nearly all months (Wacher 1986). Stanley Price (1978b) found that cows matured at about two years. Ages at first mating recorded from five captive, but partially free-range, female Fringe-eared Oryxes at Galana Ranch ranged from 2 years 49 days to 2 years 227 days. Age at first calving from this sample ranged between 2 years and 339 days and 3 years and 194 days, with at least one of these ♀♀ failing to conceive at first oestrus.

Modal gestation period indicated by counting last recorded mating to parturition was 255–259 days (8.5 months, $n = 24$ pregnancies) on Galana Ranch (Wacher 1986). The modal interval from birth to postpartum oestrus (indicated by mating) was 15–19 days after parturition ($n = 32$ births recorded from 18 individuals). The modal inter-calving interval from a sample of 68 births recorded from 19 individual female Fringe-eared Oryxes was 275–279 days (9.1 months); individual ♀♀ were recorded maintaining a ca. 9 month inter-calving interval under semi-captive natural range conditions over a period of six years on Galana Ranch (Wacher 1986). A radio-tracked wild ♀ was detected calving precisely at a 288-day interval, well within the typical range of calving intervals recorded from tame oryx. Observations of four other radio-collared wild ♀♀ also supported maintenance of a 9-month inter-calving interval (Wacher 1986). Based on semi-captive Fringe-eared Oryxes at the Galana Ranch, male calves average 10.5 kg at birth ($n = 12$) and females 11.5 kg ($n = 7$) (R. K. Ngowah & M. Stanley Price pers. comm., Galana Game Ranch Research Project).

Predators, Parasites and Diseases Cheetahs *Acinonyx jubatus* are known to run down young animals, and hyaenas, Leopards and smaller predators are likely to take calves. Lions kill adults where both species are common, but such large predators are generally scarcer in the very arid areas that these oryxes prefer (Kingdon 1982). African Wild Dogs *Lycaon pictus* have also been recorded hunting Fringe-eared Oryxes in the Tsavo–Galana area of E Kenya with variable results. A radio-collared solitary adult bull

Beisa Oryx *Oryx beisa* in subordinate head-low posture.

known to be blind in one eye was killed and eaten by a pack of seven African Wild Dogs. A pack of five African Wild Dogs were observed approaching a herd of 21 oryxes in open grassland, including a single small calf around one month of age. They ran up to the oryxes and began walking intently forward, focusing their gaze on the calf located near the centre of the group. The adult oryxes formed a concave semi-circle facing the dogs; when the dogs were no more than 10 m from the oryx herd, the largest adult male oryx suddenly leapt forward at the lead dog making a tossing lunge with his horns. The dogs retreated at once, circled past the herd and continued on their original direction without further interest. The adult bull in this case was also radio-collared, from which it was known he was usually alone on his territory while the other 20 animals with him were newly arrived in the area and at best only intermittent associates. In a third incident, the fresh skeletonized carcass of an adult female oryx was found in front of a fallen *Commiphora* tree, which had clearly been used as a protective background support while attempting to defend herself with horns when turning to face attackers after a period of pursuit (a characteristic defence strategy of hippotragines). The oryx skull was notable for the fact that the incisiform dentition was worn down to an incomplete row of rounded pegs level with the gum, suggesting a very old animal probably poorly fed. The intact body of a dead African Wild Dog was photographed lying a few yards from the oryx skeleton, marked only by a deep stab wound consistent with an oryx horn entering the body cavity at the angle

of the hindleg. A pack of 12 live and heavy-bellied African Wild Dogs was located resting in the shade 500 m away.

Virus neutralizing antibodies to malignant catarrhal fever virus were found in the blood sera of 50 Fringe-eared Oryxes (Mushi & Karstad 1981). Antibodies to *Brucella abortus* bacterial infection have also been reported (Paling *et al.* 1988).

Conservation IUCN Category: Near Threatened (*O. b. beisa* – Near Threatened; *O. b. callotis* – Vulnerable C1). CITES: Not listed.

Although this species has declined markedly in numbers and range, it remains common in areas where livestock densities are low, with several large populations surviving in protected areas, such as Awash N. P. (in the Awash Valley), and Omo and Mago National Parks (in the south of Ethiopia), Sibiloi, Meru and Tsavo National Parks (Kenya) and Tarangire N. P. and Mkomazi G. R. (Tanzania) (East 1999). Boma N. P. is the only protected area for this species in SE Sudan (Fay *et al.* 2007). Where they have been hunted traditionally it has usually been for the good quality of their meat and the practical value of the very tough hide. The species remains susceptible to the effects of hunting and competition with livestock, since so many remaining populations are outside protected areas: according to East (1999), only 17% of Beisa Oryxes and about 60% of Fringe-eared Oryxes occur in protected areas. The most recent review of local population status within N Kenya compared aerial survey data and found continued substantial (>50%) reductions in density at important population centres in Samburu District over the period of the mid-1990s to 2008, though noting a more stable situation within Laikipia (Woodfine & Parker 2011). More effective protection and management of the remaining populations in areas where the species still occurs in substantial numbers, but is in decline, such as the Awash Valley, Omo-Mago-Chew Bahir, N Kenya and Tsavo, would greatly enhance the long-term survival prospects of this species (East 1999).

The absence of karyotypic sterility barriers (Kumamoto *et al.* 1999) suggests that, in captivity, all oryx taxa may be vulnerable to hybridization, which from a conservation perspective is highly undesirable among these distinctive and naturally allopatric antelopes. Genetic evidence supporting the historical isolation between *O. b. callotis* and *O. b. beisa* led to a direct recommendation that conservation efforts should be directed towards preserving the genetic integrity of each group on the grounds that they may have distinct evolutionary potential (Masembe *et al.* 2006). As noted already, hybridization in captivity between this species and the Gemsbok has produced 'viable offspring' (Gray 1972). Opportunities for either subspecies to hybridize with the Scimitar-horned Oryx *Oryx dammah* and Arabian Oryx and for mixing between the two subspecies of Beisa Oryx exist in some captive collections.

Comparatively small zoo-managed populations of both the Beisa and Fringe-eared Oryxes exist in zoos outside Africa, mainly in Europe and North America (EEP/SSP). Given the downward trend of wild Beisa populations in particular, and the successful role captive breeding has played for two other members of the taxon (Arabian and Scimitar-horned), the efficient long-term management and planning of captive Beisa groups may prove to be important in the future, especially if this is set up within range states where meta-population management of divided and semi-captive populations in conjunction with National Parks may become an increasing necessity.

Measurements

Oryx beisa

O. b. callotis

HB (♂ ♂): 1800 mm, n = 1

HB (♀ ♀): 1700 mm, n = 1

Sh. ht (♂ ♂): 1100 (1050–1150) mm, n = 8*

Sh. ht (♀ ♀): 1110 (1050–1150) mm, n = 20*

HF c.u. (♂ ♂): 380 mm, n = 1

HF c.u. (♀ ♀): 410 mm, n = 1

Galana Ranch, Kenya (T. Wachter pers obs., Galana Game Ranch Research Project)

*Semi-captives (all animals >36 months of age)

The average weight at maturity (ca. 3–4 yr of age) of semi-captive Fringe-eared Oryxes has been estimated at 165.0 kg for adult ♂ ♂ (n = 19) and 146.0 kg for ♀ ♀ (n = 34) (Carles *et al.* 1981). The

maximum weight recorded for a ♀ on Galana Ranch is 180.0 kg; the heaviest semi-captive ♂ weighed in excess of 210 kg (T. Wachter pers. obs.). Ledger (1968) recorded average weights of wild *O. beisa* as 176.4 kg (range 167.8–209.4, $n = 10$) for ♂♂ and 161.5 kg (range 116.0–188.4, $n = 10$) for ♀♀. Available data from semi-captive Fringe-eared Oryxes suggest that full male body size and neck development are attained after 4–5 years of age, well after the age of physiological sexual maturity. This poses further interesting questions for potential differences in reproductive strategies operating in

individuals of differing body size in this complex and fascinating species. Maximum recorded horn length for *O. b. beisa* is 109.2 cm from Ethiopia; the record for *O. b. callotis* is 110.2 cm for a pair of horns from L. Magadi in Kenya (Rowland Ward).

Oryx dammah SCIMITAR-HORNED ORYX (SCIMITAR ORYX)

Fr. Oryx algazelle (Algazel); Ger. Säbelantilope (Nordafrikanischer Spießbock)

Oryx dammah (Cretzschmar, 1827). In: Rüppell, Atlas zu der Reise im nördlichen Afrika von Rüppell, pt 1, Säugethiere, p. 22. Sudan, Northern Kordofan Prov., 'bewohnen die grossen Steppen von Haraza [vicinity of Jebel Haraza]'. The year of original publication is 1827, not 1826 (see Grubb 2005).

Scimitar-horned Oryx *Oryx dammah*.

Lateral view of skull of Scimitar-horned Oryx *Oryx dammah*.

Taxonomy Monotypic. Has frequently been called *Oryx leucoryx* (which is restricted to the Arabian Oryx), and *O. algazel*, which is invalid (see Grubb 2005). Ansell (1972) and Corbet (1978) discuss use of *O. dammah* over *O. tao*. Synonyms: *algazel*, *bezoartica*, *ensicornis*, *nubica*, *senegalensis*, *tao*. Chromosome number: $2n = 56-58$ (Wurster 1972, Gallagher & Womack 1992, Claro *et al.* 1994, Kumamoto *et al.* 1999). Majority of specimens have $2n = 58$ with fixed centric fusion of chromosomes 1 and 25; variation in diploid number (i.e. $2n = 56-57$) is the result of centric fusion polymorphisms of chromosomes 2 and 15 (Kumamoto *et al.* 1999). Sex chromosomes, X and Y, are acrocentric (Kumamoto *et al.* 1999). Scimitar-horned Oryx and Addax *Addax nasomaculatus* hybrids are known and reported to resemble the Addax in European zoos (Ruhe 1993). Hybrids born at Bou-Hedma N. P. in Tunisia (believed to be sired by an oryx ♂) were large-bodied like oryx, with typical oryx horn shape, but with obvious Addax body colouration and body shape (R. Molcanova pers. comm.).

Description A large, robust antelope, with long horns arched over the back in both sexes, and striking rufous and white coat colouration. Cream to whitish body pelage contrasts with reddish-brown colouration on neck, shoulders and upper legs. Seasonal variation in coat length and colour quite marked, with animals appearing whitest in short bright summer coat, while long winter coat is duller and creamier and may reveal faint reddish-brown lateral flank-stripe and reddish tones on rump. Head is elongated, cream with face 'mask' of reddish-brown across muzzle and blaze on forehead, and reddish-brown eye-stripe from base of horn across eye and cheek. Eyes, nostrils, lips and inner ears black. Ventral surface and insides of legs creamy-white, hooves black. Tail long (ca. 39% of HB), and cream with brown-black terminal hairs. Pedal glands present on all four feet, but there is also a small preorbital gland (not present in other *Oryx* species); inguinal glands absent. Sexes superficially similar, but adult ♂♂ larger, with heavier neck and shoulders and thicker horns at all ages. Individuals may be reliably identified by small variations in horn shape and at close range by variation in details of face-mask pattern.

The distinctive horns are long, ridged (lower one-half or one-third marked by 30–60 annulated corrugations), sharp-tipped and curved backwards in a shallow arc (80–150 cm), giving rise to the common name. Female horns are longer and thinner, with less prominent annulations; male horns are noticeably thicker at the base, generally more robust and often shorter in older individuals. Differences in horn circumference at the base are apparent in calves at an early stage and can be useful for determining sex. Hard and sharp adult

horn tips develop after sloughing off the outer keratinous sheaths that cover the horns of young animals.

Geographic Variation None recorded.

Similar Species

Oryx beisa: allopatric in East and north-east Africa only. Horns more or less straight; neck and shoulders lacking reddish-brown colouration; preorbital gland absent.

O. gazella: southern Africa only. Horns more or less straight; neck and shoulders lacking reddish-brown colouration; preorbital gland absent.

Distribution Formerly widespread in semi-arid Sahelo-Saharan zones north and south of the Sahara Desert from the Atlantic Ocean to the Nile R., but not north of the Grand Atlas Mts. Range countries include Egypt, Libya, Tunisia, Algeria, and Morocco north of the Sahara and Mauritania, Mali, Niger, Senegal, Burkina Faso, Nigeria, Chad and Sudan in sub-Saharan Africa.

Historical Distribution In Egypt, the historical range included most of the Western Desert, west of the Nile R., but mostly on oases and wadis. Oryxes were recorded in Siwa and Kharga Oases, El Faiyum area, western Giza and Wadi El Natrun (Osborn & Helmy 1980, Saleh 2001). They were reportedly hunted to extinction in the mid-1800s, with the latest records dating from the 1850s or 1860s; however, there is a record of an individual observed in 1975 in the north-west (Kock 1970, Osborn & Helmy 1980, Saleh 2001). In Libya, the species was described as widespread in the Fezzan (south-west) and Kufra (south-east) regions (Khattabi & Mallon 2001), near known populations in N Chad and the Western Desert of Egypt, respectively; there are unconfirmed historical reports of Scimitar-horned Oryx in NE Libya, from Wadi Jerari (Hufnagl 1972, Khattabi & Mallon 2001). They reportedly became extinct in the 1940s due primarily to illegal, motorized hunting and habitat degradation due to overgrazing by livestock (Newby 1988), although Hufnagl (1972) quotes a possible sighting from NW Libya in 1964.

Late nineteenth-century accounts suggest that the Scimitar-horned Oryx may have occurred at least sporadically in S Tunisia, but some doubted that an established population still existed and none were able to provide first-hand information or reliably sourced specimens (Johnston 1898, Sclater & Thomas 1894–1900, Lavauden 1920, 1926b). All published descriptions, including the presence of a stuffed oryx calf in a private museum near Tunis in 1898 (said to have been received alive from the southern frontier), could equally be explained by contact with trans-Saharan traders or the occasional appearance of wandering individuals (Devillers & Devillers-Terschuren 2005). In Algeria, oryxes inhabited the sub-desert and steppe regions north and south of the Sahara. They were reportedly hunted to extinction in the 1960s, and the last animals were shot in the Tassili region in 1987, though these may have been vagrants from the Sahel (De Smet & Smith 2001). Oryxes were widely distributed in S Morocco and the Western Sahara, south of the Oued Drâa (Loggers *et al.* 1992, Aulagnier *et al.* 2001). They were reported as extinct in Morocco in the 1930s and have not been sighted in Western Sahara since the 1950s, except for a single individual seen in 1973 (Le Houérou 1992).

Oryx dammah

Their historical range is not well documented in Senegal, but they probably occurred throughout the Sahel zone of N Senegal (East 1999), and were hunted to extinction by 1914 (Sournia & Dupuy 1990). In Mauritania, they formerly inhabited the south and western regions, along the Western Saharan frontier (Trotignon 1975, East 1999); they were hunted to extinction by the 1960s (Trotignon 1975, Newby 1988). In Mali, oryxes inhabited the sahel zone in C Mali and north into the desert zone (East 1999). They are presumed extinct since perhaps 1983 (Newby 1988), although a pair was sighted on the Burkina Faso border in 1986 (Duvall *et al.* 1997). In Burkina Faso, they ranged into the sahel zone in the north, but were hunted to extinction in the 1950s (East 1999).

Scimitar-horned Oryxes were widely distributed in sub-desert and sahel zones of C and S Niger and probably occurred in the northern desert zone with seasonal rainfall and good pasture availability (East 1999). The last reported sighting of oryxes in Niger was in 1986 (Millington *et al.* 1991). Overhunting, the introduction of deep permanent water bores for livestock excluding them from prime habitat, and desertification of the Sahel probably caused their extinction by 1989 (Dixon *et al.* 1991). Recent surveys report no evidence of live animals in the Termit region and Tin Toumma (Wacher *et al.* 2004a, 2008, 2009, 2010, Claro 2004). Oryxes formerly inhabited only extreme NE Nigeria, possibly only as a seasonal vagrant (East 1999).

Oryxes were historically abundant and widely distributed in the sub-desert and northern Sahel zones of C and N Chad, extending north into the desert zone (East 1999). Reports of migratory herds of hundreds or even thousands of animals in the sub-desert steppe habitat across NC Chad were common during the twentieth century (Gillet 1966a, Newby 1974). A population of >3500 survived under active protection in the Ouadi Rimé–Ouadi Achim Faunal Reserve between 1973 and 1978 (Bassett 1975, Newby 1980), but by 1988 it was reported that only a few dozen survived in the wild (Dixon *et al.* 1991) and repeated surveys since 1990 have failed to find any evidence

of surviving animals (Monfort *et al.* 2004, Devillers & Devillers-Terschuren 2005, Wacher *et al.* 2011).

In Sudan, Scimitar-horned Oryxes were distributed throughout the entire Sahelian zone of the Darfur and the Kordofan (Devillers & Devillers-Terschuren 2005), and were abundant in the Wadi Howar region near the Chad border. They were reportedly extinct by the mid-1970s (Newby 1988).

Current Distribution Today, the Scimitar-horned Oryx is listed as Extinct in the Wild in all former range countries (Devillers & Devillers-Terschuren 2005). However, semi-captive populations have been established within areas of natural habitat (ranging from 20–80 km²) in several former range states (mapped), including Tunisia (Bou-Hedma N. P., Sidi Toui N. P., Oued Dekouk N. R. and Dghoumès N.P.), Morocco (Souss-Massa N. P.; extralimital) and Senegal (Guembeul Wildlife Reserve and Ferlo-Nord Wildlife Reserve).

In Tunisia, Bou-Hedma N. P. covers 16,448 ha of mountainous and undulating steppe east of Gafsa, and has fenced Total Protection Zones, which are patrolled (Smith *et al.* 2001). Habitat restoration, particularly of the *Acacia raddiana* woodland, was very successful (Kacem *et al.* 1994). In 1985, ten captive-born, young oryxes (five ♂♂, five ♀♀) were translocated from European zoos to a 10 ha acclimatization area. The animals were released into a Total Protection Zone (2400 ha) 18 months later (Bertram 1988, Gordon 1991). In 1999, an additional adult ♂ from Europe was added to the population, individually managed to ensure he bred with established ♀♀, with the aim of increasing the genetic diversity (Molcanová 2004). The population has steadily increased from ten in 1985 to 70 in 1996 (Smith *et al.* 2001), peaking at an estimated 130 in 2005 (T. Gilbert pers. comm.), but had fallen to 73 by 2007 and below 50 in April 2011 (Molcanova & Wacher 2011a).

Sidi Toui N. P. lies in SE Tunisia near the Libyan border. The oryx area, established in 1993, covers 6135 ha encircled by a double fence-line. The landscape of low hills surrounded by open plains, small dunes and dry sandy wadis represents typical pre-Saharan steppe (Karem *et al.* 1993), characterized by a variety of shrubs and dwarf shrubs and a complete absence of tree cover. In 1999, 14 Scimitar-horned Oryxes selected from European zoos to represent a separate genetic line to those at Bou-Hedma N. P. were transported to Sidi Toui N. P. Ten animals (one ♂, 9 ♀♀) were released, while the remaining animals were sent to Bou-Hedma N. P. and Oued Dekouk National Reserve (Molcanova *et al.* 2001). Initial growth of this population peaked at 33 in 2005, but subsequently declined from 2005–2008 coincident with an unexpected swing to a male-biased sex ratio in a classic small population effect. As of 2011, the population size stood at 31 animals (Molcanova & Wacher 2011b).

Oued Dekouk N. R., located near Tataouine, is another fenced reserve covering 6000 ha. In 1999, three animals (one ♂♂, two ♀♀) from European zoos were transferred to Oued Dekouk with two further ♀♀ transferred from Sidi Toui N. P. to Oued Dekouk in 2003 (Molcanova 2006). The population had grown to 21 in 2008 and 26 in 2011 (Molcanova & Wacher 2008, 2011a). In February 2007, eight Scimitar-horned Oryx were translocated from Bou-Hedma N.P. to Dghoumès N.P. (8000 ha), close to Tozeur.

In Morocco, a captive population has been established at Souss-Massa N. P., which covers 33,800 ha in the Atlantic oceanic Sahara region, south of Agadir, but which is outside the original distribution range of

the species. The fenced 1500 ha Arrouais Reserve consists of bush and tree savanna, stony and sandy ground and migrating sand dunes with 5 ha pre-release enclosures (Müller & Engel 2004). Three shipments consisting of a total of 29 oryxes (17 ♂♂, 12 ♀♀) from European zoos were released between 1995 and 1997 (Engel *et al.* 2001, Müller & Engel 2004). The population had increased to 50 in 2000 (Müller 2002) and an estimated 240 in 2005 (T. Gilbert pers. comm.).

In Senegal, captive populations have been established at Guembeul and Ferlo-Nord Wildlife Reserves. In 1999, eight Scimitar-horned Oryxes (three ♂♂, five ♀♀) from the Hai-Bar Wildlife Reserve in Israel were transported to an 8 ha enclosure within the Guembeul Wildlife Reserve (720 ha) at Saint Louis in the north-west region of Senegal (Clark & Bovee 2000). The population had increased to 23 in 2002 with births and the addition of two imported oryxes from Paris Zoo (Clark 2002). Guembeul serves as an acclimatization site for release into the Ferlo-Nord Wildlife Reserve (487,000 ha of sahelian savanna grassland and bushland on gently rolling sandy terrain in NE Senegal). In 2003, eight oryxes were transferred from Guembeul Wildlife Reserve to a fenced core area of 600 ha in Ferlo-Nord (Gueye 2004); all eight animals were born in Senegal and have since produced calves. In 2004, the estimated reintroduced population in Senegal was 30, 18 at Guembeul and 12 at Ferlo-Nord (Gilbert 2004b).

Habitat Climatic changes during the last 5000 years left the Scimitar-horned Oryx population divided north and south of the central Sahara Desert. The African Sahel, the sub-Saharan steppe of hardy grasses, shrubs and drought-resistant trees that fringed the southern limits of the desert from Sudan to Senegal, constituted the most important habitat (Newby 1988). A gregarious species, its herd size varied with season, food availability, reproductive activity and human presence. Oryxes exhibited a seasonal, cyclical pattern of movement, driven by the requirement for grazing, water and shade. Grazing resources were dependent entirely on an unpredictable and variable rainfall (100–400 mm annually). In countries south of the Sahara, during the single Sahelian wet season (Jun–Sep), Scimitar-horned Oryxes used to follow the rains, migrating north to graze on freshly sprouted grasses and to areas with access to water. During the cooler months (Nov–Feb), the oryxes reached the Saharan Desert fringes and their winter grazing pastures. With the onset of the hot dry season (Mar–Jun) the grasses desiccated and the oryxes migrated south to the Sahelian dunes in search of perennial species, such as *Panicum turgidum* and *Aristida mutabilis*, fallen *Acacia* pods and persistent foliage of shrubs and herbs (Gillet 1966a, Newby 1974, Dragesco-Joffé 1993). The wooded wadis (ephemeral desert streams) and inter-dunal depressions provided essential shade during the hottest periods, when shade temperatures could reach 40–45°C, and, as a result, peak feeding activity was at dawn and dusk. Dense shade trees, such as *Maerua crassifolia*, were particularly sought after, while in sparsely wooded regions even a clump of *Panicum turgidum* could provide shade (Gillet 1966a). In Chad, the pattern of seasonal movements consisted of annual migrations greater than 600 km (Newby 1988).

Abundance Formerly abundant throughout the Sahelian zone, there were probably more Scimitar-horned Oryxes south of the Sahara than in the northern range countries (Newby 1988). Historically, aggregations of several hundred or even thousands congregated at favourable pasture or during the seasonal migrations

(Brocklehurst 1931, Edmond-Blanc 1955, Gillet 1966a, Newby 1974). Oryxes were still considered common throughout northern Africa in the mid-1900s, but herds have not been observed since the 1970s. As late as 1985 there were an estimated 500 animals in Chad and Niger, but by 1988 it was reported that only a few dozen survived in the wild and since then there have been no confirmed reports of any surviving wild oryxes. Sadly, the prediction by John Newby (1978b) that 'the Scimitar-horned Oryx will be extinct in the wild before the end of the century' turned out to be true.

Adaptations Although the physiology of the Scimitar-horned Oryx has not been subject to investigation like that of its southern or East African counterparts, it is likely that many of the adaptations to survival in arid environments detailed for the Gemsbok by Knight in this volume also hold true for the Scimitar-horned Oryx. They have the ability to survive for months without drinking, obtaining most of their moisture requirements through their food, but will drink freely when water is available. Physiological adaptations and behavioural mechanisms help them control water balance. For example, the light-coloured coat helps reflect and reduce radiant heat and they are inactive during the heat of the day. In extreme heat they seek shade or lie in shallow scrapes in the sand (Newby 1974, R. Molcanova pers. comm.). The coat is short and thick, and grows longer during the winter (Dolan 1966b, Gordon & Wachter 1986). Studies on the related Beisa Oryx *Oryx beisa* found that dehydrated animals conserve moisture by storing heat during the day (body temperature may exceed 45 °C for eight hours with no apparent ill effect); during the cooler night the heat is transferred back to the environment (Taylor 1969). Body temperature fluctuations are normal in hippotragine antelopes (Kock & Hawkey 1988). Milk analysis of a sample taken three days post-partum consisted of 12.7% fat, 5.4% protein and 24.5% non-fat milk solids (Mayor 1983). Such highly concentrated milk is consistent with the requirement to conserve water in an arid environment.

A nomadic species with movements adjusted to seasonal rains, oryxes used to walk long distances to exploit newly sprouted vegetation and water. They have a highly developed sense of sight and smell, sensing changes in the atmospheric humidity (Gillet 1966a) or responding to distant lightning and the 'smell' of the rains on the winds (Newby 1974). They have large hooves adapted to walking great distances over sandy or loose, stony terrain, and walk at an amble, nodding their heads while walking fast. Captive animals have adapted readily to life in temperate zones.

Foraging and Food Scimitar-horned Oryxes are ruminants and show a pronounced preference for grazing, but also browse. Gagnon & Chew (2000) in their review of the dietary preferences of African bovids classified them as variable grazers. They graze predominantly on a wide variety of grasses, legumes and perennials that vary seasonally in their availability (Gillet 1966a, b, Newby 1974, R. Molcanova pers. comm.). Plants with a high moisture content are selected, such as the leaves and fruit of the wild desert melon *Citrullus colocynthis*, a characteristic species of the Sahelian sub-desert steppes and an important forage species with its leaves and stems staying green well into the hot season (Newby 1974). The animals graze in the early morning, evening and at night, when plants have been observed to collect small droplets of moisture on the leaves (Gillet 1966a, b).

Plants of the genera *Aristida*, *Brachiaria*, *Dactyloctenium*, *Echinochloa*, *Fagonia*, *Indigofera*, *Panicum*, *Requienia*, *Stipagrostis* and *Tephrosia* were important food sources in Chad, as were high protein *Acacia* pods, particularly for lactating ♀♀ (Gillet 1966a, b, Newby 1974). Sahelian populations also fed on foliage from persistent shrubs, including *Cornulaca monacantha*, *Chrozophora senegalensis* and *Cassia italica*, and a few herbs, such as *Heliotropium strigosum* (Newby 1974, Dragesco-Joffé 1993). Animals returned to Tunisia fed primarily on grasses, including the drought-resistant *Cenchrus* sp., used their horns to hook down *Acacia* branches and explored a range of small herbs and shrubs. They showed exploratory tasting behaviour of a range of plant species that were unfamiliar when they were first introduced to natural range. They also avoided the toxic species *Peganum harmala* and *Pergularia tormentosa* (Gordon 1991, T. Wachter pers. comm.). A list of species known to be eaten by the Scimitar-horned Oryx both in the wild and at release sites for reintroduction programmes is provided by Gilbert & Woodfine (2004).

Social and Reproductive Behaviour The most detailed observations of Scimitar-horned Oryx behaviour are those of Gillet (1966a, b) and Newby (1974, 1988) in the wild in Chad and more recent studies in semi-captive conditions in Tunisia (Molcanova & Wachter 2010, 2011a,b, Molcanova *et al.* 2011). Herd sizes in Chad typically ranged from 10–30 (Talbot 1960, Gillet 1966a, Newby 1974, Wilson 1980). The average of 37 herds observed was 14.8 (range 6–28). Typical herds were mixed sex, comprising at least one old ♂, with subadult ♂♂, ♀♀ and juveniles (Newby 1974). Observations from Tunisia show a similar predominantly mixed-sex structure with a mean herd size of 12 (range 2–30) (Molcanova & Wachter 2011b).

Within herds, linear social hierarchies exist, typically with the largest adult ♂♂ dominant to adult ♀♀, but herd movements are usually initiated by an older dominant ♀ (Newby 1974, Knowles & Oliver 1975, Pfeifer 1981, Mayor 1983, Gordon *et al.* 1989, Engel 1997, Molcanova *et al.* 2001, C. Morrow pers. obs.). Generally tolerant relations between ♂♂ in mixed-sex herds have been reported in Chad (Newby 1974) and Tunisia. Dominance is primarily established with ritualistic displays. Both ♂♂ and ♀♀ use spatial displacement, erect posture and lateral horn presentation, often combined with tilting the head to aim the horns toward an opponent. Submission is expressed by turning away with a brief lowering of the head (or, in extreme cases, lying down). Displaying ♂♂ may thrash the ground or vegetation with horns from a standing or kneeling position. If ritualized displays are insufficient, equally matched ♂♂ fight initially face to face, sometimes kneeling, or swinging round side by side, enabling vigorous over-the-shoulder stabbing (Molcanova & Wachter 2011b), the loser breaking off to run away. Fighting may cause horn breakages. Serious injury and/or death has been recorded (Gordon 1989, Blumer *et al.* 1992, Molcanova & Wachter 2007, 2011a,b). Damage or loss of horns results in reduction in social rank in some circumstances, although some long term territory-holders in Tunisia were also one-horned.

Solitary wild ♂♂ were encountered in Chad; although not known to patrol or demarcate territorial boundaries, they did make vigorous attempts to keep ♀♀ together as a herd (Newby 1974). In semi-captive conditions (Tunisia), territorial behaviour by solitary ♂♂ has been described in detail by Molcanova & Wachter (2010, 2011a,b). Territorial ♂♂ occupied restricted areas (typically around 8 km²), in

some cases held for periods of more than six years. These ♂♂ were frequently alone and areas were defended against ♂♂ of similar status. On territory they expressed dominance by characteristic squat defecation displays; on rare excursions off territory (for example, to visit the single drinking point), they defecated in normal standing posture. When herds move onto territories, resident ♂♂ are comparatively tolerant of submissive subordinate ♂♂ in the absence of receptive ♀♀, using ritualized displays to confirm status. Cases of sub-adult ♂♂ transitioning to territoriality, associated with a change from herd-based to a more solitary existence and development of restricted movement in an exclusive area have also been recorded.

Courtship follows a highly ritualistic pattern: the ♂ approaches the ♀ with head high, sniffs the anogenital region and may perform flehmen. A non-oestrous ♀ will continue grazing or walk away, the ♂ losing interest. A ♀ coming into oestrus may lower her head and run a short distance, the ♂ following. Oestrous ♀♀ walk and vocalize more, eat less and solicit attention from the ♂. The ♂ will perform flehmen in response to urination (sampling mid-stream or from the ground). The pair engage in lateral head-to-tail circling ('mating circles') and the ♂ will repeatedly perform laufschiag ('foreleg lift') to test for female receptivity before attempting to mount. Laufschiag may be performed from directly behind the ♀, from the side or on an angle, with the ♂ facing the female's tail. The ♂ will also lean heavily and/or push on the female's hindquarters to test for receptivity. If the ♀ stands during the hindquarter pushing and laufschiag he will perform repeated mounts (82 ± 13 , mean \pm SEM, range 3–155 in artificially synchronized captive ♀♀) followed by a strong pelvic thrust in which his hindfeet may leave the ground. Bouts of courtship activity (4.7 ± 0.7 , mean \pm SEM, range 1–8 in synchronized ♀♀) are interspersed with other activities (grazing, walking, resting).

Females separate from the herd for a few days prior to and following parturition. During labour, ♀♀ exhibit increased walking and alternating periods of standing and lying. Calves can stand and follow their mothers within hours of birth. Ano-genital licking and grooming is the most common mother–calf interaction and occurs independently of suckling. If in good condition, ♀♀ frequently come into post-partum oestrus during this period of isolation. They are usually joined by (or find their way to) an adult ♂ and form mating consortships (usually with territorial ♂♂) over several days in semi-captive populations. Courtship bouts are frequent and the ♂ may also tend the calf assiduously at this time, working to keep the mother-calf pair within his territory. Female oryx may choose to associate with different ♂♂ during the post-partum period. This can involve running to escape blocking manoeuvres by the ♂, and may not be without risk. Fresh stab injuries have been noted on ♀♀ following successful transition between territorial ♂♂ (Molcanova & Wachter 2011b).

Between periods of suckling, calves spend most of their time lying out hidden in vegetation with other calves of similar age for 3–8 weeks (Newby 1974, Gill & Cave-Browne 1988). Females typically return to herds with their calves within 2–3 weeks. Older calves may kneel on carpal joints while suckling. Social play in captive calves of both sexes from 2–15 weeks of age consists of running in circles, leg kicking, head tossing, sparring, circling and pawing the ground (Pfeifer 1985). Once returned to herds, older calves often associate together, forming distinctive crèches (for example, resting at one

side while adults graze), or two or three calves may keep company with one adult ♀ (Molcanova & Wachter 2011a).

Scimitar-horned Oryxes make a variety of sounds: ♂♂ and ♀♀ vocalize more when ♀♀ are in oestrus and ♀♀ are more vocal with calves at foot; ♂♂ grunt. Six vocalizations were distinguished from sonograms: adult contact, juvenile contact, adult alarm snorts, calf 'moans' and mother 'purr' calls (Gill & Cave-Browne 1988).

Reproduction and Population Structure Limited data on reproduction exist for Scimitar-horned Oryxes in the wild (see Table 9), but comprehensive research on captive populations has provided data on ovarian cycles, seasonality and assisted reproductive technologies (ovulation induction, semen collection and cryopreservation procedures) (see Morrow 1997, Morrow *et al.* 1999, 2000 for reviews). Captive oryxes are seasonally polyoestrous, spontaneous ovulators with a 23.4 ± 1.3 day ovarian cycle (luteal phase 18–20 days) and intermittent, short, 8–12 day cycles; oestrus lasts 3–41 hours (Morrow 1997). A loosely synchronized spring anovulatory interval of 36–95 days was recorded in a small captive herd (Morrow *et al.* 1999). Ultrasonography and elevated periovulatory and luteal phase oestrogen concentrations suggests follicular recruitment throughout the ovarian cycle.

Gestation ranges from 222 to 257 days (median 250 days) in captivity and 258 to 274 days in the wild (Table 9). Twin births are uncommon (0.7%; North American Studbook), and twin litters have a high mortality rate (56%), reflecting anatomical limitations imposed by a duplex uterus. Postpartum oestrus occurs in wild (Newby 1974), reintroduced (Gordon 1991, Molcanova & Wachter 2007) and captive (Knowles & Oliver 1975, Nishiki 1992) populations. Oryxes in Chad and those re-established in Tunisia exhibit asynchronous breeding in favourable climatic and nutritional conditions with births every 8–10 months (Gillet 1966a, Newby 1988, Gordon 1991, R. Molcanova pers. comm.). At Sidi Toui N. P., over the course of seven years ($n = 40$ births), calvings peaked in Mar and Oct, with births recorded in all except the hottest two months of Jun and Jul (Molcanova 2006). In captivity, calves have been born every month of the year (Table 9) and it is recommended that the breeding ♂ be removed at certain times of the year to manage births. However, analysis of North American Studbook records of unmanaged breeding herds confirm an 8–11 month reproductive periodicity; ♀♀ that calved in the winter/spring had a longer inter-birth interval than ♀♀ that calved in the summer/autumn (Morrow *et al.* 1999). Median inter-birth interval was 277 days with 75% of intervals less than 11 months.

Calves average about 8–9 kg at birth (range 5–11 kg), and are a light gingery brown colour for the first 2–3 months, with a narrow whitish area on the belly, and faint hint of adult face pattern. The cryptic colouring serves as an anti-predator adaptation during the lying-out phase. Horn buds are visible at birth. Adult colouration is attained between three and 6 months of age, and weaning occurs between six and ten months (Molcanova & Wachter 2010). Estimates of age of sexual maturity range between 10 and 27 months for ♀♀ and 22 and 30 months for ♂♂ (Table 9). Although no comparative data exist for wild animals, in a semi-captive population a ♀ reproduced at 17 years (Molcanova & Wachter 2011b) and captive ♀♀ in good health can continue to reproduce past the age of 20 years. The high reproductive potential is due to a combination of low

Table 9. Reproductive data for Scimitar-horned Oryx.

mortality, adult longevity and an 8–11 month inter-birth interval. A captive animal was still alive after 27 years (Weigl 2005). Although sex ratios in small captive populations have been reported to be nearly 1 : 1 (Yoffe 1980, Gill & Cave-Browne 1988, Nishiki 1992), an analysis of 1129 births suggested that sex ratios in North America (1985–94) were male-biased (1 : 0.84) (Morrow *et al.* 1999).

Predators, Parasites and Diseases Few large predators inhabited the arid environment of the Scimitar-horned Oryx, but there were once overlaps in range. Spotted Hyaenas *Crocuta crocuta*, Striped Hyaenas *Hyaena hyaena*, African Wild Dogs *Lycaon pictus*, Cheetahs *Acinonyx jubatus*, Golden Jackals *Canis aureus* and Lappet-faced Vultures *Torgos tracheliotus* were likely predators of young and infirm animals (Gillet 1966a, Newby 1974). Death of adults and calves from hunger, heat exhaustion and disease was common during droughts (Newby 1988). Although survival of calves in the wild was high, calf abandonment was also high during drought conditions (Newby 1988). In reintroduced semi-captive populations, calf deaths have resulted from starvation (mismothering or insufficient lactation; Gordon 1991, Molcanova *et al.* 2001), predation by Golden Jackals (Molcanova *et al.* 2001, Molcanova 2002) and aggression by dominant ♂♂ (Gordon 1991). In captivity, calves have in some cases suffered high mortality attributed to inbreeding (Mace & Pemberton 1988, Nishiki 1992).

Normal haematological and serum chemistry values have been examined in captive populations (Bush *et al.* 1983, Hawkey & Hart 1984, Ferrell *et al.* 2001, Flach 2004a). Deaths from *Parelaphostrongylus tenuis* (meningeal worm) infection (Ferrell *et al.* 1997), disseminated intravascular coagulation (Pearce *et al.* 1985), perforation of the large bowel (Mayor 1983), bovine spongiform encephalopathy (Kirkwood

& Cunningham 1999), and serious internal injuries from horn punctures (C. Morrow pers. obs.) have been reported for captive individuals. Tuberculosis is also a potential problem in captivity (Greth *et al.* 1994). Clinical malignant catarrhal fever, bovine viral diarrhoea virus, yersiniosis, gastrointestinal helminths, coccidial oocysts, acidosis, copper deficiency and hoof problems have been reported (Flach 2004a). Reported deaths of Scimitar-horned Oryxes at Hai-Bar N. R., Israel, have included coccidiosis, mouth tumour, parturition and worms (Yoffe 1980).

Immobilization and anaesthesia protocols are well established (Kock & Hawkey 1988, Pearce & Kock 1989, Roth *et al.* 1998, Morrow *et al.* 2000, Flach 2004b). Because of the ability of desert antelopes to accumulate body reserves, individuals may be prone to obesity in captivity. Common veterinary treatments include trauma (broken horns, puncture wounds, lacerations) and hoof/joint disorders (lameness).

Conservation IUCN Category: Extinct in the Wild. CITES: Appendix I. CMS: Appendix I.

The reasons for the catastrophic decline of the Scimitar-horned Oryx are well documented and include habitat loss (desertification due to repeated droughts, development of permanent boreholes and resulting competition with domestic stock and human disturbance), civil war and exploitation through motorized hunting (Newby 1978b, 1980, Mallon & Kingswood 2001a, Devillers & Devillers-Terschuren 2005). Their meat and hide was prized by local people, the thick hide being used for ropes, bags, shoes and shield coverings. They were ruthlessly hunted for their magnificent horns by trophy hunters (Gillet 1966a, Barrett 1967, Newby 1978b). Hunting parties using all-terrain vehicles and modern firearms replaced the

traditional method relying on spears and camels, horses and/or dogs (Brocklehurst 1931, Talbot 1960). Between 1973 and 1978 a wild population flourished (>3500) under active protection in Ouadi Rimé–Ouadi Achim Faunal Reserve in Chad (Bassett 1975, Newby 1980), but between 1978 and 1986 protection in the Reserve was abandoned because of political unrest.

The last known photograph of wild Scimitar-horned Oryx, a group of four, was taken by John Newby in the Air–Ténéré of Niger in May 1980 (Newby *et al.* 2004). As with other ‘last observations’ in Algeria and Egypt (see Distribution), it seems likely that these individuals may have been wandering far from normal locations. Despite sporadic casual reports, no wild Scimitar-horned Oryxes have been confirmed alive in the last 15-odd years. Extensive surveys dedicated to detection of Sahelo-Saharan antelopes carried out in Chad and Niger have produced only five fragments from former haunts in the Ouadi Rimé–Ouadi Achim Faunal Reserve and the central Termit Mts of Niger (Newby *et al.* 2004, Wacher *et al.* 2004a, 2011). No evidence of living oryxes has been obtained.

The Scimitar-horned Oryx has thrived in captivity, and in 2008 it was estimated that there were 1675 animals in 204 institutions (Gilbert 2008). There are perhaps more than 4000 in private collections. However, despite being well represented in captive populations, almost all individuals are derived from a genetic base of fewer than 40–50 founders captured in Chad in the 1960s (Bertram 1988, Dixon *et al.* 1991). A large population of Scimitar-horned Oryxes (>2000) in private collections in the United Arab Emirates are descended from animals captured in N Sudan representing a separate genetic line than the European Endangered Species Programme (EEP) and American Zoos and Aquariums’ Species Survival Plan (SSP) populations (R. Molcanova pers. comm.). In captivity, small, fragmented populations are vulnerable to losses in genetic diversity and fluctuations in size, age and sex ratios. This vulnerability was recognized in the early 1980s, and breeding plans were instituted in North America (SSP; Species Survival Plan), the United Kingdom and Europe (EEP; Europäisches Erhaltungszucht Programm), and Australasia (ASMP; Australasian Species Management Plan) to maximize genetic variation from different founder lineages. Despite being well organized on a regional and global basis, the conservation of this species presents a paradox to zoo managers and conservation biologists. Existing genetic management strategies necessitate the exchange of valuable breeding stock; however, insufficient funding and enclosure space can preclude breeding among genetically valuable pairs. Reproductive technology (e.g. artificial insemination) has proven potential for overcoming the risk and expense of transporting live animals, and for optimizing the use of limited enclosure space, while simultaneously preserving gene diversity (Garland *et al.* 1992, Morrow *et al.* 2000).

Largely due to the success of rearing this species in captivity, populations of Scimitar-horned Oryxes have been re-established in protected, fenced enclosures in Tunisia, Senegal and Morocco (details provided in Distribution). While successful, these populations represent an intermediate stage between captivity and true reintroduction in range countries. Conservation of aridland antelopes

by necessity requires protection of large areas that could never be fenced to accommodate the seasonal migratory behaviour to pastures following the rains. Human encroachment, overgrazing, reduction of tree cover (shade) and the lack of resources have hampered efforts to create protected areas for Scimitar-horned Oryxes (Wacher 2001, Devillers & Devillers-Terschuren 2005). Plans to establish founder populations and a metapopulation management plan within range countries with the ultimate goal of restoring free-living, self-sustaining populations outside of protected areas are gaining momentum (Houston 2003, Wakefield 2003, Woodfine & Engel 2004).

The conservation of this species and other Sahelo-Saharan antelopes was the focus of a workshop convened by the Secretariat of the Convention on the Conservation of Migratory Species and the Institut Royal des Sciences Naturelles de Belgique at Djerba, Tunisia in 1998. This workshop developed an Action Plan for the Conservation and Restoration of Sahelo-Saharan Antelopes and adopted the Djerba Declaration for improving the conservation status of these species (UNEP/CMS 1998, 1999). In 2003, a second seminar on the Conservation and Restoration of Sahelo-Saharan antelopes and their habitats was held at Agadir, Morocco, to review and update the activities and projects in the previous five years (UNEP/CMS 2004).

The Sahelo-Saharan Interest Group (SSIG) was established in 2000 as a network of institutions and individuals keen to conserve Sahelo-Saharan wildlife and the habitats they require for survival (Monfort 2000). The SSIG works to maintain living, healthy deserts that sustain both the wildlife and people who rely on those ecosystems for their livelihood and survival (Monfort & Correll 2004). The SSIG holds an annual meeting and members are actively involved in conservation, research and training across the Sahelo-Saharan regions. In 2005, the SSIG unveiled the Sahara Conservation Fund, an international, non-governmental organization committed to conserving the wildlife of the Sahara and bordering Sahelian grasslands. SCF is spear-heading an initiative to reintroduce Scimitar-horned Oryxes to their former stronghold in Chad, Ouadi Rimé–Ouadi Achim Faunal Reserve.

Measurements

Oryx dammah

HB (♀ ♀): 1360 (1200–1620) mm, n = 31

T (♀ ♀): 530 (440–600) mm, n = 26

Sh. ht (♀ ♀): 1150 (1060–1210) mm, n = 31

WT (♀ ♀): 151.0 (129.0–177.0) kg, n = 19

WT (♂ ♂): 153.0 (144.0–166.0) kg, n = 3

North American captive population (C.J. Morrow pers. obs.; calf data NZP/CRC records 1980–1992)

Maximum recorded horn length is 127.3 cm for an animal from Fada, Chad (Rowland Ward)

Tribe CAPRINI

Sheep, Goats

Caprini Gray, 1821. London Med. Repos. 15: 307.

The Caprini are a large tribe of bovids with 34 living species (Grubb 2005). They are largely native to Eurasia and the Rocky Mts, and form a monophyletic unit in morphological and molecular phylogenies (Hernández Fernández & Vrba 2005, Ropiquet & Hassanin 2005a, Hassanin *et al.* 2012). The latter authors have constructed a molecular tree that presents an improved picture of how the species and genera are related to one another within the tribe.

Some taxonomists prefer to place caprines in their own subfamily, but we have followed previous practice and Ropiquet & Hassanin (2005a) in assigning a tribal level to this diverse and interesting group. In earlier treatments, as a subfamily, several tribal subdivisions were recognized. The most recent classification by Grubb (2005) recognized four tribes: (1) Naemorhedini, including *Capricornis* (serows) and *Naemorhedus* (gorals); (2) Ovibovini, including *Ovibos* (Muskox) and *Budorcas* (Takin); (3) Caprini, including *Capra* (goats and ibexes), *Ammotragus* (Barbary Sheep), *Hemitragus* (tahrs), *Pseudois* (Blue Sheep), *Ovis* (sheep), *Rupicapra* (chamois) and *Oreamnos* (Rocky Mountain Goat); and (4) Pantholopini, including *Pantholops* (Chiru or Tibetan Antelope). However, the molecular results of Ropiquet & Hassanin (2005a) indicate that all tribes classically defined in the literature are not monophyletic, thereby supporting the inclusion of all caprine species into a unique enlarged tribe Caprini (and see Hassanin *et al.* 1998, 2012, Hassanin & Douzery 1999). This phylogeny also supports the inclusion of the Chiru *Pantholops hodgsoni* in the caprines (and see Gatesy *et al.* 1997, Vrba & Schaller 2000).

Only three caprines are found in Africa, namely Nubian Ibex *Capra nubiana*, Walia Ibex *Capra walie* and the Aoudad or Barbary Sheep *Ammotragus lervia*. Of these, only the Walia Ibex can be regarded as non-Palaearctic. Himalayan Tahr *Hemitragus jemlahicus*, a species native to the Himalaya of China, N India and Nepal, were introduced to the Western Cape Province of South Africa around 1930 (see below).

Outside Africa, caprines range in size from around 30 kg (*Naemorhedus* spp.) to as much as 350 kg (Muskox *Ovibos moschatus*); ♀♀ may attain only about 60% of the body weight of adult ♂♂. As with other bovids, the presence of horns is marked by strong inter-specific, inter-sexual and individual variation; male horns are often

long or large, notably in the sheep and goats. Sinuses within the frontal bones spread far up the length of the horn cores. This is an obvious weight-reducing benefit for agile animals in which the ♂♂ fight by ramming and clashing their horns (Schaffer & Reed 1972), although similar fighting techniques also occur in living Bovini (cattle). Pelages include fine undercoats that become the woollen fleece of domestic sheep or the 'pashm' of Kashmir (cashmere) goats. Males often have ruffs, manes, fringes or beards. There are no face, pedal or inguinal glands, and ♀♀ have a single pair of inguinal nipples. The molar teeth have a simple clear-cut occlusal pattern. They are extremely similar in sheep and goats despite the former being primarily a close-cropping grazer and the latter more catholic in its diet. Metapodials are often shortened and the body conformation is stocky. Chromosome numbers differ among the various species karyotyped to date, ranging, for example, from $2n = 60$ in *Capra*, $2n = 52-58$ among members of the genus *Ovis* (and $2n = 58$ in the Barbary Sheep *Ammotragus*) and $2n = 42$ in the Mountain Goat *Oreamnos americanus* (e.g. Schmitt & Ulbrich 1968, Wurster & Benirschke 1968, Nadler *et al.* 1974).

Schaller (1977) described caprines as generalized and flexible feeders, living in habitats of simple structure and in areas of low primary productivity. He pointed out that they are often the only ruminant in a particular area or habitat: thus, caprines have a demonstrable association with mountain ranges, high plateaux, precipitous cliffs, uneven hilly country or jebels. Some of these habitats may be wooded, but they are more often barren, rocky, open and of low productivity. Each regional caprine tends to be an adaptable, medium-sized herbivore with a broad niche in a simple, impoverished habitat. Caprines have not flourished in the richer Eurasian habitats, where they are generally replaced by deer (which have made ecological radiations comparable to those of some African antelopes). Some Eurasian caprine distributions look like a relict pattern resulting from withdrawal in the face of human exploitation. While this may often be true, the animals' anatomical peculiarities and agility on rocky terrain reflect long-term adaptation to such habitats. Their pre-human distributions were more likely an evolutionary response to competition from other ungulates (Kingdon 1982).

Bovine fighting techniques: *Syncerus* (below right) compared with *Ovis* (top right) and Nubian Ibex *Capra nubiana* (left).

Fossils of Caprini are reasonably well known from Eurasia and sometimes occurred additionally in North Africa. It would seem that from about 12 mya onwards, different bovids throughout Eurasia, for example *Aragoral* and *Protoryx*, were gradually acquiring characters of the diverse Caprini that later inhabited the same land mass (Gentry 2000). Parallel evolution was evidently rife in the acquisition of characters such as anterior keels on the horn cores or shorter metapodials. Extinct relatives of *Ovibos* were widespread in the later Pliocene, even into North America, and Caprini had entered Africa by the start of the Pliocene. Better-known examples include the South African later Pliocene ovibovine *Makapania broomi*, a Pliocene species of *Budorcas* from Ethiopia, and the puzzling *Nitidarcus asfawi* from the Pleistocene of Ethiopia (Vrba 1997).

Although Pliocene and Pleistocene sheep are not very common and are unknown in Africa, goats or goat-like forms are known from Ethiopia in the middle Pleistocene (*Bouria angettyae*; Vrba 1997) and from North Africa in the later Pleistocene.

It is thought that humans began exerting some control over herds of wild Caprini many millennia ago, perhaps around 8000 BC in Africa, and evidence of domestic sheep is known from the southern tip of Africa about 500 years BC.

In the early 1930s, Groote Schuur Zoological Gardens, situated on the slopes of Devil's Peak, Table Mountain, near Cape Town in the

Western Cape Province of South Africa, obtained a pair of Himalayan Tahrs from the National Zoological Gardens, Pretoria. The pair escaped from their enclosure and established themselves either on Devil's Peak or on Table Mountain. In 1972, there were an estimated 330 individuals (Lloyd 1975), by which time Himalayan Tahrs occurred across much of the north/north-west and south/south-east faces of both Devil's Peak and Table Mountain (and the Saddle linking them) and the north-west faces of the Twelve Apostles range. This uncontrolled increase in the numbers of Himalayan Tahrs, within a Nature Reserve and especially a reserve with a unique flora, posed a serious threat and the local conservation authority, Cape Nature Conservation, initiated a research study to investigate the problems involved. This survey recommended that, as total eradication was probably impossible, there should be a drastic reduction in the population (Lloyd 1975). Between 1975 and 1981 over 600 tahrs were removed by Parks and Forestry officials and members of Cape Nature Conservation. A survey conducted by the Mountain Club and officials of the Parks and Forestry showed that at the end of this period, 88 tahrs were still living on Table Mountain (see Skinner & Smithers 1990 for further discussion).

Michael Hoffmann & Jonathan Kingdon

GENUS *Ammotragus*

Aoudad

Ammotragus Blyth, 1840. Proc. Zool. Soc. Lond. 1840: 13.

Ammotragus includes only the Aoudad *Ammotragus lervia*, which inhabits montane desert habitats in northern Africa. The classification of the Aoudad has changed over the years since it was first included in the genus *Antelope*, with its affinities with *Ovis* and *Capra*, in particular, having been widely discussed in the literature. Several taxonomic works have included the species in the genus *Capra* (Ansell 1972, Corbet 1978), with which it shares a series of morphological traits. Aoudads may interbreed with domestic goats and produce live and fertile offspring (Petzsch 1957, Van Gelder 1977b), although this hybridization does not occur readily. However, Aoudads also share a series of sheep-like characteristics with *Ovis* (Valdez & Bunch 1980), and one author has suggested it is related to the common ancestor of both goats and sheep (e.g. Geist 1971), due to its unique morphological and behavioural characteristics, which, along with fossil remains, would place it near the origin of the Palaearctic sheep lineage, close to the rupicaprids. Analysis of proteins has only served to confuse matters, with seroprotein (Schmitt 1963) and immunoglobulin (Curtain & Fudenberg 1973) analyses revealing a closer relationship to *Ovis* than to *Capra*, while the sequence of amino acids of several haemoglobin chains (Manwell & Baker 1975) showed a closer relation to *Capra* as well as some unique characteristics. Immuno-diffusion studies by Hight & Nadler (1976) paradoxically establish a closer relationship between *Ovis* and *Capra* than between either of them and *Ammotragus*.

A study on phylogenetic relationships based on the comparison of 12S rDNA sequences between eight caprine species, including *Ammotragus*, *Pseudois*, *Capra aegagrus* and five *Ovis* species, show two distinct clusters, one formed by all *Ovis* species and another grouping the other three genera together (Ludwig & Fischer 1998). A complete estimate of the phylogenetic relationships in the Ruminantia unequivocally supports the grouping of *Ammotragus* with the goats and tahrs (*Hemitragus*) (Hernández Fernández & Vrba 2005), although its own morphological, biological, ecological and behavioural characteristics suggest that it should be placed in its own genus *Ammotragus*. A molecular phylogeny of caprines groups *Ammotragus* with *Capra*, *Hemitragus* and *Pseudois* (Ropiquet & Hassanin 2005a), with *Ammotragus* most closely allied with the Arabian Tahr *Arabitragus jayakari* (Ropiquet & Hassanin 2005b).

Common names referring to either sheep (genus *Ovis*) or goats (genus *Capra*) are misleading and names of an Arabic origin should preferentially be used, for example, Aoudad or Arrui. *Ammotragus* differs from goats and sheep in its long face and sharply bent-down braincase, long neck fringe and relatively long tufted tail. It differs additionally from sheep in that the wrinkling on horns does not form prominent ridges, the horns are not keeled, in the presence of a beard and the absence of preorbital and interdental glands.

Peter Grubb & Michael Hoffmann

Ammotragus lervia AOUDAD (BARBARY SHEEP, ARUI)

Fr. Mouflon à manchettes; Ger. Mähnspringer (Mähnschaf)

Ammotragus lervia (Pallas, 1777). Spicil. Zool. 12: 12. 'Africae borealori propria'; restricted to Algeria, Department of Oran (Harper 1940).

Aoudad *Ammotragus lervia* male.

Aoudad *Ammotragus lervia* female.

Taxonomy Polytypic species, with six subspecies described (Allen 1939, Ansell 1972, Gray & Simpson 1980), though not without controversy (see, for example, Ellerman & Morrison-Scott 1951). The somewhat vague morphological differences between them (see below), the fact that most of the subspecies were defined from a few specimens, and the presence of several potential areas of hybridization, makes it difficult to expound reliably on the ranges of the different subspecies. A reassessment of subspecies boundaries is clearly necessary. Synonyms: *angusi*, *barbatus*, *blainei*, *fassini*, *jaela*, *ornata*, *sahariensis*, *tragelaphus*. Chromosome number: $2n = 58$, with a large acrocentric X chromosome and a minute bi-armed Y chromosome (Nadler *et al.* 1974, Bunch *et al.* 1977), identical to that of *Ovis aries cycloceros* and *O. a. vignei*.

Description The Aoudad is goat-like in proportions, with head relatively long, legs short and stocky, and tail long and naked underneath. A characteristic feature is the mane, which extends down from under the throat along the front of the neck to the chest, and continuing down each of the forelegs in mature animals. This hair pattern on the legs is referred to as leggings or chaps. A mane is also found in wild sheep such as *Ovis orientalis* and *O. aries*, but chaps are unique to Aoudads. They do not have a typical goatee, and, like some wild sheep, they have a haired chin and a short erect dorsal fringe extending from the neck to the middle of back. The genus name *Ammotragus* means 'sand goat', probably in reference to the colour of the pelage, which is pale, tawny-brown grading to a whitish underside with dark brown areas about the head and shoulders, although variability in colour tones is notable among the subspecies (see below). Unlike sheep, the Aoudad lacks preorbital, interdigital and flank glands, but it has subcaudal glands. The lack

of these glands lends support to the argument that *Ammotragus* is a distinct genus.

Both sexes have horns, relatively large and moderately long (even in ♀♀, compared with goats and sheep), with a somewhat high spiral angle. Horns are elliptical and keeled in cross-section, with a broad frontal surface, and have numerous shallow and uniform sulci as well as periodic growth checks or annuli (Ogren 1965, Schaffer & Reed 1972). The horns curve outwards, backwards and point inwards towards the neck, tending to converge over the nape in mature ♂♂.

The skull is distinguished by the placement of the foramen magnum beneath the horn bases, shaping the cranium accordingly, and the presence of sinuses covering most of the brain as well as complex septa. Aoudads share this advanced skull pattern with the Himalayan Tahr *Hemitragus jemlahicus*, bharals *Pseudois* spp. and *Ovis ammon*. Also, along with the Himalayan Tahr, Aoudad horn bases are displaced behind the eye orbit, while in most Caprini they are usually placed above its posterior half. Finally, the species is characterized by extensive cornual sinuses. All these characteristics are less pronounced or moderate in ♀♀ compared with ♂♂ (Schaffer & Reed 1972).

Geographic Variation

- A. *l. lervia* (Atlas or Moroccan Aoudad): Morocco (and possibly Western Sahara), N Tunisia and N Algeria. Horns scarcely, if at all, depressed; face with an indistinct dark median stripe; beard uniform sandy; body mid-tawny.
- A. *l. ornata* (Egyptian Aoudad): formerly quite widespread throughout the Eastern and Western Desert of Egypt. Horns strongly depressed, turning sharply downwards before bending

Lateral view of skull of Aoudad *Ammotragus lervia*.

backwards; face with no stripe; beard uniform sandy; body sandy rufous.

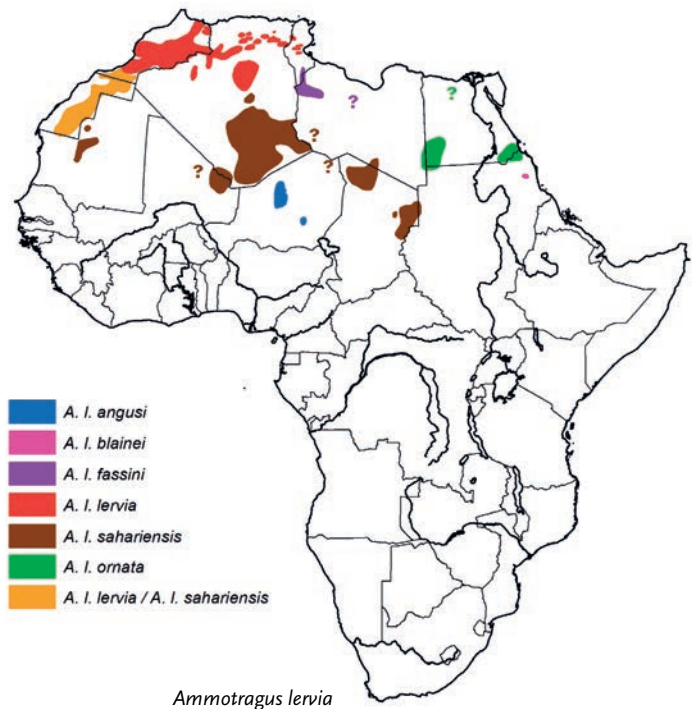

- A. l. sahariensis* (Saharan Aoudad): C and S Algeria, SW Libya, Mauritania, Mali and Tibesti Massif and Ennedi Plateau in Chad; presumed to be the subspecies in Western Sahara, but limits with *A. l. lervia* unclear. Horns like *A. l. ornata*; face with no stripe; ears with a white patch below; beard uniform sandy; body pale sandy rufous.
- A. l. blainei* (Kordofan Aoudad): E Sudan. Horns strongly depressed but not bent backwards so much as in previously named subspecies; face with no stripe, but dark owing to admixture of blackish hairs; beard on sides of lower jaw nearly black; body brownish-grey, less rufous than any previously named subspecies; mane brownish.
- A. l. angusi* (Air Aoudad): originally in Air Massif (Niger) and Termit Massif. Horns much more upright on head than previously named subspecies and curving further backwards and inwards; face with no stripe; beard on sides of lower jaw cinnamon-rufous; body very deep rufous, darker than *A. l. ornata*, dorsal fringe mixed with black, more strongly on front half; chaps sparse.
- A. l. fassini* (Libyan Aoudad): originally in extreme S Tunisia and Libya. Horns less depressed than *A. l. ornata* and *A. l. sahariensis* and more backward-turned than *A. l. blainei*; face with no stripe, but dark due to mixture of brownish and rufous hairs; ears with a dark patch below; beard black, and on lower jaw mixture of tawny and brown; body light tawny-reddish, more rufous than *A. l. sahariensis* and *A. l. blainei*.

Similar Species

Capra nubiana. Confined to Egypt, Sudan and Eritrea, its distribution may overlap with that of the Aoudad, particularly in some mountainous areas of the western coast of the Red Sea: at the edge of the Egyptian Eastern Desert, and a few areas in Sudan (see below). Similar in size to the Aoudad (♂♂ weighing around 90 kg), but shows a characteristic long goatee in mature ♂♂, lacking any mane or the like; male horns are long (up to 1400 mm in some individuals), projected upwards and forming a semi-circle over its back, whereas the ♀ of this species has shorter horns that grow only up to 380 mm in length.

Distribution Endemic to North Africa.

Historical Distribution Formerly widespread in any rugged and mountainous terrain from deserts and semi-deserts to open forests in North Africa (Brentjes 1980, Shackleton 1997). Known also within its present range from late Pleistocene fossils, Holocene rock art and Ancient Egyptian mummified remains.

Current Distribution The distribution of the six subspecies, while imperfectly known, can be summarized as follows.

Atlas or Moroccan Aoudads are found in the mountains of Morocco, except the western half of the Rif (Aulagnier & Thévenot 1997, F. Cuzin pers. comm.), as well as the northern part of Algeria (Kowalski & Rzebiak-Kowalska 1991, De Smet 1997b) and Tunisia (De Smet 1997a), where more than 30 years ago the Aoudad was approaching extinction (Schomber & Kock 1960). The boundary between this subspecies and the Saharan Aoudad in Morocco/Western Sahara is unclear. It has been presumed to be the subspecies imported to European zoological gardens at the end of last century, and from there to American zoos about 1900 (Gray 1985). This subspecies would then form the basis of free-ranging populations inhabiting the S USA (Gray 1985). However, no conclusive evidence to support the notion that this was the sole subspecies used in extralimital transplants has been found (J. Cassinello pers. obs.). On the contrary, Ogren (1965: 9) stated that the pelage of some of the individuals introduced to New Mexico resembles each of the six recognized subspecies, which suggests the existence of hybrid forms. Gray (1985) also supposes that this is the subspecies introduced in the Sierra Espuña mountains of Murcia (Spain), a population that has expanded throughout the whole south-east of the country (Cassinello 2000, Cassinello *et al.* 2004).

The Egyptian Aoudad is native to deserts in Egypt (see Gray 1985), and was assumed to be extinct (Amer 1997). However, there are reports of its continued presence in remote areas, including herds located in the extreme southern region of the Egyptian Eastern Desert (mainly within the boundaries of the Gebel Elba Protected Area) and the Gebel El Uwieinat and Gilf El Kebier Plateau (Western Desert, at the extreme southern corner of the country) (M. A. Saleh pers. comm.). In addition, Wachter *et al.* (2002, and references therein) also report evidence of the presence of Aoudads in both the Elba Protected Area and the Western Desert between 1997 and 2000. Manlius *et al.* (2003) and Manlius (2009) provide further information on their distribution in these remote areas.

The Saharan Aoudad has a very large geographic distribution that, according to Gray (1985), includes parts of S Morocco and Western Sahara (the boundary with the Atlas Aoudad is unclear; see also Aulagnier & Thévenot 1997), the Sahara of S Algeria (Kowalski & Rzebik-Kowalska 1991; although De Smet 1997b only accounts for *A. lervia* in Algeria), SW Libya (see also Shackleton & De Smet 1997), the mountains of the Adrar de Iforas in Mali (Lamarche 1997a), N Niger (although Magin & Newby 1997 only account for *A. l. angusi* in Niger), and Mauritania (Lamarche 1997b). According to Mekonlaou & Daboulaye (1997), this subspecies used to be widespread in Chad, but today it is probably restricted to the sandstone massifs in Ennedi (Alados *et al.* 1988 reported this population as *A. l. blainei*) and the Tibesti Massif in NW Chad. The species was recently reported from Western Sahara (Cuzin 2003), where there have been no reliable reports of Aoudad since the surveys of Valverde (1957). This is presumably the subspecies that has been successfully breeding in captivity in a public research institute in SE Spain since 1975 (EEZA, CSIC, Almería, Spain, see, for example, Alados *et al.* 1988).

The Kordofan Aoudad was once relatively widespread from W Sudan to the Red Sea coast, but currently is probably restricted to the Red Sea hills of E Sudan (Nimir 1997). According to Alados *et al.* (1988), and contrary to Mekonlaou & Daboulaye (1997), this is the subspecies that may occur in the Ennedi and Uweinat mountains in NE Chad. This may be the form in SE Libya. In 1923, *A. l. blainei* was introduced into the Sabaloka reserve on the Sixth Cataract of the Nile (Gray 1985), where it no longer survives.

The Air Aoudad inhabits the Air Massif in Niger (Magin & Newby 1997). There is a small but apparently viable population that inhabits the Termit Massif region in Niger, isolated from others geographically and probably since long ago, thus of extreme interest both from conservation and taxonomic perspectives (J. Newby pers. comm., T. Rabeil pers. comm; see also Claro & Sissier 2003, Claro 2004, Wachter *et al.* 2008). According to Alados *et al.* (1988) this is the form in the Tibesti in Chad, not *sahariensis* (see above).

The Libyan Aoudad is found in Libya (Hufnagl 1972, Shackleton & De Smet 1997) and in the extreme southern part of Tunisia (Gray 1985, De Smet 1997a). Like the Saharan Aoudad, this subspecies was introduced into the EEZA, but the whole population was moved into the Barcelona Zoo, also in Spain, in the late 1980s.

As noted above, Aoudads have been successfully introduced as a game species in mountainous desert regions of Texas, New Mexico and California (USA), N Mexico and S Spain.

Habitat Aoudads tend to inhabit rocky and precipitous terrain, from near sea level up to the summits of the Air Mts in Niger, which may reach 2100 m (Magin & Newby 1997) and to snow-free areas at about 4100 m in the Atlas Mts (Cuzin 2003). They also require at least some tree cover for shade, and might wander far from water sources for long periods of time. No detailed studies have been carried out in Africa, but empirical data obtained from populations introduced in USA (Johnston 1980) and Spain (Cassinello 2000) revealed the following habitat preferences according to season: open lands and protective rocky slopes during the breeding season (spring), woodlands during summer and grasslands during rutting (autumn) and winter, although in dry regions Aoudads can also be seen in dry forest areas during rutting. A recent study on habitat suitability of the exotic free-ranging population inhabiting SE

Spain shows an impressive expansion potential and adaptation to different environmental conditions, but constrained by low winter precipitation, high altitude, high terrain slope and the presence of forest (Cassinello *et al.* 2006).

Abundance There are no total population estimates available, but numbers are probably in the order of 5000–10,000 individuals. The total population in Morocco has been estimated at between 800 and 2000 individuals (Cuzin *et al.* 2007), which is higher than that suggested by Aulagnier & Thévenot (1997) at 800–1000. Several thousand individuals survive in Algeria (De Smet 1997b), while low numbers occur in Chad (Mekonlaou & Daboulaye 1997), the Adrar des Iforas in Mali (Lamarche 1997a), and in Mauritania (Lamarche 1997b). In Niger, some 3520 Aoudads were estimated to be present in Air Ténéré National N. R. in 1989 (making this the most important stronghold for wild Aoudad on the continent), and 670 outside the limits of the reserve (Poilecot 1991). Numbers are suspected to be increasing in protected areas in the Air mountains, but declining elsewhere in Niger (Magin & Newby 1997). Aoudads seem to be locally numerous in the Eastern and Western Deserts of Egypt (M. A. Saleh pers. comm.), where they were once thought extinct. There are no estimates for Lybia (Shackleton & De Smet 1997) or Tunisia (De Smet 1997a); there also are no estimates for Sudan, where they are very rare and declining (Nimir 1997).

Small groups scattered irregularly over large ranges are the typical pattern of the distribution of the species in the wild, so that obtaining population estimates in the field is difficult. Free-ranging populations in USA and Spain vary in group composition and density both monthly and yearly (Gray & Simpson 1982a, Cassinello 2000).

Adaptations This is a mountain-dwelling caprine perfectly adapted to inhabiting rocky and steep terrains. There is no convincing explanation for the existence of its conspicuous mane, but given that it is a sexually dimorphic character, the most likely explanation is that the mane is used for display purposes by ♂♂ and it is possible that it may act as a dispenser of scent from squirts of urine. Ogren (1965) postulates that it might provide protection against sand storms, by covering the face; it would also prevent flies from disturbing the animal while foraging. Finally, the mane might also contribute to display in agonistic and sexual contexts; captive adult ♂♂ have been seen waving their manes by twisting their heads, raised on their hindlegs while laying the forelegs on fences confronted with other all-male enclosures (T. Abáigar pers. comm.). They use their horns as shovels when sand bathing, a common behaviour probably related to protection against ectoparasites or, as Ogren (1965) suggests, to homeothermy.

Foraging and Food Little data on food habits have been reported from the wild (see Poilecot 1991, Chaveas 2000). This species is a generalist herbivore combining grazing with browsing. In Spain their diet comprises all kind of shrubs, succulent and non-succulent forbs, creepers, dwarf shrubs and grasses, depending on seasonal availability (Miranda *et al.* 2012). In the Air Massif, and probably elsewhere, the green seed pods of acacia trees (*Acacia tortilis raddiana*, *A. ehrenbergiana*) are much sought after by Aoudads; they are even reported butting tree trunks to make the pods fall (J. Newby pers.

comm.). Aoudads can survive without drinking water for long periods, eating just succulent forbs, but if they have the chance they will drink daily from ponds or wells. They probably make small migratory movements in relation to food availability, but there is no specific information.

Social and Reproductive Behaviour The Aoudad is a gregarious species. There is limited information from the wild, but their behaviour is well documented in exotic, free-ranging herds in the USA and Spain. Gray & Simpson (1982a) found that ♀♀ lead the group when adults of both sexes are present, while group composition and group size vary seasonally. Six group types can be distinguished in free-ranging populations: solitary; nursery (females, young and juveniles); mixed; all-male; all-female; and all-juvenile (Gray & Simpson 1982a, Poilecot 1991, Cassinello 2000, Chaveas 2000). Mixed groups are mostly found during rutting, and nursery groups during spring and summer. Adult ♀♀ and juveniles are the sex–age classes most commonly observed. Yearly fluctuations in group dynamics in the same areas are evident, but generally are characterized by a prevalence of adult ♀♀, followed by subadults and finally a lower percentage of adult ♂♂ (Cassinello 2000). However, the percentage of adult ♂♂ observed in the Tirghist Reserve in Morocco is slightly higher than that of subadults (Chaveas 2000).

From the meagre information available (e.g. Dupuy 1966, Chaveas 2000), group size in populations in the wild resembles that in free-ranging populations in USA and Spain. In their Spanish range, herds tend to be small, the majority of groups consisting of less than 11 individuals (Bigalke 1986, Cassinello 2000). In the Texan population, mean group size can oscillate from 5 to 20 individuals (Gray & Simpson 1982a). The mean home-range size ranges from 259 to 3367 ha, and dispersal is particularly accentuated in summer (Simpson *et al.* 1978, Dickinson & Simpson 1980). The species is not territorial, and ♂♂ that reach adulthood leave maternal herds to create their own all-male group or to join existing ones.

Social rank determines each individual's position in a hierarchical order. In captivity, the rank of an adult ♀ may vary according to proximal factors, such as mating, parturition and weaning of young (Cassinello 1995). Aoudad fighting techniques present a variety of forms (Katz 1949, Haas 1959, Ogren 1965, J. Cassinello pers. obs.), some of them ancestral in Caprini, from reverse-parallel pushing to horn-locking; although horn clashing is also present, they do not rise on their hindlegs (as goats do) and they usually clash from short distance, so that collision is not as violent as in wild sheep. Typically, the contestants approach with heads lowered in a threat posture, and when closer they bring the heads down even further, thus directing the bases of the horns forward. Contestants then run toward each other and collide, the blow being delivered with the base of the horns, the force of the collision producing a loud sound that can be heard as far as 300 m away (Habibi 1987). Even infants display all fighting forms when playing (Haas 1959, J. Cassinello pers. obs.).

Courtship is carried out by the most dominant ♂♂ and follows a conspicuous and ritualized display, similar to that of other caprines, with low-stretch posture, tongue-licking and female chasing; also, a sort of guarding behaviour has been observed in dominant ♂♂ following copulation with a ♀ (see Habibi 1987). Females in good

condition bias their investment towards their sons, allocating their resources preferentially (the suckling rate of sons is significantly higher than daughters) and producing more sons than daughters (Cassinello 1996, Cassinello & Gomendio 1996). Mother–offspring conflict during weaning has been investigated. There seems to be a progressive cessation of investment, with no behavioural conflict arising between mother and offspring, except when she resumes sexual activity before weaning has taken place (Cassinello 1997a). Sporadic allosuckling events have been reported in captivity, carried out by alien young of a similar age to that of the allo-mother's true offspring (Cassinello 1999).

Aoudads may produce up to six types of vocalizations: sheep and goat-like bleats (the only sound youngsters produce), short nose snorts, mouth blows, rasping screeches, and grunts (see Gray & Simpson 1982b).

Reproduction and Population Structure Males and ♀♀ can be regarded as sexually mature when aged 14 months and 9 months, respectively (Cassinello 1997b). The mating season peaks from Sep to Nov, and the average gestation period is 22 weeks (Gray & Simpson 1980). In captivity, twins may be produced as frequently as once every four or five births; triplets have been reported in free-ranging populations (ARMAN 1991). Young weigh about 4.5 kg at birth. Singletons are heavier than twins, and high-ranking mothers tend to produce heavier young than low-ranking mothers. Birth-weights also increase with maternal age (see Cassinello 1997b, Cassinello & Alados 1996, Cassinello & Gomendio 1996). Inter-birth intervals average 10 months in captivity, and weaning takes place at a mean age of 8.2 months. The population sex ratio seems to be 1 : 1.

Studies in captivity have shown that variation in female reproductive success is determined first by longevity, followed by fecundity, offspring survival at one month and age at first parturition. Among the factors that affect the components of reproductive success, longevity depends on physical condition, fecundity is higher in top-ranking ♀♀, offspring survival increases with birth-weight, and age at first parturition increases with population density and inbreeding coefficients (Cassinello & Alados 1996).

Aoudads may live up to 20 years in captivity (Ogren 1965, Weigl 2005), but longevity probably rarely exceeds 10 years in the wild (Gray & Simpson 1980).

Predators, Parasites and Diseases Presumably, Lions *Panthera leo* and Leopards *Panthera pardus* were among the natural predators of the species in the past, but today Striped Hyaenas *Hyaena hyaena*, Golden Jackals *Canis aureus* and feral domestic dogs may be the most common natural predators. Also, raptors may predate newborns and young, as reported in Aoudad populations in Spain (accounts from forest rangers of the Golden Eagle *Aquila chrysaetos* taking young). The free-ranging populations in S USA seem to be remarkably free of disease and parasites (Ogren 1965, Pence 1980).

Conservation IUCN Category: Vulnerable C1. CITES: Appendix II.

The lack of surveys carried out in North Africa make determining the precise current status of the species difficult. In its native habitat,

the major threats are habitat loss, competition with livestock and poaching (Alados & Shackleton 1997), resulting in a steady decrease in numbers throughout its range and increasing isolation of populations. Some populations or subspecies are at serious risk of extinction, and the confirmation of the presence of *A. l. ornata* in Egypt (Wacher *et al.* 2002; M.A. Saleh pers. comm.) lends support to the dire need for population surveys in other areas, and clarification on the taxonomic status of the recognized subspecies.

The degree to which Aoudads are legally protected across their range varies. For example, Aoudads have been fully protected in both Morocco and Tunisia since 1966, while in Niger hunting has been banned since 1964; on the other hand, they receive no formal protection in Mali, and although they are listed under Schedule II as a protected species in Sudan, they can still be shot by anyone with the appropriate licence. Aoudads occur in a number of protected areas, including: Takherkhort Hunting Reserve (established in 1967 specifically to conserve this species), the adjacent Toubkal N. P., and Eastern High Atlas N. P. (Morocco); Belezma, Tassili n' Ajjer, and Ahaggar National Parks, and in Djebel Aissa State Forest (Algeria); Fada-Archei Faunal Reserve (Chad); Adrar Mouflon Partial Faunal Reserve (Mauritania); and the vast Aïr Ténéré National N. R. (Niger) (see Shackleton 1997 and chapters therein). The population in Djebel Chambi N. P. in Tunisia was reintroduced in 1987; some animals escaped and a wild population has survived (De Smet 1997; K. de Smet pers. comm.). A few Aoudads are held in captivity in Djebel Bou-Hedma N. P. (De Smet 1997a), and the species was also released in Oued Dekouk N. R. (K. De Smet pers. comm.). Aoudads were introduced into Tripoli N. R. in Libya (Shackleton & De Smet 1997).

In contrast to the situation in the wild, introduced US and Spanish populations are either well established or steadily

increasing (Gray 1985, Cassinello *et al.* 2004). However, it is a priority to register and keep information on subspecific origins of captive and introduced populations and prevent undesirable hybridization events, particularly if reintroduction programmes are to be implemented.

Measurements

Ammotragus lervia

HB (♂ ♂): 1490 (1050–1760) mm, n = 18

HB (♀ ♀): 1290 (1040–1500) mm, n = 41

T (♂ ♂): 190 (170–210) mm, n = 3

T (♀ ♀): 170 (160–190) mm, n = 4

Sh. ht (♂ ♂): 960 (890–1050) mm, n = 3

Sh. ht (♀ ♀): 780 (760–800) mm, n = 4

WT (♂ ♂): 86.0 (50.0–132.0) kg, n = 17

WT (♀ ♀): 42.0 (12.0–68.0) kg, n = 39

Free-ranging population, New Mexico, USA (Ogren 1965), except HB and WT, which correspond with sexually mature individuals (♂ ♂ older than 1.5 yr; ♀ ♀ >1 yr) from the captive population at EEZA (CSIC), Almería, Spain (Cassinello 1997b)

Maximum recorded horn length is 88.0 cm for a pair of horns from the Ennedi Mts, Chad; however, record horn length from an extralimital population introduced in Colorado, USA, is 90.1 cm (Rowland Ward)

Jorge Cassinello

GENUS *Capra*

Ibexes

Capra Linnaeus, 1758. Syst. Nat., 10th edn, 1: 68.

Capra is a polytypic genus that includes eight species: Markhor *C. falconeri*, Goat *C. hircus* (wild populations commonly called *C. aegagrus*) and the ibexes (Nubian Ibex *C. nubiana*, Walia Ibex *C. walia*, Siberian Ibex *C. sibirica*, Alpine Ibex *C. ibex*, Spanish Ibex *C. pyrenaica* and Tur *C. caucasica*) (Grubb 2005). There is no agreement on the true number of species recognized, and as few as two (*hircus* and *falconeri*; Haltenorth 1963) and as many as nine have been recognized (the Tur sometimes being split into two species, *C. caucasica* and *C. cylindricornis*) (Heptner *et al.* 1961).

The genus is distributed from the Iberian Peninsula, the Alps and the Caucasus Mts through the Middle East, south into Egypt, Sudan, Ethiopia and the Arabian Peninsula and east across Iran, Afghanistan and Pakistan into the Hindu Kush, Pamirs, Tien Shan and Altai Mts of central Asia, in upland precipitous habitats. There is a substantial Pleistocene fossil record in Europe; only the supposed Pliocene *C. primaeva* (doubtfully in this genus) is recorded from Africa. Only two species, the Walia Ibex and Nubian Ibex, occur in Africa: the former is found only in and around Simien Mountains N. P. in Ethiopia, while the latter is found in Egypt, east of the Nile, NE Sudan, N Eritrea,

Israel, Jordan, SE Oman, Saudi Arabia and SE Yemen (and extinct in Lebanon and Syria). Analysis of mitochondrial cytochrome *b* and Y chromosome DNA sequences suggests that the two species form a monophyletic clade, although the Walia Ibex potentially has been isolated for up to 0.8 million years from Nubian Ibex (Gebremedhin *et al.* 2009).

Members of the genus are robust animals with stout limbs, short hoofs and short tail. The rhinarium is hairy, and there is a beard on the chin. Long hair extends over forequarters in the Markhor, but not in other species. Males and ♀ ♀ are strongly sexually dimorphic; ♂ ♂ are larger with large horns, ♀ ♀ with relatively small, slender horns. Horns grow during life but growth is seasonal, forming rings or checks during the quiescent phase, which aids ageing individuals in the field. There is a wide range in size between species and sexes (50–130 kg). The skull is characterized by a short narrow facial region, but is broad across the frontals, with tubular orbits; the skull is strengthened by secondary bony deposition leading to disappearance of the nasofrontal suture, though the naso-maxillary suture remains open.

Nubian Ibex *Capra nubiana* male with tightly curved horns.

Capra nubiana NUBIAN IBEX

Fr. Bouquetin de Nubie; Ger. Nubischer Steinbock

Capra nubiana (F. Cuvier, 1825). In: E. Geoffroy Saint-Hilaire and F. Cuvier, Hist. Nat. Mammifères 6, pt 50, 'Bouc sauvage de la Haute-Egypte', p. 2, pl. 397. Egypt, 'de la Haute-Égypte ... ou de Nubie'; Nubia (Lydekker 1913: 153; G. M. Allen 1939: 549) or Upper Egypt (Ellerman & Morrison-Scott 1951: 407), which are virtually synonymous; restricted by Grubb (2005) to Sudan, Northern Prov., Nubian Desert, east of Nile R.

Nubian Ibex *Capra nubiana*.

Species are differentiated by size, form of the horns in ♂♂ (much variation between species), length of pelage and colour pattern. Along the anterior surfaces of the horns, ibexes have prominent bosses (secondarily lost in some populations of Tur and Spanish Ibex). African ibexes (Nubian and Walia) have contrasting black-and-white leg markings and horns that are long and semi-circular in outline, placed further forward on the skull compared with other ibexes, associated with the development of a swelling on the frontal bones just below the horn bases. They differ from each other in size and horn features (slender or robust, strongly or slightly laterally compressed).

Ansell (1972) included the Barbary Sheep or Aoudad *Ammotragus lervia* in this genus, but this has not been followed here and is in conflict with molecular data (Ludwig & Fischer 1988, Ropiquet & Hassanin 2005a).

Peter Grubb & Michael Hoffmann

Taxonomy Monotypic. Considered a subspecies of *Capra ibex* (Ellerman & Morrison-Scott 1951, Ansell 1972, Corbet 1978, Harrison & Bates 1991), but treated as distinct by Uerpmann (1987) and Grubb (1993c, 2005). Synonyms: *arabica*, *beden*, *mengesi*, *sinaitica*, *typical*. Chromosome number: $2n = 60$ (Schaller 1977).

Description Tan to greyish, mid-sized ungulate of mountainous desert terrain, with prominent horns and striking black and white leg markings. Mature ♂♂ much larger and heavier than ♀♀, with dark beards and scimitar-shaped horns. During the rut, breeding ♂♂ develop enlarged necks and dark pelage on chest, shoulders and flanks. Both sexes have whitish belly, inner legs and buttocks, and short dark tails. Nostril, mouth and orbits outlined in black. Eyes have amber irises and horizontal black pupils. Chin and hairs surrounding mouth and nostrils are usually whitish. Darker band extends from eye to edge of mouth. Nasal area may be rufous-brown. Ear backs grey, and fronts have black centres with contrasting white edges. Summer body pelage of adults and young comprises short, tan guard hairs (replaced in winter by brown to grey guard hairs with underfur). Mid-dorsal band of longer hairs extends from nape to base of tail, and is dark in ♂♂. Belly whitish, partially edged with a dark band in many adults. Fronts of upper and lower foreleg black, with white band above grey knee callus. White fetlocks and pasterns contrast with black hooves on fore- and hindlegs. Dark band above fetlock extends to leading edge of hindleg.

The flattened face of the male horns has as many as 30 prominent horizontal knobs; female horns are short and slender and bear narrow growth rings, but no knobs. Male horn dimensions vary among populations (Habibi 1994).

Capra nubiana

Geographic Variation None recorded.

Similar Species

Capra walie. Restricted to the Simien Mts in Ethiopia. Larger and stouter body, more robust horns and darker pelage.

Distribution Once widely distributed in north-east Africa, east of the Nile R., Sinai, the Near East and the Arabian Peninsula, but decimated by relentless hunting and habitat encroachment in much of their original range (see, for example, Manlius 2001). Nubian Ibexes in Africa exist mainly as small isolated populations in the Eastern Desert and Red Sea Mts of Egypt, and in the Red Sea hills of Sudan.

Locations of confirmed recent occurrences in Egypt's Eastern Desert include: Gebel Ataq, Gebel El Galâla El Bahariya (North Galala Plateau), and Gebel El Galâla El Quiblia (South Galala Plateau) (M. Saleh pers. comm.). Nubian Ibexes also occur throughout the Red Sea Mts of Egypt, from Gebel Ghârib in the north to Elba near the Sudan border. Krausman & Shaw (1986) rediscovered a population surviving in the Wadi el Assuti and Wadi Habib, where ibexes had not been seen since 1927. Recent records in Egypt's Sinai Peninsula are from Gebel El Maghara, Gebel El Halal and Gebel Yalag in N Sinai, the Gebel El Tih in C Sinai and at many sites in the mountains of S Sinai (Saleh & Basuony 1998). Manlius (2001) provides a detailed discussion of the historical ecology and biogeography of the Nubian Ibex in Egypt from 1800 to the present day.

In Sudan, small Nubian Ibex populations were observed around Erkowit, Jebel Ashat and Jebel Sherik Gebel during a 1990 survey (Nimir 1997), and the species likely occurs elsewhere in the country's Red Sea hills as far north as the Gebel Elba (Nimir 1997, I.M. Hashim pers. comm.).

No confirmed recent records are available for Eritrea, where the species had been recorded near the Sudan border (Hillman & Yohannes 1997, D. Zinner pers. comm.). Nubian Ibexes had been reported in

Lateral, palatal and dorsal views of skull of female Nubian Ibex *Capra nubiana*.

extreme N Ethiopia (Yalden *et al.* 1984), but the only recent record is an unconfirmed report from the Tendaho Estates area in EC Ethiopia near the Djibouti border (Hillman *et al.* 1997).

Extralimital to Africa, Nubian Ibexes occur in Israel, Jordan, Oman, Yemen and Saudi Arabia, but are now extinct in Lebanon and Syria (Shackleton 1997, and chapters therein; Grubb 2005).

Habitat Mountains, cliffs, hills and associated plateaux, canyons and wadis. Supports arid and semi-arid vegetation, including annual forbs and grasses dependent on seasonal rainfall, geophytes, woody shrubs and stands of *Acacia*, *Populus* and *Pistacia* trees. Dense herbaceous vegetation at runoff sites and springs are important foraging habitat. Steep slopes provide vital escape cover, especially for ♀♀ and young (Kohlmann *et al.* 1996). Springs or other open freshwater are essential. Human pressures force Nubian Ibexes to remote and inaccessible locations, and livestock grazing degrades foraging and watering sites (Alados & Shackleton 1997).

Abundance Recent African records are from opportunistic observations by biologists (e.g. Krausman & Shaw 1986) and reports by local inhabitants. Three populations in Sinai comprised 300–400 animals in the 1970s (Baharav & Meiboom 1981). About 200 Nubian Ibexes inhabit the Gebel El Galâla El Bahariya Plateau (M. Saleh pers. comm.), and small groups are reported elsewhere in E Egypt (Amer 1997). Numbers in Egypt appear stable (M. Saleh pers. comm.). Isolated bands exist in the Red Sea hills of Sudan, but populations may be declining (Nimir 1997, I.M. Hashim pers. comm.).

Adaptations A stocky body, short legs and exceptional equilibrium enable Nubian Ibexes to negotiate rugged terrain. Wide

hooves with large flexible pads may promote stability on narrow ledges and absorb shock when they jump. They respond to threats by rapidly scaling or descending steep slopes, and routinely use narrow, precarious trails. They have excellent distance vision, and group living enhances vigilance (D. Saltz pers. comm.). Their pelage is very cryptic in most desert habitats. Nubian Ibexes lack strong physiological adaptations for water conservation or thermoregulation. They obtain preformed water from plants, but require non-saline drinking water (Shkolnik *et al.* 1979). During hot summers, Nubian Ibexes are active during early morning and dusk. They avoid activity, and seek shade, during mid-day (Baharav & Meiboom 1982), and may also forage at night. In cool winters they shift their daily activity to sunlit slopes, and are active longer during the day. Nubian Ibexes have a low basal metabolic rate, perhaps reducing their energy requirements in arid environments (Chosniak *et al.* 1984).

Foraging and Food Nubian Ibexes consume a wide array of herbaceous and woody plants. Specific diet varies by locality and season. Woody browse consumed in Egypt included *Acacia raddiana*, *Lindenbergia sinaica*, *Lycium shawii*, *Capparis spinosa* and *Ficus pseudosycamoros* (Osborn & Helmy 1980). Herbaceous species eaten were *Phragmites australis*, *Imperata cylindrica*, *Juncus rigida*, *Alhagi manifera* and excavated roots of *Lotus arabicus*. In Sinai, important perennial plant foods in winter were: *Globularia arabica*, *Helianthus lipii*, *Ephedra foliata*, *Zilla spinosa*, *Thymus decussatus*, *Gymnocarpus decander* and *Echinops glaberrimus* (Baharav & Meiboom 1982). Protected Nubian Ibex populations have eaten landscape plantings and agricultural crops in Israel (Hakham & Ritte 1993).

In the Negev Desert, mature ♂♂ relied on low-quality fibrous browse during most of the year (Gross 1991). They took large bites, and had high intake rates and long rumination bouts (Gross *et al.* 1995b, 1996, S. Kohlmann pers. comm.). By contrast, the smaller ♀♀ and young ♂♂ sought higher quality, but scarcer, herbaceous forage throughout the year. Smaller animals chewed food thoroughly, and spent more time actively foraging than did the large ♂♂.

Social and Reproductive Behaviour Nubian Ibex are highly social (Habibi 1994, Gross *et al.* 1995a), typically occurring in female-based bands that include young and male juveniles to three years of age. Mature ♂♂ more than seven years of age represent a second group type, while ♂♂ 4–6 years old may form more transitory associations of six or more individuals. In a protected Negev population, adult ♀♀ maintained a stable linear dominance hierarchy throughout the year (Greenberg-Cohen *et al.* 1994), and female-based groups averaged more than 20 individuals (Gross *et al.* 1995a). Nubian Ibex bands are significantly smaller in the face of intense hunting pressure and habitat degradation. In hunted Egyptian and Saudi Arabian populations, groups averaged less than six animals (Osborn & Helmy 1980, Habibi & Grainger 1990).

Mature ♂♂ disperse in late summer, and may travel long distances to join female groups during the 6–8 week autumn rut. A travel corridor between Israel populations used by breeding ♂♂ was ≥60 km long (Shkedy & Saltz 2000). They court ♀♀ using characteristic approach behaviour, with neck outstretched, tail-up and displaying flehmen (Habibi 1994). Unreceptive ♀♀ ignore, threaten or flee persistent suitors. Younger ♂♂ also court ♀♀, but are easily displaced by mature ♂♂. Closely-matched breeding ♂♂

engage in dramatic horn clashes in which winning ♂♂ often attain higher elevations to increase the downward force of their attack (S. E. Kohlmann pers. comm.).

Neonates remain hidden for about a week after birth, and then follow their mothers who rejoin female-based groups. Kids are adept climbers and gambol and play in precarious sites. In protected populations, Nubian Ibexes have formed temporary nurseries of many young associated with only few ♀♀ (Hakham 1985, Levy & Bernadsky 1991). Young have been confined for several days or more in a natural topographical ‘trap’ in which they were visited by their mothers until they managed to escape (Müller *et al.* 1995).

Reproduction and Population Structure Females breed by two years of age. Following a 20-week gestation period, they give birth in spring (Mar–Apr) to one or two offspring at secluded sites in rough terrain. Nubian Ibexes are short-lived, rarely exceeding 12 years of age in the wild, even in protected populations (P. Alkon pers. obs.). Sex ratios at birth are even, but adult ♀♀ usually outnumber ♂♂ (Habibi 1994). Annual fluctuations in protected populations are probably regulated by yearly changes in environmental conditions as well as density-dependent mechanisms (Alkon & Kohlmann 1990). The dispersion of breeding ♂♂ among distant female-based groups during the rut (Shkedy & Saltz 2000) may promote high genetic diversity in protected populations (Stuwe *et al.* 1992).

Predators, Parasites and Diseases On the African continent the only likely predator is the Leopard *Panthera pardus*, although, on the Arabian Peninsula, Grey Wolves *Canis lupus* may occasionally prey on them (Harrison & Bates 1991, G. Ilani pers. comm.). Attacks by large raptors are rare. Parasites of wild Nubian Ibexes include nematode lungworms, coccidia and arthropods (Solomon *et al.* 1996, Yeruham *et al.* 1999). Captive animals have succumbed to sarcoptic mange (Yeruham *et al.* 1996).

Conservation IUCN Category: Vulnerable C1+2a(i). CITES: Appendix II.

The main threats to the Nubian Ibex include competition with livestock and camels in Egypt, where the availability and distribution of waterholes is likely to be a major factor in the condition of populations (Amer 1997). Hunting is also a threat in Egypt and Sudan (Amer 1997, Nimir 1997), and is implicated in the disappearance of this species from some parts of its range in Egypt (Manlius 2001).

Egypt and Sudan have enacted protective wildlife laws and established wildlife reserves, but resources for surveys and enforcement are limited. Armed conflicts also have disrupted conservation measures in parts of north-east Africa. In Egypt, Nubian Ibexes are legally protected and their hunting is totally forbidden under articles of the Agricultural Law. Nature Reserves in which they occur are Gebel Elba Conservation Area (disputed Sudan Government Administration area) and the Wadi el Assuti in the Eastern Desert, and Gebel Mûsa and Gabel Katerîna Wildlife Reserve in south central Sinai (Amer 1997). Nubian Ibexes appear to have maintained their number and range in Egypt over the past several decades (M. Saleh pers. comm.). In Sudan, Nubian Ibexes are a Schedule II species under the Wildlife Conservation Act. Hunting was banned between 1989 and 1992, since when the ban has been lifted and animals can be hunted under special permit (Nimir 1997).

Protected areas in which they occur include Tokar G. R., Sinkat-Erkawit Game Sanctuary and Erkawit Game Sanctuary, totalling 829,500 ha. No hunting of wildlife has been recently permitted in Eritrea. The Yob Wildlife Reserve (2658 km²) along the Sudanese border encompasses past Nubian Ibex range in that country (Hillman & Yohannes 1997).

Future conservation measures should include placing the Nubian Ibex on Schedule I of the Wildlife Conservation Act in Sudan to ensure full protection (Nimir 1997), government control of the area that includes the Wadi el Assuti and its junction with the Wadi Habib (one of the few places outside the Sinai where good numbers of Nubian Ibexes survive) and making Gebel Elba a National Park (requiring cooperation between Egyptian and Sudanese governments) (Amer 1997, Nimir 1997). Nubian Ibexes respond strongly to effective protection, which bodes well for future conservation measures (Habibi 1994, 1997, Alkon 1997, M. Saleh pers. comm.). Within a generation, newly protected Nubian Ibexes reduced flight distances from humans, returned to abandoned range and formed larger groups. The largest extant Nubian Ibex populations (≥ 1600 animals) are in Israel, where they are very tolerant of humans following four decades of protection.

Measurements

Capra nubiana

HB ($\sigma \sigma$): 1370 (1190–1590) mm, n = 20

HB ($\phi \phi$): 1092 (920–1210) mm, n = 25

T ($\sigma \sigma$): 116 (80–170) mm, n = 20

T ($\phi \phi$): 91 (65–160) mm, n = 27

HF c.u. ($\sigma \sigma$): 290 (260–390) mm, n = 13

HF c.u. ($\phi \phi$): 272 (240–300) mm, n = 20

E ($\sigma \sigma$): 168 (135–200) mm, n = 20

E ($\phi \phi$): 153 (130–175) mm, n = 28

WT ($\sigma \sigma$): 64.2 (42.0–85.0) kg, n = 16

WT ($\phi \phi$): 31.4 (25.0–39.5) kg, n = 30

Negev Desert, Israel (P. U. Alkon *et al.* unpubl.); ages of all $\sigma \sigma \geq 4$ years, and all $\phi \phi \geq 3$ years

Maximum recorded horn length is 138.4 cm for an animal from Khartoum Zoo in Sudan (Rowland Ward)

Philip U. Alkon

Capra walie WALIA IBEX (ETHIOPIAN IBEX)

Fr. Bouquetin d'Ethiopie (Le Wali); Ger. Aethiopischer Steinbock (Walia-Steinbock)

Capra walie Rüppell, 1835. Neue Wirbelt. Fauna Abyssin. Gehörig, Säugeth. 1: 16; 40 pp, 14 pl. 'die höchsten felsigten Gebirge Abyssiniens ... in den Provinzen Simen und Godjam'; restricted to Ethiopia, mountains of Simien (Lydekker 1913: 156).

Walia Ibex *Capra walie*.

walie, *wali*. Chromosome number: not known, but probably $2n = 60$, as for other karyotyped *Capra* species.

Description Mid-sized ungulate of robust build with outstanding rock-climbing abilities. Less massive and sleeker than the Alpine *Capra ibex* and the Siberian Ibex *Capra sibirica*, but stouter and heavier than its more elegant northern neighbour, the Nubian Ibex *Capra nubiana*. Back and upper body chestnut-brown, the chin, throat, belly and the inner surfaces of the legs whitish for both sexes. A black stripe extends down the front of each leg, a white band just above the knee cuts across the black stripe on the forelegs. This black and white pattern is less pronounced in young $\sigma \sigma$ and $\phi \phi$ than it is in $\sigma \sigma$ aged three years or older. Males aged 4–6 years have small beards, which turn into long beards from about the seventh year, at which age their chest darkens and the black streak on their back becomes more pronounced. Females and young $\sigma \sigma$ do not have beards (Nievergelt 1981, Nievergelt *et al.* 1998). Adult $\sigma \sigma$ are larger than $\phi \phi$ and have semi-circular, massive horns with transverse knobs on the front. Females have small and slightly curved horns.

Geographic Variation None recorded.

Similar Species

Capra nubiana. Occurs in Egypt, Sudan and W Eritrea, extending into the Near East and the Arabian Peninsula. Slender and smaller, dominant colour of coat bright and sandy, and horns of $\sigma \sigma$ thinner and more curved.

Taxonomy Monotypic. Originally named as a species (Rüppell 1835, Lydekker 1913, Harper 1945), it has been considered a subspecies of *Capra ibex* (Haltenorth 1963, Schaller 1977) and of *Capra nubiana* (Heptner *et al.* 1961). Now usually treated as a distinct species (Ansell 1972, Yalden & Lagen 1992, Grubb 1993c, 2005), which appears to be supported by genetic data that reveal that the differentiation between *C. walie* and *C. nubiana* is similar to the differentiation observed between the Alpine Ibex *C. ibex* and the Spanish Ibex *C. pyrenaica* (Gebremedhin *et al.* 2009). Synonyms: *wali*,

Distribution Endemic to Ethiopia. The Walia Ibex is found only in and around Simien Mountains N. P. in the North Gonder Administrative Zone of NW Ethiopia. As far as historical records go, its range seems to have always been very restricted and the total population remains small and vulnerable (Nievergelt 1981, Yalden & Lagen 1992, Hillman *et al.* 1997). Considering available records and looking at the topographic and climatic features of the heterogeneous and often fractured country, it may be assumed that the extremely deep and arid lowland-channel with the Tekeze R. is a natural border in the north and east. In the north-west, west and south, Walias probably occurred in the spurs of high Simien, ranging from Adi Arkay towards Debarq and perhaps Dabat.

Habitat The Simien Mts are remarkable for the impressive escarpments that separate the hilly high plateaux from the terraced lowlands, the original flora of which is a dense and diverse mountain forest with species such as *Juniperus procera*, *Olea africana*, *Syzygium guineense* up to roughly 3000–3200 m. An ericaceous belt dominated by the tree heather *Erica arborea* and St John's Wort *Hypericum revolutum* occurs at 3200–3800 m, and the whole of the vegetation above the timberline consists of afroalpine grassland with the megaphytic *Lobelia rhynchopetalum*. Inatye Mountain within the National Park reaches 4070 m, and the adjoining mountains Bwahit and Ras Dejen are 4430 and 4543 m, respectively. Seasonal changes in vegetation are determined by the wet season, from Jun until Sep/Oct, but variations in diurnal temperature exceed by far the variations entailed by seasonal changes.

Today, farmers have turned a large part of the original vegetation of the lowlands into terraced fields (Klötzli 1977, Nievergelt 1981, Hurni 1982, 1986, Nievergelt *et al.* 1998, Hurni & Ludi 2000) and livestock have also encroached into the forest. The higher escarpments and plateaux are intensively used as pasture for cows, sheep, goats and horses but they are too cold for agriculture.

The steep and rocky areas in the alpine and ericaceous belts along the escarpment as well as the mountain forest belt are the main habitat of the Walia Ibex. War in this region gave rise to indiscriminate hunting mainly in the western parts of the National Park, and the Walias adapted to living and ranging in adjoining habitats as well. There is reasonable evidence to suggest that Walias not only found refuge among rocks and in the denser mountain forest in lower altitudes, but that most animals of the small population moved into the escarpment towards the slightly higher and less disturbed eastern region (although it lies outside the National Park). The areas south of Bwahit Mountain were the main retreat during this critical period. They included parts of the escarpment, but also cliffs, steep slopes with almost no forests and an extensive high plateau, where the alpine steppe is so scarce that there is almost no competition from livestock. The use of flat, plateau-like areas as feeding grounds is rather untypical for most ibexes, but its use by the Nubian Ibex has been observed. This habitat preference of the Walias in the Bwahit area indicates that rich alpine steppe on the slightly lower plateaux within the National Park are suitable Walia Ibex habitat, too, provided there is no disturbance by man or livestock (Nievergelt 2012).

Abundance The population size of Walia Ibex numbered 150–300 animals between 1966 and 1969, increasing slowly until 1983 when there were possibly more than 500 animals, and then decreasing again during the period of civil unrest during the early 1990s. In 1994 and 1996, the population was estimated at 200–250 animals, but it subsequently increased, reaching about 500 animals in 2004 (Nievergelt 2012). The earlier recovery of the population after 1971 can be regarded as a positive response to the introduction of an effective control system with several outposts of game wardens. Along with this recovery, the animals slowly became less shy, and were even seen in habitats close to footpaths. In addition, a notably higher proportion of older ♂♂ was observed. After the war the animals became extremely shy again, hiding in naturally well-protected places (Hillman *et al.* 1997, Nievergelt *et al.* 1998). The more recent recovery took place exclusively in the eastern corner of the National Park, the Chennek area, and was even more pronounced in the adjoining Bwahit–Mesarerya–Digowa range outside the National Park (Ludi 2005, 2006) where, in the 1960s and 70s, no Walias could be observed at all. The most recent estimate (2009) puts the total population at ca. 750 animals (Alemayeh *et al.* 2011).

Adaptations As with all members of the genus *Capra*, the Walia Ibex is an outstanding rock-climber with strong and relatively short legs; it is more sure-footed than almost any other African ungulate, and moves safely up and down sheer cliffs. The ♀♀ give birth in extremely inaccessible places and the young learn to climb immediately. The characteristic afroalpine climate requires adaptation to cold, but this regime is also the basis of rich pastures and – between roughly 2300 and 2700 m – the dense and protective evergreen montane forest. The diurnal activity pattern shows a peak of foraging and social activities in the morning and again towards the evening.

Foraging and Food The diet of the Walia Ibex includes a great variety of herbaceous and woody plants (Dunbar 1978, Nievergelt

1981). Among the abundant trees and shrubs dietary staples include *Erica arborea* (twigs) and *Lobelia rhynchopetalum*, but they seem to be partial to a number of green herbs, such as *Simenia acaulis*, *Alchemilla rothii*, *Arabis alpina*, *Swertia* sp. and *Scabiosa columbaria*. There is little evidence of them foraging on members of the family Papilionaceae, and no reports of them foraging on Labiatae. Most herbs are foraged mainly around their respective flowering seasons. According to direct observation, fresh plants were usually selected by ♂♂ at the beginning of their flowering period, while ♀♀ favoured them at the end of this period when the plants produce highly nutritious fruits.

Social and Reproductive Behaviour Like other ibexes, Walias are highly social animals (Dunbar & Dunbar 1974b, 1981, Nievergelt 1974, 1981). They have varied social units, such as female-based groups that include young and juvenile ♂♂ until they are about two or three years, groups of adult ♂♂ and mixed groups. As can be expected from the low density, most groups are relatively small. In earlier studies, the largest group recorded included 24 animals (♀♀ and young, including ♂♂ up to three years); in 2004, in the open area east of the National Park borders, a herd of 54 Walias was observed (Ludi 2006).

Sexual segregation is pronounced, mostly during parturition and lactation. In keeping with the rutting peak (see below), the highest occurrence of mixed groups can be observed from Mar to May. The clear rank order amongst ♂♂ correlates closely with their age, body size and horn length. The linear dominance hierarchy observed in several *Capra* species can be expected in Walia ♀♀ as well. Open groups and established hierarchies give the social system its structure. Individuals are occasionally involved in fights or play-fights if the sparring partner is of similar age or rank. It is remarkable that quite a number of fights were observed between ♀♀ and ♂♂ of one or two years, when the ♂♂ attain or surpass the body weight of adult ♀♀ and start to leave the female-based groups. As has been observed in other ibexes, there seems to be no sign of territoriality. Based on seven individually known animals it is presumed that individuals or small groups usually remain for several months in areas of less than 0.5 km², but adult ♂♂ often range in larger areas.

Courting ♂♂ lower their horns while approaching receptive ♀♀, and display flehmen, lifting their tail into an almost horizontal position. Newborns stand within the first hours after birth, and follow their mother closely. Within the female-based groups, the young remain in close contact with their mothers.

Reproduction and Population Structure In contrast to the ibex species living in temperate latitudes, where winter dictates a discrete annual reproductive cycle, rutting behaviour and newborns can be observed throughout the year. However, there is a clear rutting peak between Mar and May, and, in keeping with the gestation period of five months, births peak accordingly after the wet season in Sep/Oct. Older ibexes, both ♂♂ and ♀♀, have a more synchronized cycle. Although ♀♀ could well be both fertile and sexually receptive earlier, ♀♀ younger than four years of age are only exceptionally observed with a newborn (Nievergelt 1972). This late breeding corresponds to the slow growing process of this mountain ungulate. Data on life expectancy are lacking. Based on findings concerning other caprines (Geist 1971, Nievergelt 1966),

and the examination of horns, the maximum age in the wild was estimated to be around 15 years.

Predators, Parasites and Diseases Leopards *Panthera pardus* and Spotted Hyenas *Crocuta crocuta* are potential resident predators, but there have been no direct reports of attacks by these animals. A number of direct observations indicate that numerous large birds of prey such as Verreaux's Eagle *Aquila verreauxii*, Tawny Eagle *A. rapax* and Martial Eagle *Polemaetus bellicosus* may take young (Nievergelt 1974). In samples of faeces the following intestinal parasites have been identified: *Trichostrongyloides* spp., *Nematodirus* spp., *Strongyloides* spp., *Trichuris* spp. and *Bunostomum* spp. The samples were collected after the reported death of five Walias, with symptoms of diarrhoea, in the eastern part of the range and at the end of the wet season in 2004 (Berhanu Gebre *et al.* 2004).

Conservation IUCN Category: Endangered B1ab(iii), D. CITES: Not listed.

Walia Ibexes are protected by Ethiopian law, and cannot be hunted except under a Special Permit for Hunting Game Animals for Scientific Purposes. The species has survived a period of war, and the main current threats to it now are posed by human and livestock pressure on the habitats in and around Simien Mountains N. P. (13,600 ha). The latter was gazetted by the Simen National Park Order No. 59 (1969) and has been a World Heritage Site since 1978 (when most of the people living in the lowland areas where resettled outside). The Park is administered by the Parks and Wildlife Administration Authority of the Regional Government, and has attracted increasing international attention since the World Heritage Committee placed the Park on the List of World Heritage in Danger in 1996 because of decline in the population of the Walia Ibex due to human settlement (most of the people resettled outside of the park in 1978 have returned once again and now reside either within or outside the Park), grazing and cultivation. Walia Ibexes are excluded by cultivation of the lowland terraces right up to the timberline and are further displaced by the practice of allowing domestic animals to graze at the higher altitudes. Despite the existence of national and regional legislation, the remoteness of the area, coupled with the existence of people living within and outside of the Park prior to its establishment as a Conservation Area, makes legislation difficult to enforce. Only the sheer inaccessibility of major parts of its habitat has protected the Walia from total extinction. Proposed conservation measures include: (1) extend the National Park area towards the Bwahit region so as to establish a buffer zone and increase the effective area of the Park with natural movement corridors along the escarpment range (as proposed by Hurni 1986); (2) reduce human and livestock impact in the National Park; (3) prohibit all hunting within the Park and enforce regulations effectively; (4) exclude all possibility of hybridization by prohibiting free-ranging domestic goats from the area; (5) initiate a captive-breeding programme to reduce the risk of extinction (there currently are no Walia Ibexes in captivity anywhere in the world); and (6) establish a monitoring programme that includes systematic assessment of conservation measures (Brown 1969b, Hurni 1986, Hillman *et al.* 1997, Shackleton 1997, Nievergelt *et al.* 1998).

The Walia Ibex is used by the Ethiopian Wildlife Conservation Organization (EWCO) and the Ethiopian Wildlife and Natural

History Society (EWNHS) as their emblem, and frequently features elsewhere in other Ethiopian symbolism (including the national football team, who are nicknamed ‘The Walya Antelopes’).

Measurements

No reliable body measurements are available, although Haltenorth & Diller (1980) report measures as: HB: 1500–1700 mm; T: 200–250 mm; Sh. ht (♂♂): 1000–1100 mm; Sh. ht (♀♀): 900–1000 mm; and WT (♂♂): 100–125 kg; WT (♀♀): 80–100 kg

Maximum recorded horn length is 118.1 cm for a pair of horns from Ethiopia (Rowland Ward)

Key References Dunbar & Dunbar 1974b, 1981; Hillman *et al.* 1997; Nievergelt 1972, 1974, 1981; Nievergelt *et al.* 1998.

Bernhard Nievergelt

Glossary

abbrev. = abbreviation

adj. = adjective

cf. = *confer*, compare with; as opposed to

Lat. = Latin

n. = noun

pl. = plural

q.v. = *quod vide*, 'which see'

v. = verb

acetabulum: the concave socket (fossa) in the pelvic bone in which the head of the femur articulates.

acrocentric: describes a chromosome that has the centromere (*q.v.*) very near one end and that therefore appears to have only one arm (= telocentric (*q.v.*) for practical purposes).

ad libitum: (*Lat.*) as much as one likes; having unrestricted access to a resource (e.g. water or food).

aestivate: state of torpor (*q.v.*) induced by cold or drought; usually associated with a reduced metabolic rate and inactivity.

aFN: the total number of chromosomal arms in the autosomal chromosome complement of a species (*cf.* fundamental number [FN], which includes the chromosomal arms of the sex chromosomes as well as those of the autosomal (*q.v.*) chromosomes). Each metacentric (*q.v.*), submetacentric (*q.v.*) or subtelocentric (*q.v.*) chromosome is given a value of 2; each acrocentric (*q.v.*) chromosome is given a value of 1. *See also* fundamental number.

afroalpine: describes habitats and/or vegetation occurring above the treeline on African mountains. Includes montane grassland and heathlands.

afromontane: refers to mountainous regions in Africa, e.g. afromontane forests and afromontane grasslands.

agouti: having an even mixture of pale- and dark-tipped hairs on the pelage creating a grizzled, speckled or 'pepper and salt' appearance.

Albertine Rift Valley: *see* Rift Valley (*q.v.*).

alisphenoid: bone in the skull.

Allee effect: a scenario in which populations at low numbers are affected by a positive relationship between population growth rate and density, which increases their likelihood of extinction.

allele: an alternative form of a gene. A diploid organism carries two alleles (which may be same or different) for each gene locus. At any one locus, there may be several possible alleles (although only two are present in a single organism).

Allelomimetic behaviour: behaviour in social animals in which each animal does the same thing as those nearby.

Allen's Rule: A rule that states that structures in endotherms such as limbs (which are more prone to heat loss) are reduced in size by means of natural selection over time in cooler climates (to reduce heat loss).

allogrooming: grooming behaviour directed at another individual. *cf.* autogroom (*q.v.*).

allomothering: non-parental mothering; caring for young by individuals (male or female) that are not the parents of the young.

allopatry (*adj.* **allopatric**): the situation where populations of the same or different species have non-overlapping geographic ranges; refers also to populations of the same, or different, species that are geographically separated. *cf.* sympatry (*q.v.*); syntopy (*q.v.*).

allozyme: one of a number of forms of the same enzyme having different electrophoretic properties and that are encoded by alternate alleles at the same genetic locus.

altimontane: collective term for the belts of ericaceous and afroalpine vegetation on the high mountains of tropical East Africa (White 1983).

altricial: describes young born in an undeveloped state. *cf.* precocious (*q.v.*).

altruism: behaviour that enhances the reproductive and genetic fitness of another individual at the expense of its own.

alveolus (*pl.* **alveoli**, *adj.* **alveolar**): small cavity; socket that houses the root of a tooth.

angular process: process at the posterior lower corner of the mandible; situated ventral to the coronoid process (*q.v.*).

ante-orbital (= **anteorbital**): in front of the orbit (*q.v.*).

antebrachial: anterior to the arm (forelimb).

anterior palatal foramina: the two foramina (*q.v.*) on the ventral part of the skull.

apomorphy (*adj.* **apomorphic**): situation in which a novel character evolves from a pre-existing character. In cladistics (*q.v.*), an apomorphic character shared among two or more species (synapomorphy [*q.v.*]) indicates shared descent from a common ancestor and hence monophyly (*q.v.*). *cf.* plesiomorphy (*q.v.*).

arboreal: living above the ground (in trees and shrubs). *cf.* scansorial (*q.v.*); terrestrial (*q.v.*).

auditory bulla: *see* tympanic bulla.

auditory meatus (*pl.* **auditory meati**): the external opening of the ear; the passage leading from the tympanic membrane (ear drum) to the external ear.

autapomorphy: derived trait uniquely characteristic of a taxon.

autogroom: grooming behaviour in which an individual grooms itself. *cf.* allogroom (*q.v.*).

autosomal: pertaining to any chromosome other than the sex chromosomes.

bachelor herd: a herd comprised entirely of males, usually mature, but of mixed age.

baculum (*pl.* **bacula**, *adj.* **bacular**): the os penis, or penis bone, which supports the penis in some mammals.

bai (*pl.* **bais**): an opening or clearing.

basal metabolic rate: metabolic rate required for survival in the thermal neutral zone (*q.v.*); a state that requires the lowest expenditure of energy when at rest.

basicranium: the base of the skull.

basisphenoid: cranial bone in middle of base of skull; the median posterior part of the sphenoid bone, forming part of the floor of the braincase.

Bergmann's Rule: The theory that the size of a warm-blooded animal in a single, closely related, evolutionary line, increases along a gradient from warm to cold temperatures.

bicuspid: having two points or cusps (particularly of teeth).

bifid: divided by a shallow notch.

bilophodont: describes cheekteeth having two transverse ridges.

bipedal: body supported by the two hindlimbs; movement not using the forelimbs.

blastula: a hollow ball of undifferentiated cells (derived from a fertilized ovum by cell division), which represents one of the earliest stages of embryonic development.

BP: (*abbrev.*) before the present.

brachydont: describes a premolar or molar tooth with low crowns. *cf.* hypsodont (*q.v.*).

braincase (= cranium): that part of the skull housing the brain; the part of the skull posterior to the front line of the orbits. *cf.* rostrum (*q.v.*).

buccal: On the cheek side of the mouth or teeth or penetrating to the cheek or sometimes used broadly as pertaining to the cavity of the mouth.

bullae: *see* tympanic bullae.

bunodont: describes molar teeth, entirely covered by enamel, that have low, rounded, hill-like cusps (as opposed to sharp, pointed cusps). (*cf.* hypsodont, lophodont).

bushmeat: meat for human consumption derived from non-domesticated mammals, birds and reptiles taken from their natural habitats and domiciles.

bushveld: savanna vegetation type characterized by a grassy ground layer and a moderately dense upper layer of shrubs and scattered trees.

BZ: (*abbrev.*) Biotic Zone.

C or c: (*abbrev.*) canine tooth; upper case denotes adult dentition, lower case denotes deciduous dentition (milk teeth). *See also* canine.

c.u.: (*abbrev.*) (*Lat. cum unguis* = with nail) measurement of the hindfoot when length of the nail on the claw is included in the measurement. Usually hindfoot is measured without the claw because claws may be broken or worn. When length of claw is included, it is conventional to record as 'HF c.u.'. *cf.* s.u. (*q.v.*)

caecum (pl. caeca): a blind-ending pouch in the alimentary canal (often enlarged as a fermentation chamber) located at the junction of the small and large intestines.

canine: the most anterior tooth on the maxilla bone and in a similar position on the mandible; situated immediately posterior to the incisors; if incisors are absent, the most anterior tooth in the jaw. Unicuspid; tall and pointed in most mammals. Never more than one canine on each side of each upper and lower jaw; absent in some taxa.

caniniform: having shape and appearance of a canine tooth.

carnassial shear: Found in some carnivores and formed by the blade-like cusps of the fourth upper premolar teeth and first lower molar teeth, which, occluding together like the blades of a pair of scissors, provide a shearing action for cutting through tough skin or bone. Sometimes referred to as the carnassials.

carotid: pertaining to the carotid artery located in the front of the neck through which blood from the heart flows to the brain.

cauda epididymides: the ducts of the epididymides at the posterior end of the testes that carry sperm from the testes to the vas deferens, which, in turn, carries sperm to the penis. Sometimes used to store sperm prior to copulation.

caudal: pertaining to the tail; in the direction of the tail.

Cenozoic (= Cenozoic Era): geological era, ca. 65 mya to today, comprising the Quaternary and Tertiary Periods: the Age of Mammals.

central Africa: Cameroon (south of the Sanaga R.), Central African Republic (but only south of ca. 7° N), Equatorial Guinea, Gabon, DR Congo (except SE). Mainly rainforest habitats and rainforest–savanna mosaics.

centromere: the part of a chromosome where sister chromatids are linked together during mitosis.

cerebellum: the part of the hindbrain that controls and coordinates motor movements, posture, balance and muscle tone.

cerebrum (= cerebral hemispheres): the anterior part of the brain that is involved in voluntary movements, processing sensory information, olfaction, learning, memory, communication and other functions.

cervical: pertaining to the neck.

cf. (in general usage): compare or compare with. In the context of descriptions, implies a difference or contrast: e.g. 'In *Elephantulus edwardii*, first lower premolar single-rooted (*cf.* *E. myurus* in which the first lower premolar is double-rooted).'

cf. (in taxonomy): precedes the specific name if there is uncertainty in the assignment.

cheekteeth: the premolar (*q.v.*) and molar (*q.v.*) teeth combined.

choana (pl. choanae): the openings of the internal nostrils on the skull, situated immediately posterior to the bony palate.

chromosome: one of the thread-like bodies within the nucleus of a cell, which carry the genes (genetic material) in linear order; each chromosome is composed of one long molecule of DNA (and two long molecules at cell division). Chromosomes occur in pairs (one from each parent) and are visible as rod-like bodies in cells that are dividing. The total number of chromosomes in a cell is expressed as the diploid number (2n).

CI: condyloincisive length; the length of the skull from the anterior end of the longest incisor tooth to the posterior end of the occipital condyles. *cf.* GLS.

cingulum (pl. cingula): ridge around the base of the crown of a tooth.

CITES (abbrev.): Convention on International Trade of Endangered Species of Wild Fauna and Flora; an international treaty set up to ensure that international trade in wild animals and plants does not threaten the survival of species in the wild. It accords varying degrees of protection to more than 33,000 species of animals and plants. Appendix I lists species that are the most endangered among CITES-listed animals and plants. Appendix II lists species that are not necessarily now threatened with extinction but that may become so unless trade is closely controlled. Appendix III is a list of species included at the request of a Party that already regulates trade in the species and that needs the cooperation of other countries to prevent unsustainable or illegal exploitation.

- clade:** branch of a phylogenetic tree containing the set of all organisms descended from a common ancestor.
- cladistic (analysis):** a methodology that provides a classification in which organisms are grouped in terms of the time when they had a common ancestor.
- cline** (*adj.* **clinal**): in context of geographic variation, a gradual and sequential change of a character(s) without a significant break such as would justify division into separate subspecies or species.
- CMS:** Convention on Migratory Species of Wild Animals (also known as the Bonn Convention). An intergovernmental treaty, concluded under the aegis of the United Nations Environment Programme, concerned with the conservation of migratory terrestrial, aquatic and avian migratory species throughout their range. Migratory species threatened with extinction are listed on Appendix I; Migratory species that need or would significantly benefit from international co-operation are listed in Appendix II.
- CNL:** condylo-nasal length; measurement from the most anterior part of the nasal bone to the most posterior part of the occipital condyle (exoccipital) on the same side of the skull; a similar measurement to 'greatest length of skull'.
- cochlea** (*pl.* **cochleae**, *adj.* **cochlear**): a hollow structure, spirally coiled like a snail's shell, situated in the skull and containing the internal organ of hearing.
- competitive exclusion:** the principle that two different species cannot indefinitely occupy the same ecological niche.
- concatenation:** a chain of linked elements.
- concave:** having a curvature that curves inwards; having an outline or a surface curved like the interior of a circle or sphere. *cf.* convex (*q.v.*).
- concavity:** a concave depression in an outline or surface.
- conceptus:** embryo prior to implantation.
- conductance:** in thermal biology, the rate at which heat passes across a temperature gradient, e.g. the density and thickness of the pelage affects the rate at which body heat passes from the body to the outside. Thick pelage, which traps and holds air, results in low thermal conductance.
- condylar process:** process at the posterior upper corner of the mandible, which forms the lower hinge of the jaw articulation; fits into the glenoid fossa (*q.v.*) of the skull.
- condylarth** (*adj.*): as in the Condylarthra, an extinct order of mammals.
- condyle:** a rounded process on a bone that articulates with a socket-like concavity in another bone.
- condylobasal length:** the length of a skull, measured from the anterior points of the premaxilla (*q.v.*) to the posterior surfaces of the occipital condyles (*q.v.*).
- congeneric:** belonging to the same genus.
- conspecific:** belonging the same species. *cf.* heterospecific (*q.v.*).
- contiguous:** touching; sharing a boundary (as in geographic ranges).
- convex:** having a curvature that bulges outwards; having an outline or a surface curved like the exterior of a circle or sphere. *cf.* concave (*q.v.*).
- coprophagy:** the eating of faeces. Includes the eating of an individual's own faeces as they are voided from the anus.
- copulatory plug:** plug formed in the vagina of the female after copulation; formed from seminal fluids of the male. Prevents or reduces the chance of sperm from another male(s) entering the female reproductive tract if the female copulates again soon after copulation with the first male.
- coronoid canal:** a foramen (canal) in the coronoid process (*q.v.*) of the mandible.
- coronoid process:** angular pointed process on the upper margin of the mandible, situated anteriorly to the condylar process (*q.v.*); does not participate in the jaw articulation.
- corpus luteum** (*pl.* **corpora lutea**): a glandular mass of tissue on the surface of an ovary, that develops after the extrusion of an ovum from a Graafian follicle (*q.v.*); secretes the hormone progesterone.
- cotype:** originally synonymous with syntype but now used as synonym of paratype (*q.v.*).
- CR:** (*abbrev.*) *see* crown–rump length.
- cranial profile:** the shape of the cranium (the part of the skull that surrounds the brain) when viewed from the side.
- craniodental:** pertaining to the skull and teeth.
- cranium:** that part of the skull housing the brain. Also called braincase.
- crepuscular:** at, active in, twilight, when light intensity is higher than at night but lower than during the day. *cf.* diurnal (*q.v.*); nocturnal (*q.v.*).
- Cretaceous Period:** period (within the Mesozoic Era); 146–65 mya.
- crown:** (1) top of head; (2) exposed part of a tooth (visible above gum), especially the grinding surface.
- crown–rump length (CR):** distance from the crown of head to the rump of a foetus (i.e. maximum length of a foetus in its natural form).
- cuckolding:** when an intruding male mates with an oestrous female without her mate being aware of the event.
- cursorial:** pertaining to running.
- cuspid** (*adj.* **cuspidate**): a prominence or sharp point, such as on the occlusal surface of some teeth. *See also* t.
- cutaneous:** (*adj.*) pertaining to the skin.
- Cyrenaica:** a region of North-East Libya. Includes the Cyrenaican Plateau and that part of the Mediterranean Coastal Biotic Zone between the plateau and the sea, as well as drier terrain south of the plateau.
- cytochrome b:** a protein involved in electron exchange in the mitochondria. It is the product of a gene in the mitochondrial genome. The sequence of this gene is often compared between species in phylogenetic studies to infer relatedness.
- cytogenetics** (*adj.* **cytogenetic**): the study of the microscopic structure of chromosomes, especially the mapping of genes.
- cytonuclear:** (*adj.*) pertaining to the nucleus and the cytoplasm of a cell.
- Dahomey Gap:** the geographic region where savanna habitat extends southwards to the West African coast in E Ghana, Togo, Benin (formerly Dahomey) and extreme SW Nigeria. The presence of savanna forms a break (or gap) in the extensive Rainforest Biotic Zone, which extends along the West Africa coast from Sierra Leone to Cameroon. The Dahomey Gap is an important biogeographical barrier separating the faunas to the east and west of the Gap.
- deciduous teeth:** *see* milk teeth (*q.v.*).

- Dega:** Ethiopian word for the temperate agricultural/economic altitudinal zone, about 2300–3000 m, warm enough for cereal-based agriculture.
- delayed implantation:** a means of lengthening the interval between copulation and parturition by delaying the implantation of the blastula (*q.v.*), so that both copulation and parturition can occur in the most optimal seasons. Development to blastula stage is followed by a period of halted development lasting several weeks or months; then the blastula implants and embryonic development proceeds normally, usually without any further interruption, until the young is born.
- deme:** a unit of population that is interbreeding and is separate from any other such population.
- dental formula:** a simple numerical method of denoting the number of incisor (I), canine (C), premolar (P) and molar (M) teeth on one side of the upper jaw and lower jaw, and the total number of teeth. For example, the dental formula of a primitive mammal is $I^{3/3}, C^{1/1}, P^{4/4}, M^{3/3} = 44$, which means there are three incisors, one canine, four premolars and three molars on each side of the upper jaw and also the lower jaw, making a total of 44 teeth. The formula may also be expressed in the form $^{3143}/_{3143} = 44$. Each incisor, premolar and molar is numbered according to its position in the tooth row; superscript numbers indicate upper jaw, subscript numbers indicate lower jaw (mandible) e.g. P^4 (upper fourth premolar), M_2 (lower second molar).
- dentine:** the substance, also known as ivory, comprising tusks (*q.v.*) and the interior hard part of vertebrate teeth. Lies under the enamel of teeth (but may be exposed if the enamel wears) and surrounds the pulp chamber and root canals.
- diastema:** space in the mouth between the incisor teeth and cheekteeth in those mammals that feed on grasses, herbs etc. (e.g. rodents, hares, rabbits, ruminants, etc.).
- dichromatism:** condition in which members of a species show one of only two distinct colours or colour-patterns.
- dilambdodont:** molar tooth with W-shaped ridges. *cf.* zalambdodont (*q.v.*).
- dimorphism:** *see* sexual dimorphism.
- diphyly:** the derivation of a taxon from two separate lines of descent. *cf.* monophyly (*q.v.*).
- diploid number (2n):** total number of chromosomes (including sex chromosomes) in a somatic cell of an organism.
- distal:** the end of any structure furthest away from the mid-line of the body or furthest from the point of its attachment. *cf.* proximal (*q.v.*).
- diurnal:** at, active in, daytime; when light intensity is high. *cf.* crepuscular (*q.v.*); nocturnal (*q.v.*).
- DNA hybridization:** technique of comparing the similarity between two DNA molecules by reassociating single strands from each molecule and determining the extent of double-helix formation. In phylogenetics, this technique is used to determine the relatedness of two or more taxa.
- DNA:** (*abbrev.*) deoxyribonucleic acid; the very large self-replicating molecule that carries the genetic information of a chromosome; each molecule is composed of two complementary chains of DNA.
- dorsoventral (dorsoventrally):** from dorsal to ventral surface; from back to belly of an animal.
- E:** (*abbrev.*) length of external (outer) ear (= pinna), measured from tip of ear to the posterior point of the ear conch). Length and shape usually affected by preservation.
- East Africa:** Kenya, Uganda, Rwanda, Burundi and Tanzania.
- eastern Africa:** SE Sudan, Ethiopia, Eritrea, Djibouti, Somalia, Kenya, Uganda, Tanzania, Malawi (but only south of L. Malawi and east of the Shire R. Valley) and Mozambique (but only east of Malawi and north of the Zambezi R.).
- echolocation:** the use of reflected ultrasonic pulses of sound to perceive the surroundings (including obstacles, prey and other animals).
- ecotype:** a genetically distinct geographic variety or population within a species, which is adapted to specific environmental conditions.
- ectoparasite:** a parasite that lives on the exterior of an organism (e.g. ticks, fleas, lice). *cf.* endoparasite (*q.v.*).
- ectotympanic:** a bony element within the middle ear that supports the tympanic membrane or eardrum.
- edaphic:** influenced by conditions of soil or substratum.
- emargination:** a distinct notch or indentation.
- embryo number:** number of foetuses within the uterus or uteri of the female (as assessed by autopsy). Expressed as mean number (with range from minimum to maximum, and sample size). *cf.* litter-size (*q.v.*).
- enamel:** hard material that forms a cap over the dentine component of a tooth; usually the most visible part of a tooth.
- encephalization quotient (EQ):** a measure of comparative brain size or weight defined as the ratio of the actual brain weight to the expected brain weight predicted for an animal of a given body weight.
- endemic:** restricted to, peculiar to, or prevailing in, a specified country or region.
- endoparasite:** a parasite that lives in the interior of an organism (e.g. nematodes, cestodes, blood parasites). *cf.* ectoparasite (*q.v.*).
- entoconid cusp:** the posterior cusp on the lingual (inner) side of a lower molar tooth.
- entotympanic:** an independent ossification found in the floor of the tympanic cavity in various extant and extinct eutherian groups, including, for example, Scandentia, Chiroptera, Dermoptera, Hyracoidea, Pholidota, Xenarthra, Carnivora, and Macroscelidea.
- Eocene:** geological Epoch (within the Tertiary Period); 55–38 mya.
- epiphysis (pl. epiphyses):** any part of a long bone that is formed from a different centre of ossification and that later fuses with the bone to form its terminal part.
- epitympanic recess:** a hollow located on the roof of the middle ear.
- erg:** a large, relatively flat area of desert covered with wind-swept sand with little or no vegetation cover (sometimes referred to as a dune sea).
- evaporative water loss:** the loss of water from the body through the skin and/or the lungs. A mechanism used by mammals to reduce T_b (*q.v.*) when T_a (*q.v.*) is high. Excessive evaporative water loss may lead to dehydration if free (drinking) water is unavailable.
- exfoliating:** shedding flakes (e.g. of bark), or breaking into relatively thin slabs (e.g. of granitic rock).
- exoccipital condyles:** a pair of projections from the occipital bone on either side of the foramen magnum (*q.v.*), which articulate with the first of the spinal vertebrae.

extant: living at the present time. *cf.* extinct.

F. R.: (*abbrev.*) Forest Reserve.

facultative: having the capacity to switch from one mode of life or action to another depending on conditions or circumstances. *cf.* obligate (*q.v.*).

female-defence polygyny: a mating system in which males control access to females directly, usually by virtue of female gregariousness (Emlen & Oring 1977).

fenestra (*pl.* **fenestrae**): opening in a bone, or between two bones.

flank: the side of the body of a mammal.

flehmen: an act performed by many species of mammals whereby an adult male sniffs the vulva and urine of a female to test for oestrus. The head of the male is raised, the nose pointed upwards, the lips retracted and the nose wrinkled. This muscular contraction opens the *ductus incisivus* ensuring that scent molecules reach the Jacobsen's organ for olfactory analysis.

FN: (*abbrev.*) *see* fundamental number.

foliaceous: (*adj.*) resembling the leaf of a plant.

folivore (*adj.* **folivorous**): an animal that eats leaves.

foramen (*pl.* **foramina**): an aperture (which is usually small, round or elliptical) in a bone, or between bones, for the passage of a nerve, blood vessel or muscle.

foramen magnum: the large opening at the posterior end of the skull through which the spinal cord passes.

form: a neutral term for a single individual or taxonomic unit that may be employed without reference to the formal taxonomic hierarchy of categories; one of the varieties found in a polymorphic species.

forest island: *see* relict forest.

fossa (*pl.* **fossae**): a depression or hollow usually in a bone (e.g. glenoid fossa, preorbital fossa)

fossorial: adapted for digging; burrowing. *cf.* subterranean (*q.v.*).

founder effect: the loss of genetic diversity that occurs when a new isolated population is derived from a very small number of individuals.

fovea: small pit or depression.

frontal bone: one of a pair of bones forming the anterior part of the braincase.

frugivorous: fruit-eating.

fundamental number (FN): an ambiguous term sometimes defined as (1) the total number of chromosomal arms in the full chromosomal complement of an organism (i.e. including the sex chromosomes), or (2) the total number of chromosomal arms found in the autosomal chromosomes only (i.e. excluding the sex chromosomes). When only the autosomal chromosomes are included, some authors (but not all) use aFN instead of FN to avoid ambiguity. For further details, *see* aFN.

fusiform: elongated and tapering at both ends.

fybos: the heath shrublands characteristic of the Cape Floristic Kingdom (within the South-West Cape Biotic Zone) of South Africa. Dominant plants are sclerophyllous, evergreen, low (<3 m), bushy and fine-leaved, but there are also scattered taller bushes and, less often, very widely spaced trees. Contains an exceptionally high number of endemic species of plants. The three main components on nutrient-poor sandy soils are species of Ericaceae, Restionaceae and Proteaceae. Also includes 'renosterveld' (*q.v.*) (dominated by species of Asteraceae) on nutrient-rich silt or clay soils.

G. R.: (*abbrev.*) Game Reserve.

gallery forest: type of forest outlier (in a savanna region) found in narrow sheltered valleys and ravines on hillsides, where soils are moist enough, and conditions humid enough, to support rainforest trees (Rosevear 1953).

garrigue: a type of short, Mediterranean shrubland (White 1983).

genetic drift: in population genetics, refers to changes in the frequencies of genes in small, isolated populations that occur with time, as a result of random sampling events as opposed to natural selection.

genotype: genetical term to describe the genetic constitution of an individual inherited from its parents. *cf.* phenotype (*q.v.*).

genus (*pl.* **genera**): taxonomic division superior to species and subordinate to family.

geocarpic: having fruit that mature underground.

geophagy (= **geophagia**): the eating of saline or calcareous soil.

gestation: the development of embryo/foetus, which takes place in the uterus; the period during which this development takes place. The gestation period is defined as the interval between conception and parturition (birth). Strictly speaking, the gestation period is not the interval between copulation (mating) and parturition (birth), although many authors take it to be this interval. The gestation period (*sensu stricto*) may be lengthened by reproductive delays, such as delayed implantation (*q.v.*).

glans penis: the bulbous tip of the penis.

glenoid (= **glenoid fossa**): the cavity (fossa) in the squamosal bone of the skull for the articulation of the condyle of the mandible (lower jaw) in mammals; visible on lateral and/or ventral views of skull depending on the taxon.

GLS: (*abbrev.*) greatest length of skull, measured from anterior end of incisor teeth or nasal bone (whichever is most anterior) to the posterior end of the skull (occiput, occipital condyles or auditory bullae, whichever is most posterior).

Gondwana (= **Gondwanaland**): the southernmost of the two Mesozoic (*q.v.*) supercontinents that later fragmented (as a result of continental drift) into the landmasses of Africa, Madagascar, Antarctica, Australia, South America, the Indian subcontinent and the Arabian peninsula.

Graafian follicle: the structure in the mammalian ovary that contains the developing ovum and from which the ovum is released at the time of ovulation.

gracile: lightly built. *cf.* robust.

graminivore (*adj.* **graminivorous**): feeding on grasses.

granivore (*adj.* **granivorous**): an animal that eats grains and seeds.

graviportal: having limbs adapted to bearing great weights (as in elephants).

gregarious: living together in groups, flocks, herds.

Gregorian Rift Valley: *see* Rift Valley.

guard hair: long thin bristle-like hairs, mainly on the back and flanks that project beyond the soft hairs of the pelage; when present, conspicuous but never as numerous as soft hairs; probably tactile in function.

gular: pertaining to the upper part of the throat (the gula) as in gular gland, gular pouch, gular region.

GWS: (*abbrev.*) greatest width of skull, usually measured across the widest point of the zygomatic arches (*q.v.*).

- haematopoietic** (*n.* **haematopoensis**): pertaining to the formation of blood cells from stem cells.
- hallux**: the first digit of the hindlimb.
- hammada**: flat plain covered with pebbles of various sizes on a hard substrate in an arid environment. Much of the Sahara Desert is formed of hammada.
- haplotype**: the set of alleles borne on one of a pair of homologous chromosomes; a group of genes that is inherited together from a single parent.
- HB**: (*abbrev.*) length of head and body (measured from the tip of the nose to the most posterior point of the pelvis (anterior to the first tail vertebra)).
- hemidiaphragm**: half of the diaphragm, the muscle that separates the chest cavity from the abdomen and that serves as the main muscle of respiration.
- hermaphrodite** (*adj.* **hermaphroditic**): an individual having both male and female reproductive organs.
- heterospecific**: (*adj.*) belonging to different species. *cf.* conspecific (*q.v.*)
- heterothermic**: condition when the body temperature fluctuates in relation to the ambient temperature T_a (*q.v.*). *cf.* homeothermic (*q.v.*).
- heterozygosity**: a measure of the genetic variation in a population, expressed through the presence of different alleles (*q.v.*) at one or more loci on homologous chromosomes.
- HF**: (*abbrev.*) length of hindfoot (measured from the 'ankle bone' to the tip of the longest digit usually without including the claw). *See also* c.u.; s.u.
- hibernaculum** (*pl.* **hibernacula**): a place, domicile or roost where an animal hibernates.
- hibernation**: a state of inactivity accompanied by a reduction in metabolic rate (below basal metabolic rate [*q.v.*]), lower T_b , and slow breathing. Occurs when T_a is low and food is scarce; usually lasts for weeks or months; not common in African mammals (*cf.* torpor).
- high forest**: rainforest that has matured, stabilized and reached the climax stage of succession.
- highveld**: high plateaux characteristic of inland southern Africa, dominated by grasses.
- Holocene**: geological Epoch (within the Quaternary Period) (*q.v.*) following the Pleistocene Epoch (*q.v.*); ca.11,000 mya to today. Sometimes referred to as the 'Recent' Epoch.
- holotype** (= **type**): the single specimen designated or indicated by the original author of the original description of a new species or subspecies, to be the standard reference to the essential characters of the new taxon. *see also* cotype (*q.v.*), lectotype (*q.v.*), neoparatype (*q.v.*), neotype (*q.v.*), paratype (*q.v.*), syntype (*q.v.*), topotype (*q.v.*) and type locality (*q.v.*).
- home-range**: the area (expressed in square metres, or square kilometres) routinely used by an animal for its day-to-day activities and requirements, and that contains the resources required for survival and reproduction. Within the home-range there may be a 'core area' or 'centre of activity' that is utilized more frequently than other parts (e.g. 80% or 90% of known time-based observations). *cf.* territory (*q.v.*).
- homeothermic**: describes an organism having a body temperature that is maintained at a constant level (within limits), independently of the ambient temperature T_a (*q.v.*). For the limits, see upper and lower critical temperatures [*q.v.*]. *cf.* heterothermic (*q.v.*).
- homoplasy**: similarity between different organisms or taxa resulting from evolution along similar lines (e.g. convergent evolution) rather than descent from a common ancestor.
- homozygous** (*n.* homozygosity): describes a diploid organism that has inherited the same allele of any particular gene from each of its parents. *cf.* heterozygous.
- hyoid**: a small bone or bones in the throat located at the base of the tongue and supporting the muscles of the tongue.
- hyperthermia**: elevation of body temperature above normal limits due to increase in T_a (*q.v.*) or increase in metabolic rate. *cf.* hypothermia (*q.v.*).
- hypoconulid**: the most posterior cusp on the lingual (inner) side of a lower molar tooth.
- hypogeal**: living or growing underground.
- hypothermia**: drop in body temperature below normal limits; occurs in some small mammals when T_a (*q.v.*) falls, and is a means of conserving energy in cold weather. *cf.* hyperthermia (*q.v.*).
- hypsodont**: describes a premolar or molar tooth with high crowns; has short roots. *cf.* bunodont, lophodont.
- I or i**: (*abbrev.*) incisor (*q.v.*) tooth or teeth; upper case denotes adult dentition, lower case denotes deciduous dentition (milk teeth). *See also* incisor.
- I.** (*pl.* **Is.**): (*abbrev.*) Island.
- I¹-M³**: (*abbrev.*) the length of the upper toothrow from the anterior end of the first upper incisor to the posterior end of the last molar. In taxa where the last molar is M¹ or M² (instead of M³), the measurement is I¹-M¹ or I¹-M².
- implantation**: the embedding of a blastula (*q.v.*) in the lining of the uterus.
- incertae sedis**: (*Lat.*) refers to a taxon of uncertain status and that is perhaps taxonomically invalid.
- incisive foramen** (*pl.* **foramina**): paired foramina located at the anterior end of the bony palate, just posterior to the incisor teeth.
- incisor**: tooth rooted in the premaxillary bone (most anterior bone of upper jaw) and in an equivalent position in the mandibular bone (lower jaw); always anterior to the canine teeth, if present. The number and form of the incisor teeth varies in different species. *See also* dental formula (*q.v.*).
- infraorbital foramen** (*pl.* **foramina**): foramen that connects the orbit (eye-socket) with the rostrum (premaxilla and maxilla bones); this foramen contains the masseter medialis muscle in some taxa. Also referred to as anteorbital foramen and antorbital foramen.
- infrasonic**: describes sounds with frequencies below the range that can be heard by humans.
- infundibulum**: a funnel-shaped cavity or depression.
- inguinal**: situated in the groin, that is the area between the lower lateral part of the abdomen and the thigh.
- inner**: nearest to mid-line of body, e.g. inner incisor, inner margin of ear.
- insectivore** (*adj.* **insectivorous**): an animal that eats insects.
- inselberg**: isolated rocky hill; term used mainly in western Africa. *See also* jebel (*q.v.*); kopje (*q.v.*), krantz (*q.v.*).
- inter-aural**: between the ears.
- inter-digital**: between the digits (e.g. interdigital gland).

- inter-orbit (= inter-orbital constriction):** narrowest part of the skull between the orbits when viewed dorsally at the level of the frontal bones.
- inter-parietal:** bone (not paired) on dorsal surface of the skull, lying between and partly posterior to the parietal bones.
- inter-pterygoid region:** the region between the two plate-like pterygoid bones (*q.v.*) that form part of the roof of the mouth.
- inter-specific:** between different species.
- intra-specific:** within one species; between members of the same species.
- intromission:** insertion of the penis into the vagina during copulation.
- invagination:** the formation of a cavity by the in-sinking of the outside wall or surface of a tissue or structure, thereby drawing an exterior layer into the interior of the structure to form the lining of the cavity; a cavity formed by the process of invagination.
- Isoptera:** taxonomic order containing the termites (within the phylum Insecta).
- isozyme:** any one of several different forms of an enzyme encoded by the same or different genes and that each differ in properties such as optimum pH or isoelectric point.
- iteroparous:** repeated reproduction throughout a season or a lifetime (*cf.* semelparous – reproduces once and then dies).
- ivory:** *see* dentine.
- jebel (= gebel):** isolated rocky hill in savanna and arid habitats; term used mainly in northern Africa. *See also* inselberg (*q.v.*); kopje (*q.v.*).
- jugal:** bone of the skull that forms the middle part of the zygomatic arch (*q.v.*); anteriorly joins the maxillary process (*q.v.*) of the maxilla bone and posteriorly joins the squamosal process of the squamosal bone.
- K-selection:** selection for characteristics suitable in stable environments (slow development of young, small litter size, relatively long time to maturity, relatively long life span) *cf.* r-selection (*q.v.*).
- Kaokoveld:** area of sandstone and lava hills of the Namib Desert (Biotic Zone 11b) in NW Namibia, inland from the Skeleton Coast.
- Karoo:** southern African term for grassy dwarf shrubland on the semi-arid central plateau of the western half of South Africa at altitudes of 500–2000 m.
- karyogram:** a photographic representation of a karyotype (*q.v.*) as it appears at mitosis. Individual chromosomes are arranged in pairs from largest to smallest.
- karyological:** pertaining to the nucleus and chromosomes.
- karyotype:** the chromosomes in the cell of an animal. *See also* karyogram.
- kloof:** a deep, narrow valley or gorge.
- kopje:** rocky hill with boulders, rock crevices and sparse vegetation; term used mainly in southern Africa. *See also* inselberg (*q.v.*); jebel (*q.v.*); kranz (*q.v.*).
- krantz (pl. krantzes):** a wall of rock encircling a mountain or summit; hence any precipitous or overhanging wall of rocks.
- L.:** (*abbrev.*) Lake.
- labial:** pertaining to the lips; situated near the lips; on the outer side of the teeth within the mouth. *cf.* lingual (*q.v.*).
- labially:** in the direction of the lips. *cf.* linguallly (*q.v.*).
- lachrymal bone:** small bone in skull situated at the upper anterior margin of the orbit, near the lachrymal (tear) gland.
- lambdoid crest:** *see* supraoccipital crest.
- lamina (pl. laminae):** in the context of premolar and molar teeth, a transverse row of cusps (e.g. t1, t2 and t3, or t4, t5 and t6, etc.) that, when worn, form a transverse ridge of bone and dentine across the tooth.
- larynx (= voice box):** the structure in the throat of mammals that produces sound.
- lauschlag:** a courtship behaviour in antelopes in which the male touches the female's underside with a stiff foreleg, placing it either under her flank from the side or between her hind legs from behind. Also termed the mating kick or foreleg kick.
- Laurasia:** the northernmost of the two Mesozoic (*q.v.*) supercontinents that later fragmented (as a result of continental drift) into the landmasses of Europe, Asia (excluding the Indian subcontinent) and North America.
- lectotype:** a specimen chosen from syntypes (*q.v.*) to stand as 'the type' of a species or subspecies when no holotype (*q.v.*) was designated by the author who described the new species or subspecies.
- lek:** a traditional site where males gather for the sole purpose of attracting and courting females, and to which females come for the sole purpose of mating with the male of their choice.
- limiting factor:** the principle that the growth or functioning of an organism is limited when any essential factor (or resource) is lacking or in short supply, regardless of the quantity available of any other factor (or resource). The principle may also be applied to the proliferation and/or distribution of a population or species.
- lingual:** pertaining to the tongue; situated near the tongue; on the inner (tongue) side of the mouth. *cf.* labial (*q.v.*).
- lingually:** in the direction of the tongue. *cf.* labially (*q.v.*).
- litter-size:** number of young born to a female. Expressed as mean number (with range from minimum to maximum, and sample size). *cf.* embryo number (*q.v.*).
- localized movements:** movements of an animal within part or all of its home-range within a single day or within a limited period of time. *cf.* migration (*q.v.*); nomadic movements (*q.v.*).
- longitudinal:** lengthwise; running in a head to tail direction. *cf.* transverse (*q.v.*).
- lophodont:** molar teeth having the crowns formed in transverse crests or ridges (*cf.* bunodont).
- lordosis:** dorsi-flexion of the spine, often performed by females prior to copulation.
- lower critical temperature:** the lowest ambient temperatures at which the animal must increase its metabolic rate to maintain a constant body temperature. If ambient temperature decreases further, and the animal is unable to increase its metabolic rate sufficiently to maintain a constant body temperature, it will enter hypothermia and may eventually die. *cf.* upper critical temperature.
- lowveld:** savanna at lower altitudes below the Great Escarpment of South Africa, with vegetation consisting of a grassy lower layer and a woody upper layer of shrubs and/or trees, at either high density (woodland) or intermediate density (bushveld, *q.v.*).
- lumbar:** describes vertebrae between the thoracic vertebrae and the sacrum; vertebrae of the lower back in humans.

lyrate: having curvature suggestive of a lyre.

M: (*abbrev.*) molar tooth or teeth. *See also* molar (*q.v.*).

Maghreb: *see* North-West Africa (*q.v.*).

malleus: the most external bone of the three ossicles of the middle ear, the handle of which is joined to the ear drum.

mandible: lower jaw.

mandibular ramus: one of the two branches (sides) of the mandible (*q.v.*); the two rami are joined at the mandibular symphysis (*q.v.*).

mandibular symphysis: the junction, marked by a small vertical ridge, where the left and right sides of the mandible are fused.

masseter muscle: one of the muscles that raises the lower jaw, e.g. during chewing. Particularly well developed and powerful in herbivores.

mastoid: one of a pair of bones, often with a prominent process, situated near the posterior end of the skull behind the auditory meatus (*q.v.*).

matriarchal; describes social groups dominated and/or led by a female (often one of the oldest females in the group).

maxilla (*pl. maxillae*): one of the pair of bones in the skull that forms that part of each upper jaw in which the canine (*q.v.*) (if present) and cheekteeth (premolars and molars) (*q.v.*) are rooted.

maxillary process: projection of bone from the maxilla that forms the anterior portion of the zygomatic arch (*q.v.*); usually orientated vertically to the anterior–posterior line of the skull.

maxillary: pertaining to the maxilla (*q.v.*).

meatus: a passage or channel; the opening of a passage.

medial: situated in the middle.

melanistic: having an abnormally large amount of black or dark pigment in pelage and skin.

mesa: Ethiopian word for the microhabitat (usually on slopes) within afroalpine moorlands and grasslands, where it is higher and drier than surrounding areas, so dominated by (usually) *Alchemilla*.

Mesozoic (= Mesozoic Era): geological era; ca. 250–ca. 65 mya, comprising the Triassic, Jurassic and Cretaceous Periods; the Age of Reptiles.

metabolic rate: *see* basal metabolic rate (*q.v.*).

metabolic water: water produced by oxidative processes within the body; an important source of water for arid-adapted mammals when free (drinking) water and water within the food is in short supply or unavailable.

metacarpals: the long bones of the hand, situated between the carpal bones of the wrist and the proximal phalanges of the fingers.

metacentric: describes a chromosome with the centromere (*q.v.*) at or very near the middle of its length, so there are two arms of equal or almost equal length (ratio not greater than 1 : 1.1). *cf.* submetacentric (*q.v.*).

metacone: the posterior labial (external) cusp of an upper molar tooth.

metacromion: a process projecting backward and downward from the acromion (the lateral triangular projection of the spine of the scapula that forms the point of the shoulder and articulates with the clavicle of the scapula) of some mammals.

metapopulation: in population dynamics and ecology, a group of spatially separated populations of the same species that interact at some level.

metatarsal gland: scent glands on the outside lower hind leg. In the Bovidae, only the Impala *Aepyceros melampus* possesses metatarsal glands.

metatarsals: the long bones of the foot, situated between the tarsal bones of the ankle and the most proximal phalanges of the toes.

microcomplement fixation: in molecular evolutionary studies, species can be compared by the extent to which antibodies to the proteins of one species cross-react to the proteins of another species. The extent of cross-reaction is indicative of the similarity of the proteins and, by inference, the evolutionary affinity of the two species. Albumin is a protein commonly used for these studies.

microsatellite locus (*pl. microsatellite loci*): a region within a DNA sequence where short sequences of one, two, three or four of the nucleotides (A [adenine], T [thiamine], G [guanine] and C [cytosine]) are repeated consecutively; e.g. ACACAC, CAACAA. The number of times a sequence is repeated varies between individuals, within populations of a species, or between species, which makes microsatellite loci useful tools in systematics (*q.v.*).

migration: movements of species that travel, predictably and more-or-less directly, from one habitat to another (and back again), along predetermined routes, in response to seasonal changes in climate, food supply or any other resource. *cf.* localized movements (*q.v.*); nomadic movements (*q.v.*).

milk teeth: teeth occurring in newborn mammals, or appearing soon after birth, and preceding the permanent teeth of the adult animal. Also called deciduous teeth.

Miocene: geological Epoch (within the Tertiary Period); ca. 23–5 mya.

miombo: a vernacular name applied to trees in the genus *Brachystegia*; a type of savanna woodland in the Zambezi region where *Brachystegia* spp. are the commonest trees or one of the commonest trees.

Mistbelt: foothills along the eastern Great Escarpment that experience regular fogs, with vegetation comprising mainly grasslands and patches of afroalpine forest in protected valleys and ravines.

mitochondrial DNA: the small amount of DNA contained within the mitochondria of a cell.

molar: grinding or cutting tooth rooted in the maxilla bone and the mandible; there are usually one, two or three molar teeth in each ramus of the jaw. Together with the premolars, if present, they form the 'cheekteeth'. The number and form of the molar teeth varies in different species. Not preceded by deciduous (milk) teeth.

molariform: similar in form to a molar tooth; used to describe the form of the premolar teeth in some taxa.

monoestrous: Generally, having one oestrus cycle (*q.v.*) during a single reproductive season. In some taxa, having one litter per year. *cf.* polyoestrous (*q.v.*).

monogamy (*adj. monogamous*): a mating system in which one male mates with one female. Neither sex has the opportunity of monopolizing additional members of the opposite sex. Fitness often maximized through shared parental care (Emlen & Oring 1977). *cf.* polygyny (*q.v.*).

monophyletic: describes a taxonomic group descended from a common ancestor that was itself a member of that taxonomic

- group, and including *all* the descendants of that ancestor (Groves 2001). *cf.* paraphyletic (*q.v.*); polyphyletic (*q.v.*).
- monophyly**: derivation of taxa from a common ancestor. *cf.* diphyly (*q.v.*), polyphyly (*q.v.*).
- monospecific**: describes a genus containing only one known species. *See also* monotypic (*q.v.*).
- monotocous**: normally having only one young per litter (twinning, if it occurs, is very rare and abnormal). *cf.* polytocous (*q.v.*).
- monotypy** (*adj.* **monotypic**): describes a taxon containing only one immediately subordinate taxonomic unit, e.g. a monotypic family contains only one genus; a monotypic genus contains only one species. *cf.* polytypy (*q.v.*).
- mopane**: a vernacular name applied to the tree *Colophospermum mopane*; a type of savanna woodland in the Zambezi region in which *C. mopane* is the commonest species of tree.
- Mt**: (*abbrev.*) Mount.
- mtDNA**: (*abbrev.*) mitochondrial DNA (*q.v.*).
- Mts**: (*abbrev.*) Mountains.
- multiparous**: describes either the birth of more than one offspring at once, or a female that has given birth two or more times.
- muzzle**: the snout; the nose and jaws of a mammal.
- MW**: (*abbrev.*) *see* mastoid width.
- mya**: (*abbrev.*) millions of years ago.
- myrmecophagy** (*adj.* **myrmecophagous**): the eating of ants and/or termites.
- mystacine vibrissae**: vibrissae (*q.v.*) resembling a moustache.
- n. d.**: (*abbrev.*) no data.
- N. P.**: (*abbrev.*) National Park.
- N. R.**: (*abbrev.*) Nature Reserve (not National Reserve).
- naris** (*pl.* **nares**): a nostril.
- Neogene Period**: geological period and system; 23.03 ± 0.05 to 2.5 mya, comprising the second part of the Cenozoic Era.
- neonate**: a newly born animal.
- neoparatype**: any specimen described at the same time as the neotype (*q.v.*).
- neotype**: a specimen selected as the type in cases where the primary types are definitely known to be lost or destroyed.
- nipple**: external opening of mammary gland. Nipple number and position vary according to the taxon, but are consistent within a species. Nipples arranged in pairs, one of the pair on each side of body.
- nocturnal**: at, active in, the night; when light intensity is at its lowest; between sunset and sunrise. *cf.* crepuscular (*q.v.*); diurnal (*q.v.*).
- nomadic movements**: irregular and unpredictable movements, from one locality to another, made by species living in unpredictable habitats. *cf.* localized movements (*q.v.*); migration (*q.v.*).
- nomen dubium**: when the available evidence is not sufficient to permit the identification of a species, its name is considered to be a *nomen dubium* and therefore not available for taxonomic purposes.
- nomen nudum**: a name that is not valid because, when it was originally published, the organism to which it referred was not adequately described, defined or sketched. The name is therefore invalid because it is impossible to associate it indisputably with any specific organism.
- nominate subspecies**: the subspecies that bears the name of the species to which it belongs (e.g. *Otocyon megalotis megalotis*), only brought into existence by the creation of one or more other subspecies in the same species (e.g. *Otocyon megalotis virgatus*).
- North Africa**: those parts of Mauritania, Morocco, Algeria, Tunisia, Libya and Egypt that are north of the Sahara Desert.
- North-Central Africa**: Southern Chad and southern Sudan, west of the Nile R. and south of the Sahara. Mainly savanna habitats.
- North-West Africa (= Mahgreb)**: those parts of Mauritania, Morocco, Algeria, Tunisia and NW Libya that are north of the Sahara Desert.
- nuchal**: pertaining to the nape of the neck.
- nulliparous**: not having given birth.
- obligate**: obligatory; limited to one mode of life or action irrespective of conditions or circumstances. *cf.* facultative (*q.v.*).
- occipital condyles**: the pair of smooth, rounded processes of the occipital bone at the posterior end of the skull on either side of the occipital foramen that acts as a hinge between the head and the neck.
- occiput**: the posterior part of the skull, above the foramen magnum (*q.v.*).
- occlusal**: pertaining to the biting surface of a tooth.
- oestrous cycle**: the reproductive cycle in most non-pregnant female mammals, comprising recurring physiological changes induced by reproductive hormones.
- oestrus** (*adj.* **oestrous**): The period when a female is sexually receptive.
- Oligocene**: geological Epoch (within the Tertiary period), ca. 38–23 mya.
- omnivore** (*adj.* **omnivorous**): an animal that eats a wide range of foods.
- orbit**: bony cavity (eye-socket) in which the eye is situated.
- oscillogram**: a visual representation (graph) of sound waves in which amplitude (sound wave pressure) is plotted on the vertical axis, and time on the horizontal axis (*cf.* sonogram *q.v.*).
- osmetrichia**: hairs structurally specialized for the dispersal of scent.
- osteophagia**: the chewing on bones engaged in by herbivorous animals suffering from a deficiency of phosphorus and calcium in their diet.
- outer**: furthest from the mid-line of the body.
- ovulation**: the release of female gametes (ova, eggs) from the ovary.
- ovum**: the female gamete or egg cell.
- owl pellets**: waste material, normally in an egg-like shape, regurgitated by owls, which contains undigested fragments of bone, hair, feathers and scales etc. from the prey; for mammalogists, useful in determining indirectly the species of small mammals in a habitat.
- P or p**: (*abbrev.*) premolar tooth or teeth; upper case denotes adult dentition, lower case denotes deciduous dentition (milk teeth). *See also* premolar.
- pachyosteosclerosis**: a thickening of the bones of the ribs and vertebrae, resulting in unusually solid bone structure with little to no marrow.
- Palaeartic**: a zoogeographic region comprising Europe, North Africa and Asia (except for southern portion of the Arabian Peninsula and tropical and sub-tropical parts of the Oriental Region).
- Palaeocene**: geological Epoch (within the Tertiary Period); 65–55 mya.

- palatal foramen** (*pl.* foramina): a foramen (*q.v.*) in the palatine bone.
- palate**: the roof of the mouth. The anterior part (hard palate) comprises the bony palate (formed by the premaxillae, maxillae and palatine bones), and a covering mucous membrane. The posterior part (soft palate) is composed only of muscular tissue covered by a mucous membrane.
- Paleogene**: geological period and system; 65.5 ± 0.3 to 23.03 ± 0.05 mya, comprising the first part of the Cenozoic Era.
- papilla** (*pl.* papillae, *adj.* papillate): a small projection or protuberance.
- paraoccipital process**: narrow strut-like bone that projects ventrally from the paraoccipital bone on the posterior part of the skull.
- parapatry** (*adj.* parapatric): the situation where two or more species have geographic ranges that are contiguous (*q.v.*) but do not overlap. This abutting may be along a line of habitat discontinuity, ecotone, or altitudinal/climatic contour, but may also arise from competitive exclusion of one (or both) by the other.
- paraphyletic**: describes a taxon containing units that have evolved from a single ancestral taxon but that do not contain all of the descendents of the most recent common ancestor.
- paratype**: a specimen collected at the same time and place as the holotype (*q.v.*) and designated by the original authority as such. There may be one or more paratypes.
- parietal**: one of the pair of bones forming the vault of the braincase, situated between the frontal and the occipital bones.
- parous**: having given birth.
- partim**: in taxonomy, used in context of taxon names and synonyms to indicate that not all material that has been referred to the name is currently considered to belong to that name. e.g. *auritus* (partim) is listed as a synonym of *Plecotus christii* because only some of the specimens, which were earlier identified as *Plecotus auritus*, are now considered to represent *P. christii*.
- parturition**: the act of giving birth.
- pectoral**: pertaining to or situated on the chest.
- pedal glands**: glands that are situated in the feet opening between the hooves.
- pelage**: the hairy, woolly or furry covering of the body in mammals. The pelage variously consists of hairs, guard hairs and underfur according to the species.
- petrophily** (*adj.* petrophilic): occupying habitats dominated by large boulders.
- phalanx** (*pl.* phalanges): one of the bones in a finger.
- pharynx** (*adj.* pharyngeal): the passage leading from the oral and nasal cavities in the head to the oesophagus and larynx (*q.v.*).
- phenotype**: the visible characters of an individual resulting from the interaction between the genotype (*q.v.*) and the environment.
- philopatry**: the tendency to remain in or consistently return to the place where one was born.
- philtrum**: a medial vertical cleft or groove in the rhinarium (*q.v.*) extending from between the nostrils to the upperlip.
- phylogenetics**: pertaining to the line of descent of a taxon; a method of classification that attempts to show the evolutionary relatedness of organisms.
- phylogeny** (*adj.* phylogenetic): the evolutionary history and line of descent of a species or higher taxonomic unit.
- piloerection**: the erection of hairs that occurs as a means of conserving heat (*see* temperature regulation) and, in some mammals, as a threat display.
- pinna** (*pl.* pinnae): the external (outer) ear.
- placental scars**: scars on the inner surface of the uterus of a mammal; the site where a placenta was attached during pregnancy. The number of placental scars can give an indication of the number of litters that a female has had (when the average number of young/litter is known).
- placentation**: the formation, type and structure of the placenta; the arrangement of placentae.
- plantar**: of the sole of the foot.
- plantigrade**: describes locomotion during which the entire sole of each foot touches the ground.
- Pleistocene**: geological Epoch (within the Quaternary Period); ca. 1.7 mya to 10,000 year ago.
- plesiomorphy** (*adj.* plesiomorphic): in cladistics (*q.v.*), describes a pre-existing character state across a wide taxonomic grouping. Sharing of that state (symplesiomorphy [*q.v.*]) amongst a subset of taxa within the wider grouping is not indicative of monophyly (*q.v.*). *cf.* apomorphy (*q.v.*).
- pleural cavity**: the body cavity occupied by the lungs.
- Pliocene**: geological Epoch (within the Tertiary period), ca. 2–5 mya.
- poikilothermic**: the condition when the body temperature varies with the surrounding ambient temperature.
- pollex**: digit 1 ('thumb') of forefoot ('hand').
- polygyny** (*adj.* polygynous): a mating system in which one male mates with several females. *See* resource-defence polygyny; female-defence polygyny. *cf.* monogamy (*q.v.*).
- polymorphism** (*adj.* polymorphic): the existence, within a species or population, of individuals having different forms (colour, size, shape etc.).
- polyoestrous**: Generally, having two or more oestrous cycles (*q.v.*) during a single reproductive season. In some taxa, having more than one litter/year. *cf.* monoestrous (*q.v.*).
- polyovulation**: production of many ova (and hence many corpora lutea) during a single oestrus; sometimes called 'superovulation'; recorded in some species of sengis.
- polyphyletic**: describes a taxon derived from two or more ancestral sources; not of a single, immediate line of descent (Mayr *et al.* 1953). *cf.* monophyletic (*q.v.*).
- polyphyly**: derivation of a taxon from two or more ancestral sources. *cf.* monophyly (*q.v.*).
- polytocous**: normally or often having more than one young per litter. *cf.* monotocous (*q.v.*).
- polytypy** (*adj.* polytypic): a taxon that has several taxa in the next lower taxonomic category, e.g. a polytypic family contains two or more genera, a polytypic genus has two or more species. *cf.* monotypy (*q.v.*).
- postauricular**: behind the external ear (pinna).
- postorbital process**: the bony projection arising from upper rim of orbit and projecting outwards and downwards around the posterior of the orbit.
- postorbital**: behind (posterior to) the orbit.
- postpartum oestrus**: an oestrus cycle immediately after (or very soon after) parturition and while lactating.

- precocious** (= **precocial**): describes young born in a well developed state enabling them to move around and forage soon after birth. *cf.* altricial (*q.v.*).
- premaxilla** (*pl.* **premaxillae**): one of a pair of bones at the anterior end of the skull that bears the incisor teeth.
- premolar**: tooth on the maxilla bone situated immediately anterior to the molar teeth; usually preceded in time by deciduous (milk) tooth; multi-cusped. Structure and function of premolar teeth vary according to species.
- preorbital fossa**: a bilateral depression in the skull, located anterior to the eye.
- preorbital**: anterior to the eye.
- prepuce** (*adj.* **preputial**): the skin surrounding and protecting the head of the penis; foreskin.
- preputial gland**: a gland situated adjacent to the penis or vaginal opening.
- primiparous**: a female that has given birth only once. *cf.* multiparous (*q.v.*).
- promiscuity**: a mating system in which each male mates with several females and each female mates with several males.
- pronking**: *see* stotting.
- protocone**: The main inner (lingual) cusp of an upper molar tooth.
- protuberant**: projecting forward (bulging) beyond the surrounding surface.
- proximal**: nearest to the body or to the mid-line of the body; nearest to the point of attachment. *cf.* distal (*q.v.*).
- proximate cause**: a cause that produces an effect directly without any intervening agency.
- pterygoid process**: one of a pair of narrow, ventrally projecting processes of the pterygoid bones situated immediately posterior to the bony palate and forming the walls of the mesopterygoid fossa (*q.v.*).
- pterygoid**: one of a pair of cranial bones forming part of the roof of the mouth.
- pubic bone**: anterior inferior part of the pelvis, articulating with its opposite number in the anterior midline at the pubic symphysis.
- Quaternary Period**: period within the Cenozoic Era; 2 mya to today, comprising two epochs: the Pleistocene and Holocene (Recent) (*q.v.*).
- r-selection**: selection for characteristics suitable in unstable fluctuating environments (rapid development of young, large litter size, relatively short time to maturity, relatively short life span) *cf.* K-selection (*q.v.*).
- R.**: (*abbrev.*) River.
- radius**: one of the two bones of the lower forelimb between the humerus (upper arm) and the wrist.
- ramus**: one half (left or right) of the lower jaw or mandible.
- range length**: distance between the most distant captures (by live-trapping) of an individual; a rough method of assessing home-range (*q.v.*).
- Recent**: *see* Holocene (*q.v.*).
- relict forest**: a forest that persists where local conditions are favourable after the disappearance of forest from the surrounding area as a result of climate change or human activity. Relict forests include those at the base of inselbergs that are watered by rainwater running off the inselberg, and forests growing in graveyards and sacred sites that are protected. Sometimes known as forest islands.
- relict population**: one that persists where local conditions are favourable after the extinction of the species from at least part of its former range.
- Renosterveld**: a dominant vegetation type in the Cape Floristic Region (*q.v.*), and characterized by the dominance of members of the Daisy Family (Asteraceae), specifically one species - Renosterbos *Elytropappus rhinocerotis*, from which the vegetation type gets its name.
- reproductive capacity**: number of young produced by a female during the breeding season.
- reproductive chronology**: the timing and duration of events, such as spermatogenesis, copulation, ovulation, gestation, parturition, lactation and reproductive inactivity, throughout the year.
- reproductive strategy**: the strategy adopted to maximise reproductive success, determined primarily by litter-size and reproductive chronology (*q.v.*).
- resource-defence polygyny**: a mating system in which a male controls access to several females indirectly, by monopolizing critical resources (Emlen & Oring 1977).
- retarded embryonic development**: a means of lengthening the interval between copulation and parturition so that both events can occur in the most optimal seasons. The implanted embryo enters a period of retarded (slowed) growth that may last 4–8 months, after which development proceeds normally.
- reticulation** (*adj.* **reticulated**): having a net-like pattern.
- rhinarium**: area of naked moist skin surrounding the nostrils.
- ridge** (= **commissure**): in teeth, a ridge connecting two cusps.
- Rift Valley**: deep valley extending from the Red Sea through Ethiopia and East Africa to Malawi; formed ca. 12 mya by subsidence of the valley floor and uplifting of the edges to form mountains and highlands. Four parts: (1) Ethiopian Rift Valley dividing the Ethiopian plateau into two parts; (2) Albertine Rift Valley (Western Rift Valley) in Uganda, E DR Congo and W Tanzania; (3) Gregorian Rift Valley (Eastern Rift Valley) in N Kenya, C Kenya and N Tanzania; (4) Malawian Rift Valley – the extension of the Albertine Rift Valley in Malawi. The Rift Valleys are noted for their many deep and beautiful lakes.
- riparian**: growing on or living on the banks of streams or rivers.
- riverine forest**: forest growing along the banks of a river or stream where conditions are moister than in the surrounding area. Sometimes referred to as ‘fringing forest’.
- Robertsonian fusion**: a chromosomal event involving the apparent fusion of non-homologous single armed (telocentric *q.v.*) chromosomes to form a bi-armed (metacentric *q.v.* or submetacentric *q.v.*) chromosome. Modern studies have revealed that all chromosomes have two arms, even if the smaller one is not detectable by light microscopy. Consequently, the term Robertsonian translocation is becoming more commonly used than Robertsonian fusion.
- rostral**: pertaining to the rostrum.
- rostrum**: that portion of the skull anterior to the front line of the orbits and supporting the upper part of the muzzle, comprised of the nasals, premaxillae and maxillae bones.
- rupicolous**: rock-living.
- s.u.**: (*abbrev.*) (*Lat. sans unguis* = without claw) sometimes added as a suffix to the hindfoot measurement to emphasize that HF has been

- measured without the claw. However, since this is the standard method of measurement, most authors write 'HF', not 'HF s.u.'. *cf.* c.u. (*q.v.*).
- sacrum** (*adj.* **sacral**): the fused vertebrae to which the pelvic girdle is attached.
- sagittal crest**: longitudinal crest of raised bone on the mid-dorsal line of the cranium.
- scansorial**: climbs or scrambles over logs and in low vegetation close to the ground. *cf.* terrestrial (*q.v.*); arboreal (*q.v.*).
- scapholunar bone**: a bone formed by the coalescence of the scaphoid and lunar in the carpus of Carnivora.
- sclerophyllous**: describes vegetation having hard leaves that are resistant to drought.
- scrotal**: pertaining to, or within, the scrotum (*q.v.*).
- scrotum**: an external sac containing the testes and epididymides in male mammals.
- sebkha**: A geological feature, in North Africa, that is a smooth, flat, plain usually high in salt (also sabkha).
- sectorial**: adapted for cutting.
- selenodont**: molar teeth having longitudinal crescent-shaped ridges.
- Senegambia**: Senegal and Gambia.
- sensu lato**: (*Lat.*) in a broad sense.
- sensu stricto**: (*Lat.*) in a strict sense.
- sensu**: (*Lat.*) in the sense of.
- septum**: a dividing wall separating two cavities.
- sex ratio**: the number of males to the number of females, usually expressed as a proportion to one male, e.g. 1 : 1 (equal numbers of males and females), 1 : 0.5 (= twice as many males as females), 1 : 2 (= twice as many females as males).
- sexual dimorphism**: observable (phenotypic) difference(s) (e.g. in colour, size or form) between the males and females of a species or higher taxon.
- Sh. Ht.**: (*abbrev.*) shoulder height (in ungulates, usually taken to be between the pegs, but sometimes measured over the curve).
- sibling species**: pairs or groups of true species that are reproductively isolated, but genetically closely related and so similar in appearance that they are difficult to separate solely on the basis of morphological characters.
- side-stripe**: longitudinal stripe(s) of contrasting colour on each flank, usually from shoulder to rump or upper part of hindlimbs. May be bordered by additional side-stripe above and below.
- singleton**: a neonate that is born singly as opposed to being one of a larger litter.
- sister species**: species that are thought to have arisen from a single dichotomous splitting event.
- sonogram**: a visual representation (graph) of sound in which frequency is plotted on the vertical axis, and time on the horizontal axis; can be analysed manually or with computer programs (*cf.* oscillogram *q.v.*).
- sounder**: a group of pigs.
- South-Central Africa**: Angola, SE DR Congo, Zambia and Malawi (but only west of L. Malawi and the Shire R. Valley).
- southern Africa**: south of the Cunene and Zambezi Rivers, i.e. Namibia, Botswana, Zimbabwe, southern Mozambique and South Africa (after Smithers 1983).
- spatulate**: like a spatula, i.e. narrow at the base but wider, flat and parallel-sided distally.
- species**: population(s) of closely related and similar organisms, which are capable of interbreeding freely with one another and cannot or typically do not interbreed with members of other species.
- sperm storage**: storage of sperm in the cauda epididymides (*q.v.*) of males for some time before copulation, or in the reproductive tract of females for an extended period before ovulation takes place. A type of reproductive delay that, in females, lengthens the length of gestation (*q.v.*).
- sperm**: any male gamete; the male cell that fuses with a female gamete (ovum, egg cell) to produce a fertilized egg or zygote from which an embryo will develop.
- spermatogenesis**: the formation of sperm in the testes.
- stotting**: bouncing up and down with legs held stiffly. Also referred to as pronking.
- sub, sub-**: prefix meaning under, signifying beneath or ventral to (as in anatomical features) or south of (as in sub-Saharan); less than (as in subsonic); not quite, nearly, almost, somewhat (as in subequal, subtriangular). In taxonomy, indicates a group just below the status of the taxa immediately following it (e.g. a genus may contain two or more subgenera).
- subauricular**: below the ear.
- subcaudal**: below the tail.
- subdermal**: just below the skin.
- submetacentric**: describes a chromosome with the centromere (*q.v.*) somewhat nearer one end than the other, so there are two arms of somewhat unequal length (ratio 1 : 1.2–1.9). *cf.* metacentric (*q.v.*); subtelocentric (*q.v.*).
- subspecies**: a geographically localized and isolated subdivision of a species, which differs genetically, morphologically and taxonomically from other subdivisions of the species.
- subtelocentric**: describes a chromosome with the centromere (*q.v.*) much nearer one end than the other, so there are two arms of very unequal length (ratio 1 : >2).
- subterminal**: just below the end or tip.
- subterranean**: living permanently below the ground; *cf.* fossorial (*q.v.*).
- suckling**: the act of a mother giving milk directly from her breast (mammary glands) to her young. Mothers suckle; their young suck.
- sulcus** (*pl.* **sulci**): a groove, fissure or furrow.
- superovulation**: *see* **polyovulation** (*q.v.*).
- supinate**: to turn or rotate the hand or forearm, or the hindlimb and foot.
- supracaudal**: above the tail.
- supraoccipital crest**: ridge of bone, orientated transversely across the back of the skull, at the junction of the parietal and/or supraoccipital bones and the occipital bone. Sometimes referred to as the lambdoid crest.
- supraorbital ridge**: ridge of bone along upper rim of orbit (eye-socket).
- supraorbital**: above (dorsal to) the orbit.
- supraordinal**: describes a taxon above the level of the order.
- sympatry** (*adj.* **sympatric**): the situation where populations of two or more different species have overlapping geographic ranges; refers also to populations of two or more species whose geographic ranges are partly or wholly overlapping. They may or may not interact. *cf.* allopatry (*q.v.*); syntopy (*q.v.*).

- symplesiomorphy**: a primitive or ancestral character shared by two or more groups, which is inherited from ancestors older than the last common ancestor.
- synanthropic**: associated with humans and/or their houses and other buildings.
- synapomorphy** (*adj.* **synapomorphic**): situation in which a homologous character is present in two or more taxa and is thought to have originated in their most recent common ancestor. *See also* apomorphy.
- syndactyly**: of digits; whole of part fusion of two or more digits (e.g. Digits 2 and 3 of the hindfoot in otter-shrews).
- synonym**: one or more of different names for the same taxonomic unit. A synonym may be a 'senior synonym' (the oldest name), or a 'junior synonym' (a more recent name) that is no longer considered as valid. May be used to refer to all names that have been associated, at some time in the past, with the taxonomic unit as currently understood.
- syntopy** (*adj.* **syntopic**): describes the situation where two or more species use the same or similar habitats and activity times. They may or may not interact. *cf.* allopatry (*q.v.*); sympatry (*q.v.*).
- syntype**: any specimen, or one of a series of specimens, used to designate a species when a holotype (*q.v.*) and paratype(s) (*q.v.*) have either not been selected, or have been lost or destroyed.
- systematics**: the science of arranging organisms in a way that reflects their evolutionary relationships; such relationships may be expressed as a phylogeny (*q.v.*). Often defined (somewhat incorrectly) as a synonym of taxonomy (*q.v.*).
- T**: (*abbrev.*) length of tail, measured from anterior of the first caudal vertebra to the posterior end of the last caudal vertebra (excluding any tufts, bristles etc. at tip of tail).
- T_a**: (*abbrev.*) ambient temperature; the temperature in which an animal is living. *cf.* T_b (*q.v.*).
- Ta**: ambient temperature; the temperature in which an animal is living. *cf.* T_b (*q.v.*).
- talonid**: heel at the posterior end of a lower molar tooth.
- tapetum lucidum**: light-reflecting layer behind or in the retina of the eyes of some vertebrates that reflects light back through the retina thereby increasing the sensitivity of the eye to dim light.
- taxon** (*pl.* **taxa**): any defined unit (e.g. family, genus, species, subspecies) in the classification of organisms.
- taxonomy**: the science of biological nomenclature; the study of the rules, principles and practice of naming and classifying species and other taxa. Sometimes considered as an integral part (and near synonym) of systematics (*q.v.*).
- T_b**: (*abbrev.*) body temperature; the temperature of the core (central) part of an animal. *cf.* T_a (*q.v.*).
- telocentric**: describes a chromosome that appears to have a terminal centromere (*q.v.*) and therefore only one arm. Modern studies have revealed that all chromosomes have two arms but the smaller arm of telocentric chromosomes is not visible under a light microscope.
- temporalis**: a broad radiating muscle arising from the coronoid process (*q.v.*) of the lower jaw and attaching to the upper part of the skull.
- termitarium** (*pl.* **termitaria**): a place where termites (Insecta: Isopoda) live. Often a large mound of modified hard soil. The shape and size of a termitarium is unique to each species of termite.
- terrestrial**: living on the ground. *cf.* arboreal (*q.v.*); scansorial (*q.v.*).
- territory**: an area defended by an individual against certain other members of the species, usually by overt aggression or advertisement; territory is marked by the urine, faeces or glandular secretions of the territory's owner. *cf.* home-range (*q.v.*).
- Tertiary Period**: geological period, 65–2 mya, comprising five epochs: Palaeocene, Eocene, Oligocene, Miocene and Pliocene (*q.v.*); followed by the Quaternary Period (*q.v.*).
- testes**: the male gonads, or testicles, in which spermatozoa are formed and in which the male hormone is produced.
- Tethys Sea**: the sea separating the two supercontinents, Gondwana (*q.v.*) and Laurasia (*q.v.*) during much of the Mesozoic Era before the opening of the Indian and Atlantic oceans during the Cretaceous Period (*q.v.*).
- thermal conductance**: a measure of the ability of substances (including pelage) to transfer heat.
- thermolability** (*adj.* **thermolabile**): the ability of a homeotherm (e.g. camel) to allow its body temperature to vary over a 24-hour period, without either hibernating or aestivating.
- thermoneutral zone**: the range of body temperatures within which an animal does not have to increase its metabolic rate to increase T_b (*q.v.*) (when T_a (*q.v.*) is low) and reduce T_b (when T_a is high).
- thermoregulation**: regulation of body temperature, either by metabolic or behavioural means (or both simultaneously) so that T_b (*q.v.*) is kept more or less constant.
- thoracic**: pertaining to, or situated upon, the chest.
- through-put time**: time taken for food to pass through the digestive tract.
- tibia** (*pl.* **tibiae**): one of the two bones forming the lower leg (the shin bone); part of hindlimb between knee and ankle.
- TL**: (*abbrev.*) total length from tip of snout to posterior end of tail. Equivalent to the head and body length and tail length added together. *See also* HB (*q.v.*) and T (*q.v.*).
- toothrow**: Generally, the row of teeth from the most anterior incisor tooth to the most posterior molar. In golden moles, the row of teeth from the canine to the most posterior molar. Sometimes used in contexts of specific types of teeth, e.g. premolar toothrow, molar toothrow.
- topotype**: any specimen from the type locality (*q.v.*), i.e. the same locality as that from which the holotype (*q.v.*) was taken.
- topotypical**: pertaining to the type locality (e.g. a topotypical population is one found at the type locality).
- torpor** (*adj.* **torpid**): a state in which there is a (usually short-term) reduction of metabolic rate and a lowering of T_b (*q.v.*) when T_a (*q.v.*) declines; arousal from torpor occurs when T_a increases and without high energy costs to the individual. Torpor is associated with a state of inactivity and reduced responsiveness to stimuli. Torpor lasts for only short periods of time (hours or days). *cf.* hibernation.
- tragus**: a cartilaginous structure, usually small, projecting from the inner side of the external ear just anterior to the auditory meatus (*q.v.*).
- transverse**: in a direction across the body from side to side. *cf.* longitudinal (*q.v.*).
- Triassic Period**: period (within the Mesozoic Era); 248–208 mya. The first mammals appeared in this period.

triconid: describes a molariform tooth having three cusps.

tricuspid: having three points or cusps (particularly of teeth).

trifid: divided into three by two emarginations (*q.v.*).

tubercle: a small rounded protuberance.

tusks: long, continuously growing incisor or canine teeth that protrude (usually in pairs) beyond the mouth in some mammals including elephants (in which the tusks are incisors), and warthogs and other pigs (in which the tusks are canines); comprised of dentine (ivory). Some mammals, e.g. hyraxes, have 'tusk-like' incisors.

tympanic bulla (*pl. tympanic bullae*): one of a pair of usually rounded bony capsules, on underside of skull (one on each side), housing structures of the middle and inner ear in many mammals. Also called auditory bulla (*q.v.*).

type description: the original description of a species; the original description of the holotype (and paratype[s] if included).

type locality: the locality from which a holotype (*q.v.*), lectotype (*q.v.*) or neotype (*q.v.*) was collected. Also called topotypical locality.

type population: the population from which the holotype was selected.

type series: the holotype and all specimens collected at the same place and time and used, together with the holotype, to describe a new species.

type species: usually the species that was the first to be described under the name of a new genus. Not all genera had a designated type species when they were first created; in such cases, other rules determine which species will be the type species.

type specimen: *see* holotype.

underfur: dense and often woolly layer of the pelage, situated close to the skin and below the soft hairs and guard hairs; usually short and present in those species that experience lower T_a .

unicuspid: having one cusp or point (particularly of teeth).

upper critical temperature: the highest ambient temperatures at which the animal must increase its metabolic rate to maintain a constant body temperature. If the ambient temperature increases above the upper critical temperature and the animal is unable to cool itself, it will enter hyperthermia and may eventually die. *cf.* lower critical temperature.

uvula: the conical projection from the posterior edge of the soft palate that plays a role in the articulation of sounds and the closing the nasopharynx during swallowing.

vagility: the ability to move about, disperse or migrate.

vagrant: an individual that has been found well outside the normal geographic range of its species, e.g. a bat or bird that has been wind-borne, or an animal that has been transported as a stowaway on a ship, to a distant locality.

vascularized: infiltrated with capillaries.

vasoconstriction: constriction of the capillaries of the blood system near the surface of the skin in order to reduce the rate of heat loss through the skin; a mechanism used by many mammals to conserve heat when T_a (*q.v.*) is low. *cf.* vasodilation (*q.v.*).

vasodilation: the dilation (or opening) of the capillaries of the blood system near the surface of the skin in order to increase the rate of heat loss through the skin; a mechanism used by many mammals to cool themselves when T_a (*q.v.*) is high. *cf.* vasoconstriction (*q.v.*).

veld: Afrikaans word, used mainly by southern African biologists, to refer to a wide variety of grassland vegetation types typically used for grazing. *See also* bushveld, highveld, lowveld.

vertebra (*pl. vertebrae*): any of the bones that make up the backbone.

vertebral formula: the number of vertebrae in each part of the spine, from anterior to posterior: the parts are cervical (C), thoracic (T), lumbar (L), sacral (S), caudal (Ca).

vestigial: small and imperfectly developed; a structure having a smaller and more simple form than the corresponding structure in an ancestral species.

vibrissa (*pl. vibrissae*): long stiff hairs on the face, especially around nostrils and lips; often associated with the perception of tactile sensation; 'whiskers'.

vlei: southern African term for a marsh or swamp, either permanent or seasonal.

wadi: a desert valley, usually dry at the surface except after heavy rainfall.

water turnover: the rate at which water (fluids) is utilized and replaced in the body per unit time (normally expressed as ml/kg body weight/day); the amount of water an animal processes through its body each day. Water turnover is related to water availability, the urine concentrating ability of the kidney, amount of protein in the diet and T_a (*q.v.*). Water turnover rates are characteristically low in arid-adapted mammals when compared with non arid-adapted mammals.

West Africa: ca. south of 18° N from Senegal to the Sanaga R. in Cameroon, and Bioko I. (Equatorial Guinea) (Rosevear 1965).

WT: (*abbrev.*) weight (mass) of an individual, usually expressed in grams (g) or kilograms (kg).

xiphisternum: The posterior segment, or extremity, of the sternum (sometimes called the xiphoid process).

zalambdodont: cheekteeth with three main cusps connected by crests (ectolophs) forming a V-shape; largest cusp is at the apex of the V (on the lingual or tongue side of the tooth); assumed to be derived from the primitive tribosphenic teeth found in some extinct early mammals. *cf.* dilambdodont (*q.v.*).

ZW: (*abbrev.*) *see* zygomatic width.

zygomatic arch: one of a pair of cheekbones, formed of the maxillary process anteriorly, jugal bone medially and squamosal bone posteriorly. Ranges from massive, broad, widely flared and bony, to frail, slender and cartilaginous. When present, provides protection to the eyes and orbits. Also called zygoma.

zygomatic width (ZW): greatest width between the outer aspect of one zygomatic arch to the equivalent position on the opposite zygomatic arch. *See also* GWS.
